Conception of a compartmental nitrogen model describing pure cultures of *Saccharomyces cerevisiae* and *Torulaspora delbrueckii* in synthetic media.

Paul Brou[1], Patricia Taillandier[1], Sandra Beaufort[1], Cédric Brandam[1]
1 Université de Toulouse, Laboratoire de Génie Chimique, CNRS, INPT, UPS, Toulouse, FRANCE
** Patricia Taillandier: patricia.taillandier@ensiacet.fr*

Highlights

- A mathematical model was developed to describe pure culture of two oenological yeasts.
- Compartmental nitrogen model enables to accurately describe fermentation kinetics.
- This model was validated in several synthetic media.

1. Introduction

In winemaking the use of mixed cultures combining *Saccharomyces* and non-*Saccharomyces* yeasts is more and more common in order to obtain wines with different organoleptic products. However, the behavior of these yeasts is difficult to control because of the interactions existing between them. In particular, the assimilable nitrogen is often a limiting nutrient in the grape musts and the yeasts are going to be in competition for it [1]. Modeling of the fermentation kinetics taking into account this limiting nutrient could allow to predict the kinetics of mixed culture in a second step.

2. Methods

Two commercial oenological yeasts were used in this study: *Torulaspora delbrueckii* Zymaflore alpha® and *Saccharomyces cerevisiae* QA23® Pure cultures of each yeast were performed in three synthetic media MS170, MS300 and MS300M at 20°C [2]. Each medium contained the same amount of sugars (220 g/L), vitamins and mineral elements but different concentration of nitrogen and/or lipids [1-2]. Growth, substrates and metabolites kinetics were followed during the fermentation.

3. Results and discussion

In all the pure cultures of *S. cerevisiae* and *T. delbrueckii*, it has been observed that yeasts were still growing whereas nitrogen initially present in the medium was completely exhausted (Fig 1). Therefore, after the nitrogen exhaustion the yeasts growth goes on on a nitrogen source located inside the cell. So It is necessary to consider an intracellular nitrogen source to mathematically describe the growth kinetics of the microorganisms studied. We introduce the notions of minimum cellular nitrogen and stored nitrogen to describe population, substrates and metabolites kinetics. This involves the design of a structured model in which the total assimilated nitrogen is divided into two compartments: the constitutive compartment and the storage compartment.

The constitutive compartment contains a quantity of nitrogen equal to the minimum amount of cellular nitrogen (N_{min}). This compartment provides vital minimal functions to keep the cell alive. Like the constitutive compartment, the storage compartment contributes to cell activity. However, only the storage compartment contains the nitrogen reserves available for growth.

The measured molar mass of the yeasts ($CH_xO_yN_z$) varies during fermentation. The molar mass $CH_xO_yN_{z'}$ of a cell containing an empty nitrogen storage compartment was considered constant. The latter molar mass let to propose a stoichiometric growth reaction (r1) for each yeast:

$1\ C_6H_{12}O_6 + g1\ N_S \rightarrow g2\ CH_xO_yN_{z'} + g3\ CO_2 + g4\ H_2O$

The evolution of substrates (sugar (S) and nitrogen (N)) and products (ethanol (E) and glycerol (G)) was described using additional stoichiometric reactions such as fermentation (r2), nitrogen absorption (r3), yeast mortality (r4) and glycerol production (r5):

$$\begin{cases} r1 = X_n.k_\mu.\left(1-\frac{X}{X_{max}}\right).\left(\frac{K_E}{K_E+E}\right).\left(\frac{N_s/X}{N_s/X+K_X}\right) \\ r2 = k_s.X_n.\left(\frac{S}{S+K_S}\right).\left(\frac{K_{ES}}{K_{ES}+E}\right).\left(\frac{N_s/X}{N_s/X+K_{NS}}\right) \\ r3 = k_N.X_n.N \\ r4 = X_n.e^{\left(\frac{E-E_{lim}}{10}\right)} \\ r5 = k_G.X_n.\left(\frac{S}{S+K_{SG}}\right).\left(\frac{K_{EG}}{K_{EG}+E}\right) \end{cases} \quad \begin{cases} \frac{dX}{dt} = (g2*r1-r4) \\ \frac{dS}{dt} = -(r1+r2+r5) \\ \frac{dN}{dt} = -r3 \\ \frac{dN_s}{dt} = (r3-g1*r1) \\ \frac{dE}{dt} = 2*r2 \\ \frac{dG}{dt} = r5 \end{cases}$$

X and X_n represent the living cell expressed respectively in cells/mL and mol/L. The model accurately describes the evolution of the fermentation (Fig 1 and 2). Modification of this model enables to describe precisely effects of lipid supplementation on yeast behavior (data not shown).

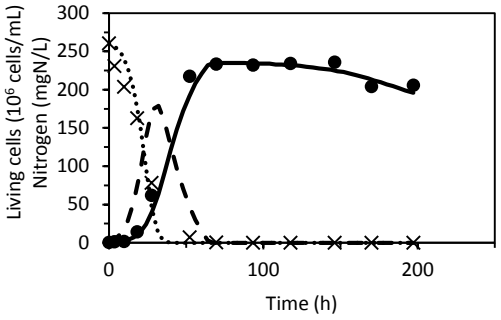

Figure 1. Pure culture of *S. cerevisiae* in MS170.
× Medium nitrogen (exp) ▪▪ Medium nitrogen (model)
● Living cells (exp) ¬ Living cells (model)
¬ ¬ Stored nitrogen (model).

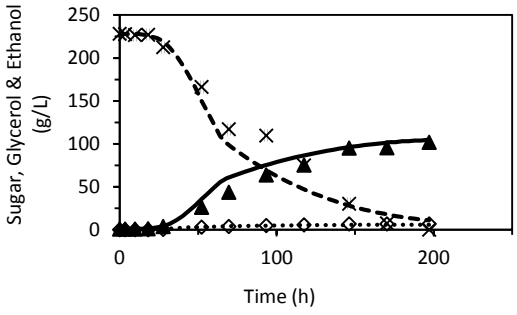

Figure 2. Pure culture of *S. cerevisiae* in MS170.
◊Glycerol (exp) ▪▪ Glycerol (model)
× Sugar (exp) ¬ ¬ Sugar (model)
² Ethanol (exp) ¬ Ethanol (model).

4. Conclusions

The proposed compartmental nitrogen model enables to accurately describe growth, substrates and metabolites kinetics during fermentation. That indicates the pertinence of the hypothesis made and constitutes a first step before modeling mixed culture fermentation.

Modelling of Enzymatic Fat Splitting Kinetics in Liquid – Liquid Multiphase System.

Sherly Rusli[1], Julia Lange[1], Janna Grabowski[1], Matthias Kraume[1]

1 Chair of Chemical and Process Engineering, TU Berlin

**Corresponding author: s.rusli@tu-berlin.de*

Highlights

- Modification of Michaelis Menten and Ping Pong Bi Bi Kinetics to accommodate surface area limitation.
- Validation of model by experimental data with in-situ drop size measurement.
- Inclusion of product inhibition in model.

1. Introduction

The enzymatic (trans)esterification process using lipase has attracted attention of both academic and industrial researchers due to its promising applications. This particular enzyme are able to react with two substrates in different phases, water or methanol in aqueous phase, and triglycerides in oil phase. Modelling its kinetics is a challenging task, as the reaction depends on the available surface area, and the surface area is dependent on the emulsification process.

2. Methods

To include the surface area, the Michaelis Menten kinetics was modified into two steps mechanism. The first step is the adsorption of enzyme molecules to the surface area, to create an activated enzyme molecule. The adsorption – desorption constants were fitted from experimental data of enzyme adsorption on single drop. To include the influence of side product Glycerol, the Ping Pong Bi Bi Mechanism is needed. The reaction are then divided into 5 steps, including formation of intermediate products Mono- and Di- Glycerides.

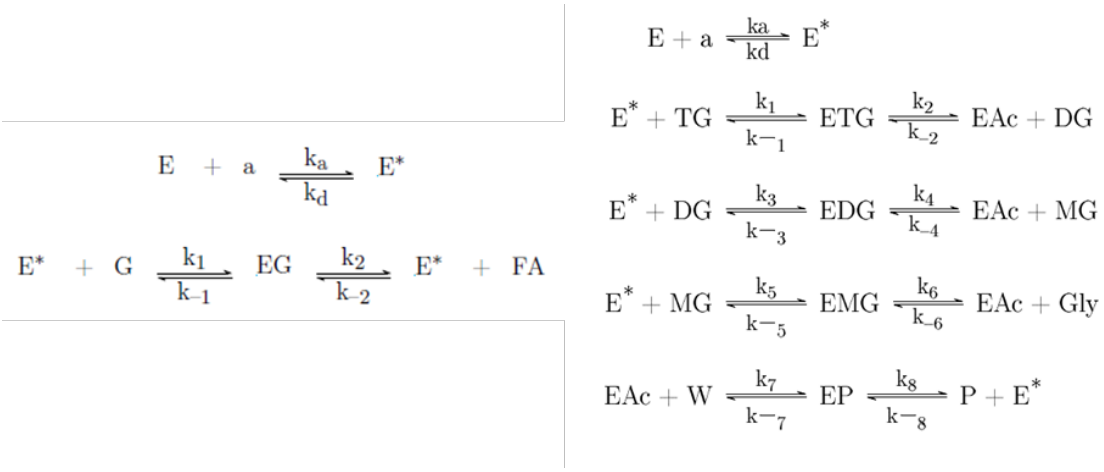

Figure 1. Modified Michaelis Menten (left) and Ping Pong Bi Bi (right) kinetics for inclusion of surface area limitation.

To validate the models, experiments were conducted in a batch stirred tank reactor, equipped with endoscope for measuring the surface area. Increasing the impeller speed decreases the drop sizes. Samples were taken from oil phase and analyzed by HPLC to quantify the amount of substrate and product.

3. Results and discussion

Experimental data shows two different kinetics. The initial reaction rate increases with increasing stirring rate, until all enzyme molecules are adsorbed. Above this point, the kinetics follow conventional enzymatic kinetics without surface area limitation. To make things more complicated, the prediction of drop sizes is dependent on the enzyme concentration, as increasing enzyme concentration decreases the interfacial tension, thus decreasing the drop sizes.

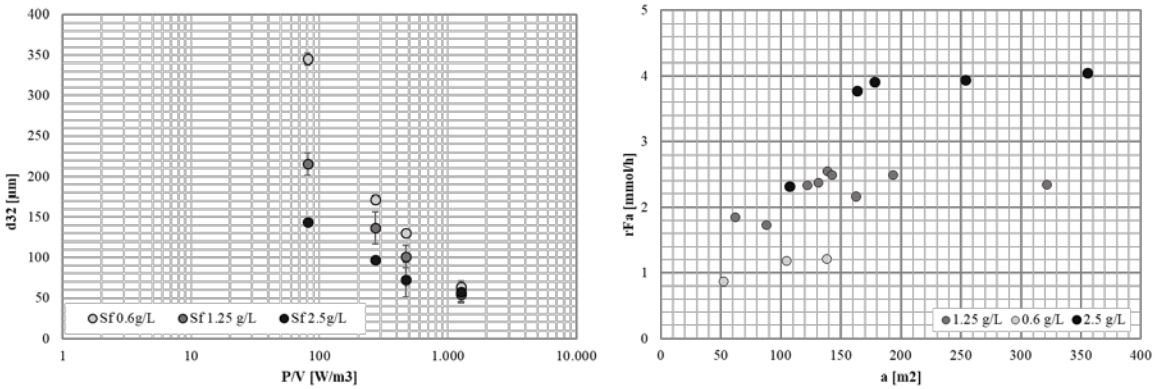

Figure 2. Effect of enzyme on drop sizes (left) and effect of surface area on reaction rate (right).

The two conditions can be predicted by a set of parameters from fitting against experimental data. The inclusion of surface area is imperative in the model, as is predicts the surface limiting mechanism. Without Glycerol inhibition, it is sufficient to model the reaction with the Michaelis Menten Kinetics, as there are no influence of the second substrate (water is in excess). However, when Glycerol is present, Ping Pong Bi Bi Kinetics is needed to predict the shift in reaction equilibrium.

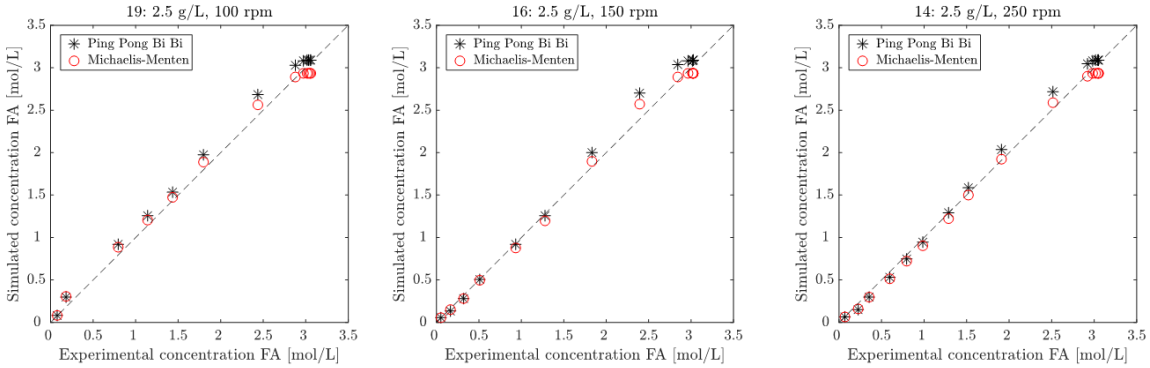

Figure 3. Deviations of experimental data and simulation.

4. Conclusions

To model the enzymatic transesterification, it is imperative to include the surface area and the glycerol concentration in the model.

A two-components model for glucose uptake dynamics of E. coli cells

Vincent QUEDEVILLE[1], Jérôme MORCHAIN*[1], Rodney O. FOX[2], Philippe VILLEDIEU[3]

1 LISBP, Université de Toulouse, CNRS, INRA, INSA, Toulouse, France; 2 IMFT Université de Toulouse, CNRS, INPT, Toulouse, France ; 2 Department of Chemical and Biological Engineering, Iowa State University, Ames, USA; 3 ONERA/DMPE, Université de Toulouse, F-31055 Toulouse, France

**Corresponding author: jerome.morchain@insa-toulouse.fr*

Highlights

- A dynamic model for glucose uptake is proposed
- Two subsystems : PTS and permeases work in parallel
- Batch and continuous culture subject to dilution shifts are simulated
- The overshoots reported in the literature are predicted

1. Introduction

The very specificity of biological systems compared to chemical ones is the ability of cells to modulate the magnitude of the mass transfer between the liquid and biotic phases. A thermodynamic law of equilibrium can be set at the interface between two phases in chemical multiphase systems. However, the situation is much more complex for living systems because cells adapt their uptake capacity dynamically to match their needs. On the top of that, a long series of works from Ferenci proved that multiple transport systems are present [1]. On the long term, a cell regulates its uptake capacity so that the maximum possible growth rate is achieved, but the dynamics toward this steady state situation is far from simple. Little has been made in the modelling community to account for these facts. Our former proposition suffered from many constitutive defaults [2]. In this version, the difference between the actual uptake and the cell needs is used to trigger the regulatory mechanisms that control the cell uptake.

2. Methods

A structured model at the single cell level is formulated and used to write overall mass balance for nutrients and cell number at the reactor scale, resulting in a set of differential equations. Two internal properties are attached to a cell: its maximum potential uptake rate and its maximum elongation rate. The former is expressed as the sum of two contributions by PTS and permeases.

$$q_S = q_{PTS}(S) + q_{perm}(N, A, S)$$

The uptake by permeases implies the product of a number of permeases, N, by a permease activity A. These two quantities evolve in time, increasing when the uptake due to the sole PTS is insufficient to satisfy the cell need for growth (known from the second cell property, its elongation rate) and decreases when sugar uptake overtakes the cell needs. A basic flux metabolic model is used to orient the carbon fluxes toward growth or overflow. Beside the biological properties defining the biological upper limit, the overall uptake rate is obviously upper-bounded by the maximum flux of substrate reaching the cell –liquid interface considering possible external limitation.

3. Results and discussion

Batch and continuous cultures of *E.coli* were simulated. Figure 1 show that PTS dominates at high concentrations at the beginning of the culture. The cell needs are high for the elongation rate is also high. As the sugar concentration decreases, the PTS contribution becomes insufficient and that triggers the activation of the permease system. Interestingly and as reported by Ferenci [3], the induction of permeases occurs well before the sugar concentration has reached the affinity constant of the PTS system (here set to 10 mg/L). This apparent ability of cells to anticipate glucose exhaustion remained unexplained until now, but emerges as a natural consequence of the flux formulation adopted in our model. At the end of the batch, the time lapse before glucose exhaustion is so short that the number of permeases cannot significantly increase.

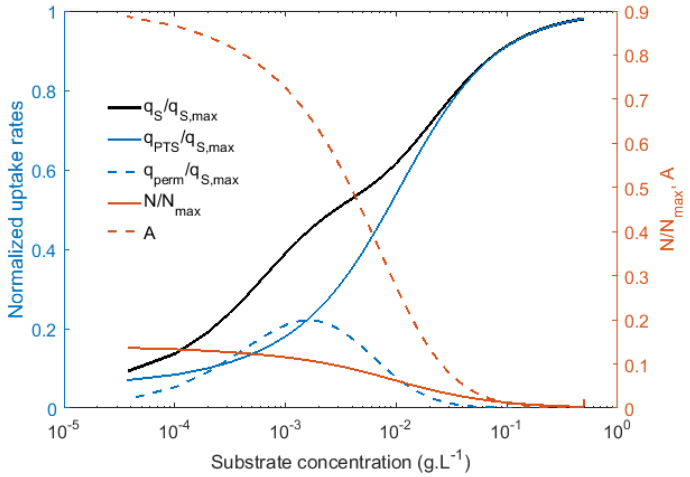

Figure 1. Evolution of PTS and permease contribution to the total uptake rate during the course of a batch culture. Number of permeases and permease activity. Read from right to left to follow the time course of the batch culture

4. Conclusions

A model for the regulation of sugar uptake under transient conditions was formulated and tested under various conditions (setp-up/step-down of the dilution rate, pulse addition). The most striking result is its ability to predict glucose uptake overshoots (far above the maximum value observed in batch) in the following of a pulse addition of substrate, as reported years ago by Neubauer and co-workers [4].

Development, Validation and Comprehensive Sensitivity Analysis of a Fermentation Model Expediting the Process Design of a Biorefinery

Nikolaus I. Vollmer[1], Krist V. Gernaey[1], Solange I. Mussatto[2], Gürkan Sin[1] *

1 PROSYS, Department of Chemical and Biochemical Engineering, Technical University of Denmark;

2 Biomass Conversion and Bioprocess Technology Group, Novo Nordisk Foundation Center for Biosustainability, Technical University of Denmark.

**Corresponding author: gsi@kt.dtu.dk*

Highlights

- Systematic Fermentation Model Development for Biorefinery Process Design.
- Production of Xylitol from Lignocellulosic Biomass.
- Validation and Comprehensive Sensitivity Analysis consolidating the Development Strategy and showing potential for Extended Applications.

1. Introduction

The Sustainable Development Goals of the United Nations (UN-SDG) demand inter alia a transition towards sustainable and responsible economic production patterns [1]. A key approach in achieving these goals is the concept of a biorefinery, in which the processing of lignocellulosic biomass (LB) serves to provide multiple value-adding products [2]. A major drawback though still remains its economic profitability. Therefore, extensive research and development efforts are required to design, analyze and holistically optimize biorefinery concepts in order to enhance their economic feasibility [3]. For these purposes, tools from Process Systems Engineering (PSE) can be employed to give adequate responses to questions from unit level up to the plant-in-market level. The focus of this contribution lies on the production of xylitol by fermentation in a biorefinery. Xylitol can be a highly value-adding product due to its increasing demand in e.g. the health industry [4]. Therefore, a first-principles fermentation model is developed to describe mechanistically the yield of xylitol and the process dynamics. A multi-stage approach is used to develop a customized model which is able to support the process synthesis and design for the biorefinery including performance prediction, sizing and costing analysis. To this end the model accounts for various process phenomena from different scale levels such as biological (e.g. the specific metabolism), chemical (e.g. acid-base equilibria) and physical (e.g. gas-liquid mass transfer) in a fermentation reactor.

2. Methods

The model development incorporates seven subsequent steps, which allow for a gradual implementation: *Step (1)* - Simple Substrate-Product-Biomass correlations, *step (2)* - Oxygen Uptake, *step (3)* - CO_2 production, *step (4)* - Nitrogen Consumption + weak acid-base equilibrium, *step (5)* – Gas-Liquid Mass transfer and Energy Balance, *step (6)* - Internal metabolism reactions and *step (7)* - Additional Products and Substrates. A model framework based upon the matrix formulation of Sin et al [5] is chosen, since it facilitates the desired stepwise implementation.

Exemplary, during *step (1)* an overall mass balance and component mass balances for the substrates, the cell biomass and the products are derived. Conversion rates for all the components are calculated with a stoichiometric matrix of all the components and a process rate vector with all the occurring reactions in the fermentation, which are biomass formation, maintenance and the production of the products [5]. All the further steps aim to add further components and processes to the matrices/vectors and introduce new component or overall mass balances and energy balances. The steps are consecutively validated with data for a specific microorganism employed for xylitol production. Finally, a comprehensive local and global sensitivity analysis is conducted.

3. Results and discussion

The purpose of this approach is to guarantee a sufficient model complexity, while taking into account all necessary mentioned factors avoiding excessive complexity. Hence, *step (1)* is supposed to serve as fundamental model base. Since most microorganisms grow under aerobic conditions, oxygen is integrated into the model in *step (2)* to yield information about the oxygen demand. Since CO_2 is an important end product in the aerobic metabolism, a quantification is important, since it can be sold as by-product. The inclusion of nitrogen in *step (4)* contributes furtherly to the accurate prediction of the biomass growth since the microorganisms require nitrogen to grow. The weak-acid base model is introduced in the same step, because nitrogen sources serve as proton donors and influence the pH value of the liquid directly, which itself influences the concentration of CO_2 in liquid. The consideration of mass transfer refines these phenomena and yield a quantitative response for oxygen and CO_2 concentrations in gas and liquid phase. Considering the evaporation of H_2O is important, since it quantifies its loss and hence equally a necessary compensation to maintain a constant reaction volume. Other contributing factors here a potential heating of the system due to thermophilic conditions or increasing viscosity which influences the mixing effort. The assessment after *step (5)* considers the sufficiency of the prediction qualities of the model. Both *step (6)* and *(7)* denote a trade-off between the model complexity and its final purpose of prediction. Due to the flexibility of the framework this assessment can always be revised, depending on the further needs of the desired application. The validation with data in the chosen case shows a sufficient result in terms of yield prediction for xylitol and the process dynamics after the fifth step, implying to cease the implementation here. The sensitivity analyses show expected results.

4. Conclusions

The presented model structure and in particular its sequential implementation with increasing complexity proves to be a perfectly suitable approach in order to provide a model for this purpose. It ascertains a flexible and easy implementation for all seven steps in case of adaption of the model framework for various microorganisms, products or substrates. Hence, it yields simple yet adequate models for the process design of a biorefinery and thus can support the transition towards more sustainable processes as demanded by the UN-SDG.

The Effect of Co-Solvent and Catalyst Type on the One-Step Supercritical Carbon Dioxide (*Trans*)esterification of *Swietenia Macrophylla* Seed

Juvyneil Cartel[1], Joseph Auresenia[2]

1 Eastern Visayas State University, Tacloban City, Philippines; 2 De la Salle University, Manila, Philippines

**Corresponding author: joseph.auresenia@dlsu.edu.ph*

Highlights

- Utilizing co-solvent gave significant effect to the oil yield where methanol showed to be the best.
- Utilizing base-functionalized MWCNT as catalyst is still more practical rather than using KOH though it exhibited to make the highest yet at par %FAME Yield.
- Cetane number of the biodiesel used showed to be high which can provide short ignition delay in diesel engines when used.

1. Introduction

Mahogany (*Swietenia Macrophylla*) seed, a non-edible seed is not only abundant in most of the localities in the Philippines. It has been found out that the seed has a significant amount of oil of around 39-58% [1, 2]. Moreover, it was proven that Mahogany seed is a potential feedstock for biodiesel production which could meet biodiesel standards, comparable to petroleum-based diesel. However, issues on the presence of a significant amount of impurities like free fatty acid (FFA), moisture, waxes, and gums may arise. To resolve these issues the process may require additional processing steps before this feedstock can be used for biodiesel production using the conventional base-catalyzed process. Otherwise, a process requiring the use of a specific catalyst and /or solvent conditions may be needed to effectively utilize this feedstock. Until now, achieving the supposed potential of seed biofuels remains in the experimental lab scale due to the mundane cost of its production, making them less attractive for long-term operations in the industrial-scale [3].

One-step (*trans*)esterification using supercritical carbon dioxide and two-reactors in series of dried Mahogany seed creates interest and was studied since there is a significant reduction in the process supply chain by combining crucial steps and increasing the residence time which could improve the conversion of triglycerides to FAME. The effect of co-solvent and catalyst type on the relatively novel process was determined and quantified in order to determine their response on oil and FAME yield.

2. Methods

The experimental set-up include: (a) Liquid CO_2 cylinder which provides the carbon dioxide in the process; (b) Micro filter which ensures that no contaminants could enter the system; (c) Chiller which brings down the temperature of the carbon dioxide to 2^{o}C, thus in liquid state; (d) HPLC (High Performance Liquid Chromatography) pump which regulates the flow rate of the carbon dioxide of the system; (e) Oven with installed pre-heater (f) that controls the temperature for the

extraction/(*trans*)esterification; (g) the reactors (approximately 10 and 50-ml capacity) where extraction and (*trans*)esterification are being held; (h) BPR (Back Pressure Regulator) which controls the pressure of the system; (i) Cyclone separator which separates carbon dioxide from the sample; and (j) is the sampler flask. The experiment was divided into two phases. First phase dealt with the effect of co-solvent type on oil yield while the 2nd phase studied on the effect of catalyst type on the FAME yield. All of these were subjected in supercritical carbon dioxide extraction/(*trans*)esterification at a pressure of 30 MPa and temperature of 90°C, and at CO_2 influx of 10 g/min. N-hexane, methanol, mixture of n-hexane and methanol were among the co-solvents used. On the other hand, potassium hydroxide (KOH), acid-functionalized MWCNT (multi-walled carbon nanotubes) and base-functionalized MWCNT were the types of catalyst utilized in this study. One-factor completely randomized design was used as the basis in designing the experiments.

3. Results and discussion

The result has shown that utilizing a co-solvent could give significant effect to the oil yield where methanol showed to be the best. Utilizing n-hexane with methanol as co-solvent could have been a good alternative for it gave a close result to methanol. However, lots of impurities have been observed that 86% have been wasted. Moreover, using more co-solvent types could just make the separation complex. On the other hand, %FAME Yield was highest when OST was run with KOH as catalyst. The result is close to that of the base-functionalized MWCNT catalyst. However, utilizing KOH is cost intensive and will not pose an economic advantage to the process.

The %FAME could have been high enough to meet the European standard of at least 95%, however, optimum conditions for one-step supercritical fluid (trans) esterification could not be met due to the limited capacity of the reactors (e.g. allowable pressure, temperature). In effect of low %FAME important properties of the biodiesel obtained under the supercritical conditions failed to conform to the standards except for Cetane number (CN) which is high. This means that with high CN, the biodiesel produced can provide short ignition delay in diesel engines.

4. Conclusions

In conclusion, it is best to use methanol as co-solvent and base-functionalized MWCNT to obtain the most practical FAME yield. Moreover, the biodiesel produced can give the highest Cetane number which is relative to short ignition delay among the feedstock studied. However, reactors have yet to be upgraded with higher capacity, especially the maximum allowable temperature to possibly obtain higher %FAME and conform to all standards on biodiesel properties.

Highlights

- lipase catalyzed biodiesel transesterification
- biodiesel purification in a microseparator
- analysis of the flow patterns
- CFD simulations of biodiesel and DES flow profiles

1. Introduction

Biodiesel is an alternative fuel, similar to classic fossil fuels that can be used in diesel engines. It is a mixture of alkyl esters of fatty acids that can be produced from vegetable oil, micro algal oil or animal fats [1,2,3]. Biodiesel production is mostly achieved through transesterification, using short-chain alcohols (typically methanol or ethanol). This reaction also produces glycerol, which along with unreacted alcohol and oil, has to be removed from the product before it can be used in commercial application. There are several approaches that can be used for biodiesel purification (sedimentation, decantation, water washing, filtration etc.) but all of them are usually characterized as inefficient, non-ecological, expensive, energy consuming etc. In order to resolve some of this disadvantages microseparators coupled with deep eutectic solvents (DESs) were proposed as solution. Microseparators have been widely used to improve the mass and heat transfer processes between two phases due to the high surface-to volume ratio, higher heat and mass transfer rates and short diffusion distance. To achieve the maximum productivity of the biodiesel purification process in a microseparator it is necessary to take into account nature of the components and the operational conditions, such as temperature, volumetric flow rate, dimensions of the used microchannel. All mentioned parameters significantly influence the flow pattern formation. In this work computational fluid dynamics (CFD) analysis was carried out to illustrate and visualize the interactions between two existing phases in separation systems.

2. Methods

Biodiesel production catalyzed by lipase from *Thermomyces lanuginosus* using edible oil and methanol as the substrates was performed in a batch reactor according to procedure described by Budžaki *et al*. [4]. After biodiesel was produced, it was placed in a separation funnel (traditional approach for glycerol removal) in order to remove glycerol for 24h. After separation of two phases and analysis of biodiesel content separation efficiency was around 90.37%. In order to remove residual glycerol, microseparator (length: width: depth = 332 mm: 500 µm: 50µm; Micronit

Microfluidics B.V. Netherlands) in combination with DES was used. Experimentally obtained data were compared with the CFD simulation results. The CFD simulations of the biodiesel and DES flow profiles in selected microseparator were performed using the finite element software COMSOL Multyphysics v.4.2. A laminar flow model with Lagrangian specification of the field and Ditrich type boundary conditions were used.

3. Results and discussion

In microseparators mass transfer occurs along the interface area between phases so stability of the area is the first necessary condition. The second condition is crucial for phase separation at the exit of microseparator where interface area has to be positioned in the middle of microchannel and flow has to be parallel. Since DES and biodiesel have different physical properties, the input flow rates had to be adjusted so that both phases occupy the same volume in the channel. Therefore, the influence of flow rates on the flow pattern was studied. This was done with the help of a microscope for different flow rates, ranging from 0 to 20 µL min^{-1} for the biodiesel and from 0.02 to 18 µL min^{-1} for DES (Figure 1).

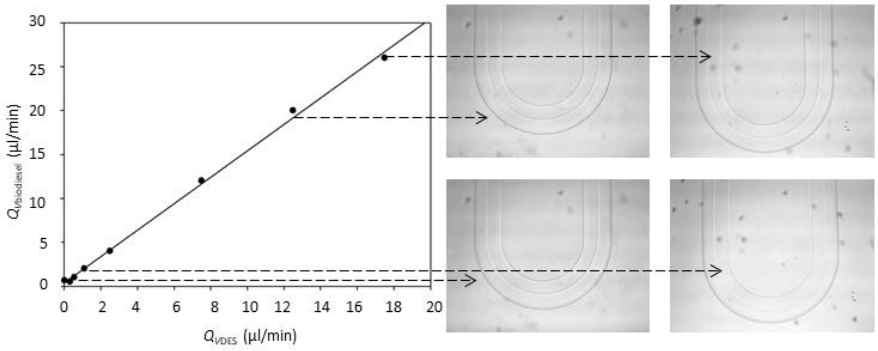

Figure 1. Influence of the velocity on the position of the interphase area

To analyze the hydrodynamics of the selected microseparator system, Re numbers were estimated. The high Re numbers leads to better mixing, and also changes the flow profile. CFD experiments for visualizations of both biodiesel and DES flow profile were carried out by estimating the fluid properties based on assumption of simple mass balance at the beginning and at the end of the microseparator.

4. Conclusions

In this study biodiesel purification using DES in a microseparator was performed. Obtained results indicate that microseparator system is efficient technology for the biodiesel purification. CFD simulations ensure delight insight in the hydrodynamics of biodiesel purification process.

Highlights

- Bacterial cellulose (BC) is an innovative support for biomass immobilization.
- The active material *A. ferrooxidans*+BC can be used in continuous bioleaching processes.
- The immobilized biomass remains active even at 15 g Cu^{2+}/L.

1. Introduction

Bioleaching is a microorganism-assisted process used to dissolve metals through the action of oxidizing agents. It has been proposed as a sustainable alternative to conventional micromachining and extracting processes for the recovery of valuable metals [1].

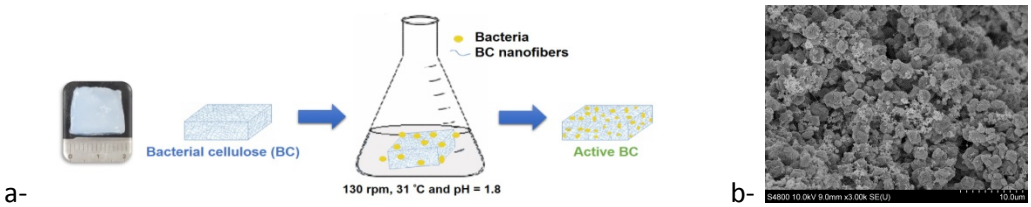
Several authors have investigated the immobilization of the bacterium *Acidithiobacillus ferrooxidans* (the most widely studied microorganism for metal bioleaching) on different support materials with a view to increasing microbial density inside the bioreactor and facilitating biomass replacement when required [2,3]. Bacterial cellulose (BC) is a promising candidate to be used as a support material for biomass immobilization due to its peculiar 3D network structure of ribbon-shaped cellulose nanofibrils (2-4 nm in diameter) and its high specific surface [4].

This study's main objective was to assess the response of an innovative active material when used to immobilize *A. ferrooxidans* bacteria. An immobilization methodology was proposed, and the study focused on the influence that the number of attached bacteria and the concentration of dissolved copper had on the time required to recover the oxidant.

2. Methods

Bacterial cellulose (BC) was synthesized following the procedure described by Retegi et al. [5]. Bacteria were immobilized on BC by immersing the biopolymer into an Erlenmeyer flask with a nutrient medium containing 6 g Fe^{2+} L^{-1}. A 5% inoculum of *A. ferrooxidans* in the exponential growth phase was added, and cells were cultivated until the complete oxidation of the Fe^{2+} to Fe^{3+} (Figure 1a). Thus, the active BC was obtained (*A. ferrooxidans*+BC).

The relationship between the number of immobilized bacteria and Fe^{2+} oxidation time was studied by culturing 4, 6 and 8 pieces of the active BC (20x20x7mm) in a fresh medium. In addition, a study was conducted on the effect of copper concentration on the activity of the immobilized bacteria by cultivating active BC pieces in nutrient media containing 0, 5, 10 and 15 g Cu^{2+} L^{-1}.



a- b-

Figure 1. a- Preparation of the active BC; b- SEM analysis of A. *ferrooxidans* attached to the BC.

3. Results and discussion

A. ferrooxidans cells successfully colonized the support material, and the time required for the microorganisms to oxidize the Fe^{2+} was not affected by the presence of the BC. It is noteworthy that only one growth cycle was required to obtain the active material (Figure 1b).

The average Fe^{2+} oxidation rate with eight BC pieces was about 25% higher than with four pieces. Regarding the inhibitory effect of dissolved copper on the biological activity of A. *ferrooxidans*, the oxidation time increased linearly with copper content (up to threefold for the highest metal concentration). Nevertheless, when the immobilized bacteria previously exposed to the three concentrations of copper were cultivated in a second cycle, the time needed for the complete conversion of Fe^{2+} was significantly reduced, being similar in all the bioreactors. The most significant difference was recorded in the flask with 15 g Cu^{2+} L^{-1}, where the oxidation time was reduced by 68% compared to that in the first oxidation cycle. These results suggest that the attached bacteria gradually adapted to the presence of Cu^{2+}. Moreover, active BC pieces adapted to 5 and 10 g Cu^{2+} L^{-1} were not inhibited when cultivated in media containing 15 g Cu^{2+} L^{-1} (in a third cycle). These results confirm the successful adaptation of the immobilized bacteria regardless of the initial copper concentration.

4. Conclusions

Bacterial cellulose is an outstanding innovative support material for the immobilization of *A. ferrooxidans,* and therefore a promising carrier for continuous bioleaching processes. Oxidation time was reduced according to the number of active BC pieces, and the immobilized bacteria gradually adapted to the toxicity of high concentrations of dissolved copper, even at 15 g Cu^{2+}/L.

Highlights

- Exo-inulinase produced by fermentation of *Kluyveromyces marxianus* in yacon extract.
- Checking glycerol, mannitol and sorbitol as stabilizing substances in biocatalysis.
- Improvement of the thermal and kinetic stability of the semi-concentrated inulinase.

.

1. Introduction

The exo-inulinase of Kluyveromyces marxianus NRRL-Y 7571 is an extracellular enzyme that catalyzes the hydrolysis of inulin into practically pure fructose. Also inulinase has been found transfructosilación activities. The biggest problem facing the use of inulinase is its poor kinetic and thermal stability. One way to stabilize an enzyme is to use substances that increase its thermodynamic stability.

2. Methods

A batch culture of K. marxianus was carried out in an automated 2 L fermenter with optimized liquid medium, containing yacon extract, to generate the enzymatic extract, then the separation by centrifugation and semi-concentration of the inulinase by precipitation with ethanol.
The activity and thermal stability data were obtained, incubating 10 mL of the enzyme semi-concentrate containing 5% and 10% of glycerol, mannitol and sorbitol, as corrected, in 0.05 M citrate phosphate buffer, pH 5.0, at 55ºC for different periods, after which the remaining activity was measured. Enzymatic activities were determined by measurements of initial velocity on a standard 20 g / L sucrose solution. The analyzes of reducing sugars and proteins were made by DNS and Bradford.

3. Results and discussion

The results showed that the presence of each of the cosolutos: glycerol, mannitol and sorbitol in their two concentration levels, increased the catalytic activity of inulinase by an average of 15.81%, which shows that each substance had a power-inducing effect catalytic enzyme. Correspondingly, the three cosolutos improved the biocatalytic and thermodynamic stability under non-reactive conditions of the exo-inulinase, with 5% glycerol contributing the best (Fig. 1), reaching the lowest value of the kinetic constant of equal denaturation at 0.0845 h^{-1} and 7.5 times the average life time of the inulinase acting without stabilizer. This is because the substances contributed to maintain the native conformation of the enzyme, deduced that it became more rigid, at least in certain areas of its surface, supported by the mechanism of the exclusion of substances from the surface of the protein, which increases the structured water around that area.

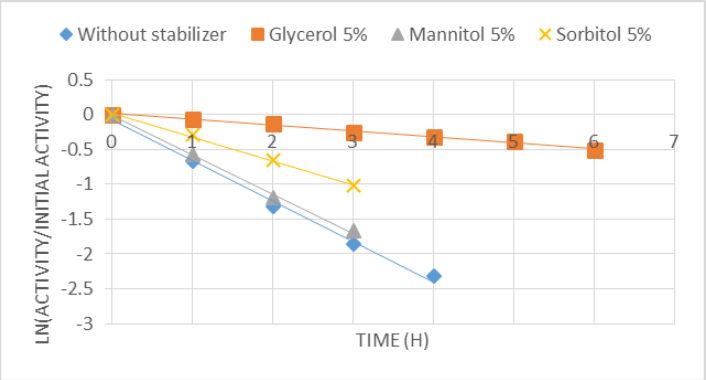

Figure 1. Effect of glycerol, mannitol and 5% sorbitol each on the thermal stability of *K. marxianus* NRRL-Y 7571 inulinase acting on sucrose.

4. Conclusions

The presence of each of the substances: glycerol, mannitol and sorbitol, improved the biocatalytic and thermodynamic stability under non-reactive conditions of the semi-concentrated exo-inulinase of *K. marxianus* NRRL-Y 7571, with glycerol contributing more significantly.

Valorisation of solid waste: Briquettes production from corn-stover

Oluwaseun Oyekola[1], Ongama Soka[1], Felicia Ngubane[1]

1 Department of Chemical Engineering, Cape Peninsula University of Technology, Bellville Campus, Symphony way, Cape Town

**Corresponding author: oyekolas@cput.ac.za*

Highlights

- Effect of temperature, heating rate and hold time on the char HHV from the slow pyrolysis of corn-stover was investigated.
- The optimum conditions for maximal char HHV were found at a temperature of 431°C, 6°C/min heating rate and a hold time of 29 minutes.
- The biochar HHV was 28.64 MJ/kg comparable to that of coal (23.9-26 MJ/kg).
- Briquettes with high density and durability were obtained

1. Introduction

With increasing global population and industrial activities, the world is currently challenged with energy crisis and the associated global warming, and environmental pollution. These issues have been the subjects of intensive research in recent years. Energy shortage is a serious problem in developing countries and the energy sector is looking for alternative sources of energy, which are environmentally friendly and cheaper. South Africa is the largest producer of maize in Africa (10-12 million tonnes per year) (FAO, 2016). Approximately 9 million metric tonnes of corn residues, corncob and corn-stover are produced per annum as agricultural wastes in South Africa (FAO, 2015). Hence, this can be a major pollutant as a solid waste and the disposal thereof can be challenging which can pose as a harmful threat to the environment. Corn-stover is a naturally abundant domestic energy source that is promising to relieve energy scarcity (Morissette et al., 2014). It is sustainably available with no competition for resources with food/feed production and other biomass applications. While there have been comprehensive reports of laboratory-scale studies in South Africa for bioethanol, biochar, bio-oil and gases (Mohlala et al., 2016), there is dearth of literature reporting the use of corn-stover for the generation of briquettes. Briquettes are made from waste materials or partially compressed biomass waste (Morisette et al., 2014). They are eco-friendly alternatives as fuel instead of charcoal, firewood or coal. The purpose of this work is to promote material and energy valorisation of corn-stover. This study investigated the optimisation of the carbonisation of corn-stover. Densification process of biochar resulting in briquette production was carried out.

2. Methods

The corn-stover was collected from a maize farm. The collected samples were dried to 10% and milled to a particle size range of 3.5mm-0.63mm. Biochar was produced via slow pyrolysis using a retort reactor in the absence of oxygen by purging with nitrogen. The ASTM D3175-17 standard methods were used to obtain the ash content of the samples. A central composite design (CCD) of gram scale experiments was used to study the effects of the of temperature, heating rate and hold

time on the char HHV. Design Expert® Software Version 10 (Stat-Ease, Inc., Minneapolis, USA) was used to study the CCD. With regards to the design of experiments (DoE), the selected DoE conditions were 300, 400 and 500°C for temperature, 5, 12.5 and 20°C/min for heating rate and 5, 17.5 and 30 minutes for holding time. Briquettes were produced by adding a starch binder (5 and 10%) to the biochar. Finally, the mixture was compressed using a piston press cylinder to densify the biochar/binder mixture.

3. Results and discussion

The optimum conditions for char production were 453°C, 5°C/min and 29 min. Under these conditions, an average char yield of 34.5% was determined. The final prediction equation obtained from Design Expert® software version 10 for char HHV by temperature (x_1), heating rate (x_2) and hold time (x_3) of a fixed bed reactor is provided by equation 1. The positive quadratic factor coefficients (+1.48 and +0.26) indicate that char HHV tends to increase with a rise in temperature and hold time respectively (Equation 1). While the negative quadratic factor coefficient (-0.5) indicates that an increase in heating rate will result in a reduction in char HHV.

$$\text{Char HHV} = 24.06 + 1.48x_1 - 0.5x_2 + 0.26x_3 - 0.54x_1x_2 - 0.071x_1x_3 - 0.41x_2x_3 - 2.46x_1^2 + 0.15x_2^2 + 0.68x_3^2 \quad \textit{equation 1}$$

The ash content of the untreated corn-stover was 4.96% while the biochar was 13.34%. This indicates its potential to produce smokeless solid fuel. Higher heating value (HHV) of the untreated corn-stover was found to be 18.7 MJ/kg while the biochar HHV was found to be 28.92 MJ/kg comparable to that of coal (23.9-26 MJ/kg) (Morissette et al., 2014). The carbon rich biochar is obtained with higher amounts of fixed carbon of 63.70% and ash content of 13.34%, but lower amounts of volatiles of 20.38% than corn-stover biomass feedstock which means that the biochar produced has improved burning properties because lower volatile matter results in increased burning time and no smoke during burning. The compressive strength obtained from densification was in the range 3.45-6.11 N/mm^2 with increasing binder concentration between 5 and 10%. The density obtained through densification process (20-40MPa) ranges from 420-788 kg/m^3 shows the durability obtained through densification which ranges from 97-100%.

4. Conclusions

Briquettes with high density, durability and fuel properties were obtained. These have potential to substitute or augment reliance on coal.

A simulation study to evaluate the potential of semi-transparent solar panels coupled with a closed intensified photobioreactor

Julien Louveau[1], Jeremy Pruvost[1], Mariana Titica[1], Navid Moheimani[2]

1 University of Nantes, Oniris, CNRS, GEPEA, UMR 6144, 44602 Saint-Nazaire Cedex, France

2 Murdoch university WA 6150, Murdoch, Australia

**Corresponding author: Julien.louveau@eut.univ-nantes.fr*

Highlights

- A model coupling semi-transparent solar panels and photobioreactors has been developed
- Synergies and trade-offs between biomass and electricity coproduction were analyzed

1. Introduction

In contrast with open ponds, closed photobioreactor (PBR) technology allows a tight process optimisation which leads to significant productivity enhancement. Nevertheless, when set outdoor (to benefit from natural sunlight), these PBRs are sensitive to climatic fluctuations. Ensuring optimal growth conditions becomes critical. This especially concerns the temperature as enclosed culture volumes tends to overheat [1]. Then, active temperature control could become prohibitive in terms of energy needs.

As microalgae only need a small portion of the solar light (the photosynthetic active range: PAR, [400 – 700] nm), removing the unnecessary light (infra-red: IR and ultra-violet: UV) could reduce the heating of the PBR. To filter the incoming light, the use of semi-transparent solar panels (PV) has been suggested by [2]. Those solar panels are able to capture and convert into electricity some specific radiations depending on their wavelength. Other radiations are transmitted and can be used for biological conversion. Coupling a PBR and a semi-transparent solar panel opens then the perspective to coproduce biomass and electricity while preventing the overheating of the PBR.

In this context, the work presented here has investigated, with a model-based approach, the impact of such coupling on PBR's thermal behaviour, microalgae productivity and electricity production.

2. Methods

The investigation of this study has been done by numerical simulation. Three validated models from the literature were coupled to set a predictive model able to simulate PBR-PV associations. It aims to maximize biomass production while decreasing energy needs. A generic thermal model [1] was used to determine the thermal behaviour of the PBR and the amount of energy required for temperature control. The range of operating temperature was fixed to [15 – 34]°C which is considered suitable for microalgae growth without significant loss in productivity (Todisco et al,. 2019). Second, a microalgae growth model [3] was used to calculate the productivity of the culture in solar radiation conditions, considering light alone limits growth. Finally, an electricity production model [2] was used to compute the production of the solar panel. Different light filters (solar panels) have been tested. Numerical simulations have been performed considering a thin-film solar

photobioreactor: AlgoFilm© *(figure 1)* [1]. The meteorological data used describes the average weather of a year for the city of Nantes. In all simulations, the input light was set in spectral form.

3. Results and discussion

Different simulation scenarios were performed, with a view to analyse synergies and trade-offs between biomass and electricity coproduction. An example of results is presented in Figure 2.

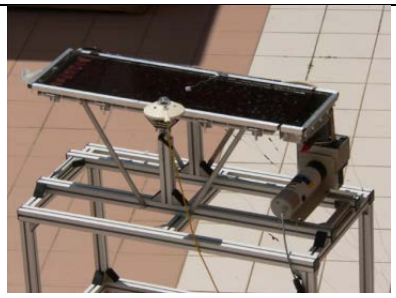

figure 1: The thin-film solar photobioreactor [1]

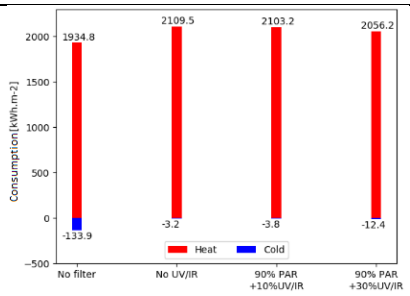

figure 2: Cumulated energy consumption

The simulation study revealed that the use of semi-transparent solar panels allows a significant reduction in PBR's cooling needs. However, it also results in an important raise in heat needs. In winter, with the tested weather, the nights can be as cool as 0°C, thus keeping the reactor at the lower set point requires a large amount of energy *(figure. 2)*. This is particularly true for the considered reactor which has been designed to prevent overheat (large contact area with the ambient air for a small volume). Thus, adding a solar panel was found detrimental for the winter period. Those results points out the necessity to find a compromise. For example, passive cooling and electricity production are increased by reducing the PAR transmitted to the culture. This was found to have a major impact on the reactor heating. It however reduces the biomass productivity (10% to 40% loss). Our model was found useful to obtain input data for a techno-economic analysis which would help to define an association strategy of such a promising hybrid system.

4. Conclusions

An integrated model was developed to simulate PBR-PV association, for the optimal design of a hybrid solar PBR maximizing biomass production while decreasing energy needs. This study showed that the use of semi-transparent solar panels significantly reduced the overheating of our solar PBR. It could however induce negative effects, such as the increase in heating need during the night. Predictions were found useful to determine the best compromise in terms of biomass and electricity production, but also energy saving for thermal regulation. Such a tool also enables to investigate other climates such as Australia where the monthly average temperature reaches 20°C. As the reactor could be warmer even in the night, this may be an interesting passive cooling solution for this location.

Highlights

- The use of *Shewanella* bacteria and baker's yeast to recover precious metals.
- Bioreductive deposition of PGMs from the leachate of spent catalysts at pH 6.
- Selective and efficient biosorption of Au from the CPUs leachate at pH 1.
- New biotechnologies to extract PGMs and gold from post-consumer products.

1. Introduction

Many post-consumer products, such as electronic goods and catalytic converters in cars, are important sources of precious and rare metals. Although conventional thermal and chemical techniques remain the best methods for recycling precious and rare metals, these metals have yet to be fully utilized. Therefore, further research and development is needed to fully recycle precious and rare metals from secondary sources. We believe that biological technologies now provide an attractive and eco-friendly alternative strategy. This paper describes our research results from using new biotechnologies to fully recycle platinum group metals (PGMs) from spent automotive catalysts and gold from electronic waste.

2. Results and discussion

We focused on using the metal ion-reducing bacterium, *Shewanella algae*, to recover PGMs from the aqua regia leachate of spent automotive catalysts (Figure 1). The Shewanella bacteria were able to reduce PGMs ions (Pd(II), Pt(IV) and Rh(III)) in the catalyst leachate as metallic nanoparticles on the bacterial cells at room temperature and pH 6 within 60 min, using formate as the electron donor.

We also employed baker's yeast, *Saccharomyces cerevisiae*, as a commercially available biomaterial for collecting gold ions from the aqua regia leachate of spent central processing units (CPUs) from electronic waste (Figure 2). The baker's yeast was able to rapidly and effectively collect only gold ions from the CPUs leachate at pH 1 within 10 min. Importantly, baker's yeast did not react with other heavy metal ions, such as copper, nickel, and iron.

This flow diagram compares the conventional wet chemical process with our new bioprocess for recycling PGMs and gold (Figure 3). Our new bioprocess integrates a complex multistep method into a single-step procedure that separates and concentrates the precious metal from a leaching

solution. Unlike conventional processes, the benefits of this process include a significant reduction in energy consumption and material consumption, and a low environmental impact.

Our highly efficient bioprocess could be introduced at local collection points for post-consumer products and operate as a regionally distributed technology for fully recycling metal resources from post-consumer products, which will lead to the sustainable use of precious metals.

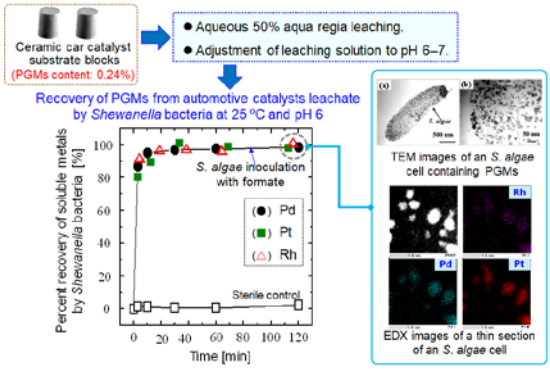

Figure 1. Microbial recovery of platinum group metals (PGMs) from aqua regia leachate of spent automotive catalysts.

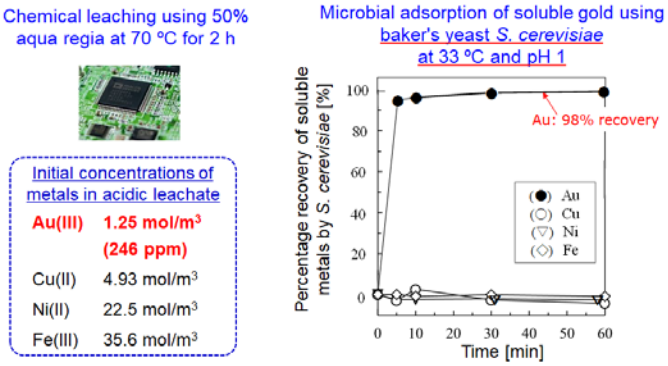

Figure 2. Selective recovery of gold in aqua regia leachate of CPUs at pH 1, 33°C, and 16 kg-dry yeast/m^3.

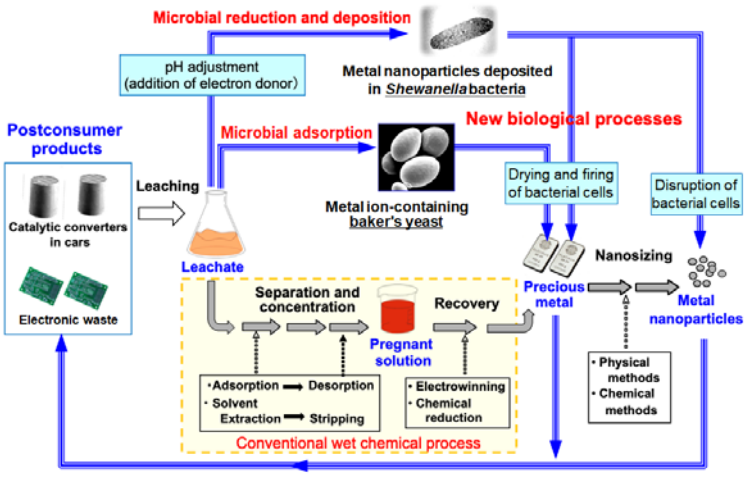

Figure 3. Sustainable use of platinum group metals and gold through biotechnological recycling.

3. Conclusions

We successfully developed new biotechnologies to extract PGMs from spent automotive catalysts and gold from electronic waste.

Fluid dynamics of stirred photobioreactor cuvette

Tomáš Juřena*, Jiří Hájek, Jiří Vondál

[1]*Institute of Process Engineering, Faculty of Mechanical Engineering, Brno University of Technology, Technická 2, 616 69 Brno, Czech Republic*

**Corresponding author: jurena@fme.vutbr.cz*

Highlights

- Modelling approach for bioreactors is described
- Methods of data analysis from CFD models are critically assessed
- Results of fluid dynamics simulation in a mixed, bubbled cuvette are given

1. Introduction

The modeling of bioreactors is a broad sense multi-disciplinary, as it involves fluid dynamics, multiphase flow and mass transfer, radiative energy transfer, and also the growth of the living cells [1]. The complex modelling is however only just emerging [2] and there are many questions that can be answered by simpler models that do not include a complex description of a photobioreactor, only some of the relevant processes [3]. Assessment of parameters connected to mixing and flow pattern can be safely assumed independent of the light intensity and growth dynamics of microalgae.

The modelling of fluid dynamics in a stirred vessel may be performed by any of several approaches, which differ by their inherent assumptions, limitations and answers that they can provide. In the case of a stirred laboratory photobioreactor, its typical structural components include rectangular glass walls, a magnetic stirbar, several sensors (e.g. thermometer, CO_2 probe) and aerator tube. The fluid dynamical system is then composed of three main components, namely the medium, the algae and bubbles. Physical characterization of all the three components is relatively simple.

The purpose of this contribution is comprehensive characterization of the fluid dynamics in a typical laboratory cuvette using computational fluid dynamics (CFD). Model properties, components and numerical performance are critically assessed as well.

2. Methods

The modelling is based on Euler-Lagrange approach, where bubbles and/or algae are tracked in Lagrangian framework, while the medium is described in Eulerian framework as a Newtonian liquid. Governing equations are discretized and solved by the finite volume method.

For all intents and purposes related to fluid dynamics, the medium is water. In this work, we use fresh water, without loss of generality. The cuvette is a standard laboratory equipment, in our case with a volume of about 400mL. The algae exist in a wide variety of species and strains, but for the purpose of fluid dynamics we need to distinguish them only by size and shape. In this

work, we focus on microalgae that are coccoid in shape and their size (diameter) is around 2.5µm. The characterization of bubbles is slightly more difficult, as a bubble may change its shape and even size. The size change is caused either by shedding small bubbles from large ones or by merging (coalescence).

Special care is given to mesh quality and independence of the results on the mesh is documented. The results are reported with focus on choosing the best available parameters that characterize the fluid dynamics meaningfully with respect to the purpose of the photobioreactor. Scalar indicators are sought to provide a global perspective of the system. Local indicators are used sparingly.

3. Results and discussion

The results cover fluid dynamics model development for the specific case of a cuvette equipped with a stirbar, aerator and two probes, as illustrated In Figure 1. Results also include analysis of fluid flow properties in several studied scenarios with different stirbar rotation velocities.

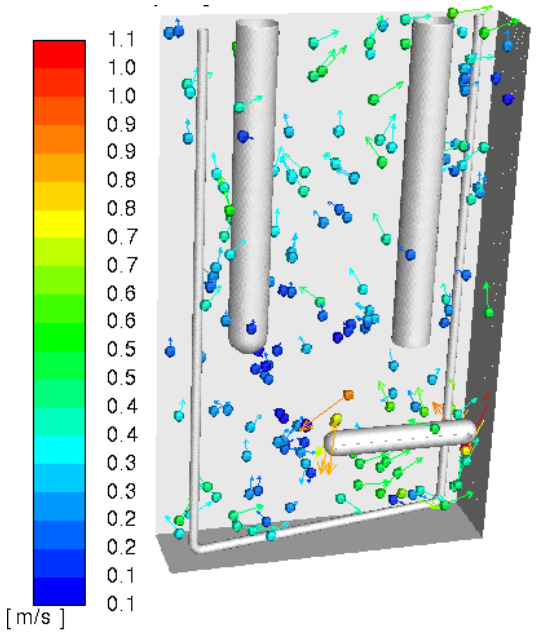

Figure 1. Bubbles colored by their velocity, also shown are their velocity vectors

4. Conclusions

Modelling methodology for fluid dynamics in a photobioreactor including mesh properties has been developed. Suitable indicators and statistics have been defined to characterize the operating conditions.

State Substitution: A novel method for parameter identification of large-scale bio-chemical kinetic models

Paulius Rasiukas[1], Chris O'Malley[2], Mark J. Willis[3]
1 School of Engineering Newcastle University, p.rasiukas@ncl.ac.uk; 2 School of Engineering Newcastle University, chris.o'malley@ncl.ac.uk; 3 School of Engineering Newcastle University, mark.willis@ncl.ac.uk

Highlights

- A new method to identify unknown parameters in large scale dynamic models.
- State substitution using a non-parametric model allows decoupled equations to be solved independently.
- A computationally efficient and accurate parameter identification method when compared to alternative techniques.

1.0 Introduction

The ability to identify the parameters of models of complex large-scale (bio) chemical systems is critical in order to develop an understanding of a system as well as to use the model as a basis for process control or process optimization. Established methods of parameter identification normally simultaneously solve the entire set of nonlinear ordinary differential equations (ODEs) that describe the system to determine the model parameters. Generally, the ODEs are numerically integrated and the model parameters obtained using an optimisation algorithm that minimises the difference between the model predictions and the measured process data. However, this is known to be a non-trivial task, often requiring significant solution times and being prone to sub-optimal parameter identification. In this contribution we propose a new method for the identification of unknown parameters of large scale (bio)chemical kinetic models.

2.0 Methods

We decouple the set of ordinary differential equations (ODEs) describing kinetic phenomena into separate sub-systems, whose unknown model parameters can be identified separately. Each ODE is considered a separate sub-system and state substitution is used to replace any coupled model components, i.e. the additional states that would normally be obtained as a result of the numerical integration of the entire system model. The state substitution method we employ relies on the use of measured state variables that are regressed against time using a suitable non-parametric model, e.g. polynomial, spline, neural network. The nonparametric model is then used to replace the states of any of the coupled components of each ODE. This allows numerical integration of each ODE separately and the use of traditional parameter identification techniques to identify any unknown parameters of each sub-model. In a final stage of our method, we then integrate the entire set of ODEs using a global optimisation algorithm using the numerical values of the model parameters obtained from the optimisation of each sub-system as the initial guess. This not only reduces computational time significantly compared to current simultaneous solution methods it ensures statistical optimality of the final parameter values.

To demonstrate the method, it is applied to a biochemical process model described in [1], and compared with a Latin hypercube induced multi-start method, which has been reported to be an efficient method for model calibration in systems biology models [2,3]. The model is shown below where it may be observed that there are 15 unknown kinetic parameters, $p1, \dots, p16$, and each state $x1, \dots, x6$, is assumed measured,

$$\frac{d}{dt}\begin{bmatrix} x1 \\ x2 \\ x3 \\ x4 \\ x5 \\ x6 \end{bmatrix} = \begin{bmatrix} 1 & -1 & 0 & 0 \\ -1/p8 & 0 & -1 & 0 \\ p9/p8 & 0 & p9 & 0 \\ -1/p12 & 0 & 0 & 0 \\ p13/p12 & 0 & 0 & 0 \\ 0 & 0 & 0 & 1 \end{bmatrix} \begin{bmatrix} f1 \\ f2 \\ f3 \\ f4 \end{bmatrix}$$

$$f_i = u_i x1\,, i = 1{,}4$$

$$u_1 = p1\frac{x2}{(p2+x2)}\frac{x4}{(p3+x4)}$$

$$u_2 = p4\frac{1}{(p1-p5x3)}\frac{1}{(p1-p6x5)}\frac{p7}{(p7+x4)}$$

$$u_3 = p10\frac{x2}{(p11+x2)}$$

$$u_4 = p14 + p15\frac{u1}{p16+u1}$$

In the results that follow, the non-parametric model used for state substitution was a cubic spline and each decoupled ODE was integrated using the MATLAB function *ode45*. The optimisation algorithm used to determine the unknown model parameters was the MATLAB function *lsqnonlin* via repeated integration each decoupled sub-component of the overall kinetic model. Simultaneous optimisation of the full kinetic model used MATLAB's genetic algorithm routine.

3.0 Results and discussion

A significant number of comparative studies have been made via adjustment of the number of data measurements assumed available and the level of measurement error (measurement noise). Table 1 indicates a typical scenario comparing the estimated parameter values to the actual (known) model parameters.

Name	$p1$	$p2$	$p3$	$p4$	$p5$	$p6$	$p7$	$p8$	$p9$	$p10$	$p11$	$p12$	$p13$	$p14$	$p15$	$p16$
(1)	1.09	1.1	0.3	0.09	0.01	0.06	0.02	0.11	1.8	1.7	19	0.38	0.85	3.5	25.7	0.02
(2)	1.09	1.06	0.24	0.05	0.03	0	0.40	0.12	1.82	4.07	53.9	0.41	0.86	2.92	26.80	0.02
(3)	1.12	0.91	0.27	0.11	0.01	0	0.50	0.12	1.83	0.79	1.94	0.405	0.82	2.87	25.73	0.01
(4)	4.31	0.01	7.93	4.05	0.10	0.80	286.8	0.34	1.85	18.5	60.1	0.68	0.49	3.86	19.45	0.01

Table 1. Parameter estimates obtained assuming, $x1, \ldots, x6$, are measured every 0.3 h (total number of measurements of each state being 12) with a measurement error of 10% (assumed to be white noise). In the table, (1) Actual values, (2) State – substitution, (3) Multi-start with Latin Hypercube experimental design (4) Simultaneous solution and optimization of the full model.

It may be observed that the parameter estimates obtained using the state-substitution method (2) and the use of a multi-start strategy with Latin Hypercube experimental design to obtain the initial parameter values of each run of the algorithm (3) are of comparable accuracy and are generally significantly superior to that of the simultaneous solution (4). While algorithm run-time will be machine dependent, as an indication of the typical performance of the methods; the state-substitution method (2) took 2371s to find a solution, whereas the multi-start method (3) took 5778s to find a solution while the simultaneous solution (4) ran for 255h and was still not able to converge to reasonable solution.

4.0 Conclusions

A new method for the identification of unknown parameters of large scale (bio)chemical kinetic models was been proposed. For the example given, this provided a fast and reliable parameter estimation procedure. The full paper will present a more detailed assessment of the method using additional bench-mark models [4]. Furthermore, we will use Monte Carlo simulation to provide a statistical perspective on our run-time results and parameter estimates and assess the impact that unmeasured species states have on the identification procedure.

Influences of environmental factors on *Lactobacillus reuteri* growth and 3-hydroxypropionic acid production in the context of coupling with extraction

Thi-Lan-Phuong Nguyen[1*], Claire Saulou-Bérion[1], Catherine Béal[1]

[1] *UMR 782 GMPA, AgroParisTech, INRA, Université Paris-Saclay, 1 av. Lucien Brétignières 78850 Thiverval-Grignon, France*

Highlights

- Glycerol bioconversion into 3-hydoxypropionic (3-HP) was performed through a whole-cell biocatalysis strategy with *Lactobacillus reuteri* following bacterial growth.
- Plackett-Burman experimental design was used for screening growth factors influencing bioconversion performances.
- Increased glucose concentration during growth decreased the molar ratio between 3-HP and its coproduct 1,3-propanediol (1,3-PDO).

1. Introduction

In the framework of bioeconomy, 3-HP is gaining interest due to its desirable industrial applications. As a bifunctional molecule, 3-HP can be chemically converted into a variety of added-value chemicals, such as acrylic acid, or biodegradable polyesters. Among non-GMO microorganisms naturally able to produce 3-HP, *L. reuteri* is noticeable thanks to its ability to produce 3-HP from glycerol, a by-product in biodiesel manufacturing industries. This Gram-positive probiotic bacterium is an interesting candidate due to its G.R.A.S. status and ability to synthesize vitamin B12, an essential co-factor for the first enzyme of the bioconversion metabolic pathway. Moreover, *L. reuteri* does not use glycerol as a carbon source, thus avoiding the synthesis of by-products that can hinder conversion yield and further *in situ* extraction. However, the effects of nutritional and environmental factors encountered by cells during growth on their ability to perform bioconversion have not been elucidated yet. The aim of this work is to better understand the effect of these factors on *L. reuteri* growth and bioconversion performances, in order to identify the optimum conditions for 3-HP production.

2. Methods

2.1. A 2-stage process for 3-HP production by *L. reuteri*

L. reuteri DSM 17938 (BioGaia AB, Stockholm, Sweden) was cultivated in batch mode with a controlled 5-L bioreactor until stationary phase of growth. Cells were then harvested by centrifugation (7500 rpm, 10 min, 4°C) before being introduced into a 2-L bioreactor working in fed-batch mode with glycerol addition at 0.5 $g.h^{-1}$. Cell concentration was quantified by flow cytometry (FCM), cellular states were assessed by FCM using carboxyfluorescein diacetate and propidium iodide staining [1], and substrate consumption and metabolite production were measured by liquid chromatography [2].

2.2. Experimental design by Plackett-Burman method

A Plackett-Burman experimental matrix was designed to test the effects of 11 growth factors on the growth phase and bioconversion ability of *L. reuteri* [3]. The tested factors include addition of glucose, yeast extract, phytone peptone, 1,2-propanediol (1,2-PDO), cysteine, betain plus KCl, tween 80, vitamin B12, various pH and base solutions to regulate, various temperature. Models were defined by the general form: $Y_i = k_i + \Sigma a_i \cdot Y_{(+)i}$ (Y_i: response variable; k_i: constant corresponding to the value of Y_i when all 11 variables are at their low levels; a_i: linear coefficient of each variable to express the effect of the high level; $Y_{(+)i}$: value of the plus level of the variable) [3]. Statistical analyses were performed with the software Statgraphic plus, with a 95 % confidence intervals for coefficient estimations.

3. Results and discussion

3.1. Effects of environmental factors on *L. reuteri* growth

As expected, our results showed that increasing glucose concentration during growth led to a higher cell concentration in the stationary phase, together with a higher viable cell concentration. Meanwhile, lower cultivation temperature resulted in less growth and lactic acid production.

3.2. Effects of growth environmental factors on cell ability to perform further bioconversion

By increasing glucose concentration during growth, the molar ratio between 3-HP and its coproduct 1,3-PDO decreased during bioconversion. This can be explained by the fact that the supplemental NADH produced through glycolysis was re-oxidized to NAD^+ preferentially through the glycerol reduction into 1,3-PDO, at the expense of glycerol oxidation into 3-HP. Surprisingly, the addition of vitamin B12 gave a negative impact on 3-HP production. A supplementation of this element during bioconversion instead of during growth may give a better influence. Regarding the duration of 3-HP production, some interesting factors were pointed out, including the addition of betain, 1,2-PDO, and phytone peptone. It seems consistent with previous studies that betain leads to an increased tolerance of *L. plantarum* to osmotic stress [4]. Meanwhile, the presence of 1,2-PDO helps preparing cells to deal with glycerol thanks to the expression of genes encoding the enzymes and structural proteins involved in the bioconversion pathway [5]. Regarding the protein source, phytone peptone was identified as the best for maximizing *L. reuteri* growth [6], so it may be linked to a higher enzymatic ability to synthesize metabolites thereafter.

The experimental design performed in our study allowed identifying a set of growth conditions that lead to a 3-HP production enhanced by 20 % compared to the reference.

4. Conclusions

The present study figured out the influences of growth factors on *L. reuteri* biomass production and ability to produce 3-HP afterwards. The identified factors having positive impacts on the bioconversion performances will be used for growth step. A second experimental design will now be performed in order to optimize the environmental conditions during the bioconversion step.

Highlights

- Production kinetics was obtained during expression at 28, 30, 33 and 37°C
- Lower expression temperatures yielded higher protein than higher temperatures
- The highest productivity was 0.046 mg/g cdw/h, attained after 10 h at 30°C

1. Introduction

The production of recombinant antibodies in *E. coli* has been widely studied in shake flasks [1], mainly for the study of protein yields under the *lac* promoter expression system. The effect of the inducer (IPTG) concentration during induction has been studied [2-3], but there are no studies on the temperature effect on protein production kinetics. The duo temperature-duration after induction most commonly used is either 37°C-4h or 28°C-12h and only final titers are reported.

In this work the effects of temperature in the production of the chimeric format of bispecific nanobody NbF12-10 against AahI'/AahII toxins of scorpion venom in *E. coli* WK6 were studied at bioreactor scale. The strategy implemented allowed first the production of biomass in fed-batch mode at 37°C, and then the expression of protein under glucose feed and induction temperatures of 28, 30, 33 and 37°C.

2. Methods

Experiments were conducted with *Escherichia coli* K12 / WK6 { Δ(lac-pro), galE, strA, nal; F' lacIq ZΔM15, pro+ } harboring pHEN6 plasmid (derived from pBR322) encoding the bispecific nanobody VHHF12-VHH10 (called NbF12-10) and the chimeric format VHH10-VHHF12 (called CH10-12) retrieved from the combinatorial libraries. Cultures were performed in a 5L bioreactor, Biostat B-DCU (Sartorius) using glucose as carbon source in 1.5 L of defined medium [4]. Batch phase was carried out at 37°C, and at depletion of the 10 g/L of initial glucose, fed-batch mode was applied with an exponential feed imposing a specific growth rate of $\mu = 0.38\ h^{-1}$. Protein expression was induced with 1 mM of IPTG when biomass reached approximately 26 g cdw/L. At induction, glucose feed rate was set to 4.5 g Glc/h (at 300 g Glc/L) imposing a $\mu \leq 0.03\ h^{-1}$. Temperature and duration after induction were set to 28°C-12h, 30°C-10h, 33°C-6h, and 37°C-4h. Cell samples were taken every 2 h for the experiments at 28 and 30°C, and hourly for experiments at 33 and 37°C. After pelleting the cells, the periplasmic proteins were extracted by osmotic shock and purified by

IMAC using His-Select Ni affinity gel (Sigma-Aldrich). After washing with PBS, His-tagged proteins were eluted with imidazole. Biomass was measured by optical density and gravimetric method. Residual glucose and organic acids were quantified by HPLC (Aminex column HPX87H). Quantification of protein was made by a new method of image analysis of electrophoresis gels [5].

3. Results and discussion

The biomass production phase of the four cultures showed high reproducibility, obtaining a μ_{max} of 0.71 h^{-1} in batch mode and the expected μ of 0.38 h^{-1} in exponential feeding fed-batch. During protein expression, a linear growth was maintained, sufficient to satisfy both bacterial and protein production. The protein was produced only after the induction with IPTG. The induction at 37°C was extended and stopped at 6 h. After 5 h of induction, the highest protein yield was 0.015 mg/g cdw at 28 and 30°C, and decreased with the temperature, down to 0.005 mg/g cdw at 37°C. The maximum protein yield achieved was 0.074 mg/g cdw (Figure 1a), after 10 h of induction at 30°C, which is two-fold the yield achieved for the same induction duration at 28°C (0.04 mg/g cdw).

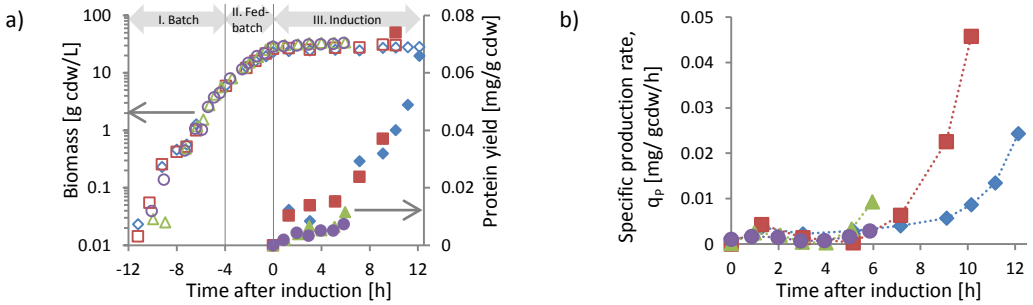

Figure 1. a) Biomass and protein yield evolution in all cultures, and b) Specific production rate of the nanobody produced after IPTG pulse. Symbols: ◊ 28°C, □ 30°C, Δ 33°C, ○ 37°C.

The specific production rate of the protein (Figure 1b) increases after 5 h of induction for all cultures, obtaining the highest productivity of 0.045 mg/g cdw/h at the induction temperature of 30°C. This is more than five-fold the productivity at 28°C at the same production time (10 h), and two-fold the productivity at 28°C at 12 h.

4. Conclusions

The effect of temperature during the induction of a periplasmic-expressed nanobody was tested at bioreactor scale. Culture repeatability was demonstrated, and protein production was achieved during glucose feed. The highest protein titers were obtained at the induction temperature of 30°C. The production of the nanobody at 30°C should be analyzed over a longer period of time to determine the production limits of the strain.

Highlights

- In-line Biomass measurements via Photon Density Wave spectroscopy
- Yeast and bacterial cultivations up to 67 g L^{-1}
- Separate quantification of scattering and absorption properties
- Detection of process deviations

1. Introduction

The ability to monitor and control the formation of biomass during industrial bioprocesses is of high interest as critical factors like maximal biomass production, the physiological state of cells, product formation rate, and product quality are dependent on the specific growth rate [1]. Especially at high cell densities or in very turbid and disperse fermentation media established optical process analytical technologies face signal saturation effects or are prone to probe fouling. In this contribution Photon Density Wave (PDW) spectroscopy will be introduced as an in-line analytical tool for monitoring and control of bacterial and yeast cultivations.
A fully autoclavable and chemically sterilizable, calibration-free process analytical technology suitable to highest concentrations (i.e. > 40 vol%) in stirred or flowing systems is found in Photon Density Wave spectroscopy [2][3]. It allows for the independent quantification of the absorption and scattering properties of disperse materials, i.e. the absorption and the reduced scattering coefficients, respectively. The absorption coefficient exhibits information about concentration changes of light absorbing media components during the investigated process. The reduced scattering coefficient, however is related to the size and concentration of the dispersed particles such as cells.

2. Methods

Fed-batch cultivations of *Escherichia coli* and *Kluyveromyces marxianus* were performed in 3.7 L and 10 L bioreactors respectively using both defined and complex media while focusing on high biomass concentrations. Optical density and cell dry weight (CDW) were obtained by offline sampling. As reference PDW spectroscopy was implemented to track the biomass formation in-line and its performance was compared to other in-line methods, such as turbidity and backscatter measurements.

3. Results and discussion

The reduced scattering coefficient μ_s' obtained by PDW spectroscopy proved to be a reliable indicator for the respective biomass concentration during reactor cultivations. Especially at high turbidities correlation coefficients of $R^2 = 0.99$ between μ_s' and CDW were obtained, while the reference methods showed non-linear responses driven by saturation effects.

More comprehensive understanding of the process could be generated by investigating the simultaneously measured absorption coefficient μ_a in relation to μ_s'. This way process disturbances induced by e.g. inadequate control strategies were detected in-line and early into the cultivations.

4. Conclusions

First investigations show Photon Density Wave spectroscopy to be a promising technique for the monitoring of stirred tank reactor cultivations. It enables the real-time measurement of biomass formation under process conditions without the indication of concentration-induced saturation effects.

Highlights

- Three thermal fouling sensors (MEMS structures) are compared
- Hot wire method in steady thermal regime and linearized responses were applied
- Metrological limits (accuracy and upper LOD) are reported

1. Introduction

Food and bioprocess efficiency is impacted by (bio)fouling [1, 2]. Monitoring and quantification of deposit through *in-situ* and local sensors constitute technological and scientific challenges. In present work, three fouling sensors based on a thermal excitation (steady thermal regime) with different technology (Macro and MicroElectroMechanical Systems MEMS), geometry (intrusive cylindrical, flush plan) and packaging (nude and encapsulated structure) are compared. Thermal responses are discussed versus heat transfer theory. Performances with model deposit are reported to deduce accuracy to monitor fouling and to determine metrological limitations.

2. Methods

Prototype sensors are based on the hot wire method [1] with powered and regulated Joule effect. Hot wire and fluid temperatures are continuously recorded. According to heat conduction's law in steady thermal regime (equations), the temperature difference ($\Delta\theta$) evolves as a linear function of heat flux (φ) and thermal resistance (R_{th}).

Ref	Temperature difference	Local heat transfer	Deposit thermal resistance
TS1	$\Delta\theta = \theta_{hw} - \theta_b$	$\Delta\theta = \varphi.\left(\frac{1}{h} + \frac{th_p}{\lambda_p} + \frac{th_d}{\lambda_d}\right)$	$Rth_d = \frac{th_d}{\lambda_d}$
TS2			
TS3	$\Delta\theta = \theta_w - \theta_b$	$\Delta\theta = \varphi.\left(\frac{1}{h(r+th_d)} + \frac{r}{\lambda_d} ln\left(\frac{r+th_d}{r}\right)\right)$	$Rth_d = \frac{r}{\lambda_d} ln\left(\frac{r+th_d}{r}\right)$

Three different structures are compared (Figure 1). TS1 is composed of a flat square MEMS structure (red line, 250µm) between a printed circuit board (PCB, green line, 800µm) and a protective packaging (stainless steel and resin layers, grey line, 450µm) in contact with bulk. TS2 is equivalent to TS1 without protective packaging. TS3 is based on a macroscopic cylindrical structure including a central heat wire and a wall temperature measurement (thermocouple). Sensors were tested in a 5L reactor (fluid: water, *Re*=2.6x10^6 and 20±1°C). Multiple layers of PVC scotch (TESA® 53948, *th*=130 µm, and ρ_d=1300 kg.m^{-3} [3]) were used to mitigate fouling. Thermal

conductivity and heat capacity were measured at $\underline{\lambda_d}$=0.115 W.m^{-1}.K^{-1}, Cp_d=1025 J.K^{-1}.kg^{-1} (Neotim FP2C). Experiments were performed in clean (reference) and fouled (up to 5 layers) conditions. Five successive heat flux steps were applied (from 0.2 to 7.5 kW.m^{-2}, 30 min/step). The efficiency was indicated by the evolution of theoretical and experimental thermal resistances.

3. Results and discussion

Considering nominal flux (Figure 2), a non-linear response is observed for all sensors. Strong differences are noticeable and can be attributed to different structures and to heat loss contribution. For plan sensors, TS1 and TS2 inflection inform about the balance between efficient flux and back side and edge heat loss. As expected, the absence of front side packaging improves sensor response (TS2). Initial slope (*Rth*=0) informs about the ratio between efficient and nominal flux equal to 7.8, 29 and 80% for TS1, TS2 and TS3 respectively.

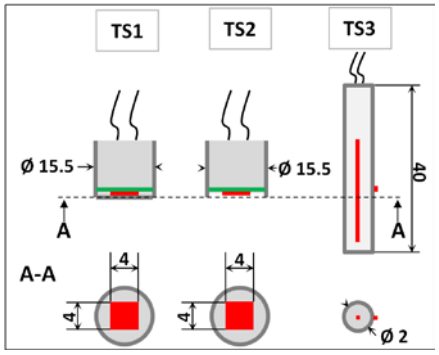

Figure 1: Schemes of TS1, TS2 and TS3 structures

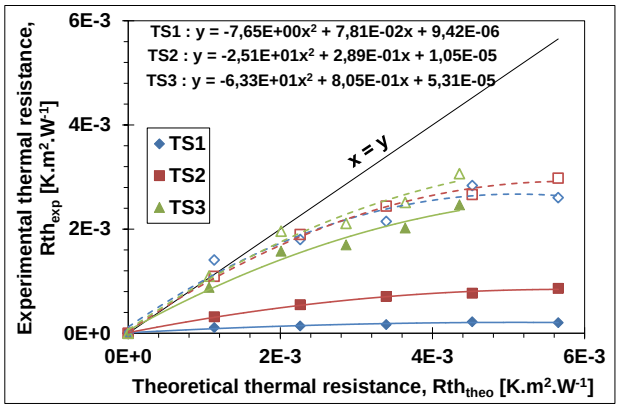

Figure 2: Estimated versus theoretical thermal resistances considering nominal (continuous line) and efficient (dotted line) heat flux.

Considering efficient flux, estimated thermal resistance is consistent with theoretical values even if inflexion is noticeable for all structures with increasing fouling. Under clean condition, heat convection coefficient is highly superior to 1000 W.m^{-2}.K^{-1} and for TS1, thermal resistance of front side packaging (stainless steel and resin layers) is close to 2.8E-03 K.m²/W. For food and bioprocess, it is assumed that a deviation of 30% between estimated and real fouling heat resistance is acceptable to control and regulate the process. In present case, the experimental upper LODs are equal to 3.4, 3.6 and 4.0E-03 K.m²/W for TS1, TS2 and TS3 respectively. Considering a dense biofouling (λ_d=0.6 W.K^{-1}.m^{-1}), it enables to estimate a thickness close to 2mm.

4. Conclusions

Three fouling sensors based on a thermal excitation have been compared and their metrological performances reported. Considering nominal heat flux, intrusive cylindrical structure should be preferred. However, an accurate estimation of efficient flux demonstrates that cylindrical or plan structures exhibit similar performances and upper LOD, which fulfill specifications. Further work will investigate periodic thermal excitation to qualify and quantify deposit.

Highlights

- Urine nitrifying sequencing batch reactor studied for inhibition by FA, FNA and pH
- Large parallel batch testing and 15 inhibition models considered
- Noncompetitive FA, uncompetitive FNA, 2 way Prosser pH model found best
- Ammonia oxidizers insensitive to FA, both nitrifying organisms sensitive to FNA.

1. Introduction

Nitrification is a key biological wastewater treatment process, yet application to high strength wastewaters is challenging due to substrate and product inhibition as well as wide pH variations in poorly buffered systems. Understanding how these inhibitions affect removal kinetics is critical to optimum system design but is confounded by the close relationship between the inhibitors: free ammonia (FA), free nitrous acid (FNA) and pH [1]. Sequencing batch reactors can achieve higher rates of treatment [2], but are also more stressed by these inhibitors compared to more widely studied continuous flow systems [2,3]. Moreover, disagreement remains over the most suitable inhibition models [1,4]. This study undertakes a large set of extended batch tests across a wide range of pH, FA and FNA concentrations and extensive model assessment to determine the most suitable kinetic equations describing high strength nitrification of source separated urine.

2. Methods

A 13.8 L nitrifying SBR was operated with real urine diluted to 30% strength at a loading rate of 380 mg-N.L^{-1}.d^{-1}. Between days 227 and 332 a series of 18 separate 6 h batch experiments were conducted with constant pH using a consistent urine dose and additional spiking of NH_4Cl and $NaNO_2$ to adjust FA and FNA. The tests covered FA concentrations up to 225 mg-N.L^{-1}, FNA concentrations up to 0.20 mg-N.L^{-1} and a pH range of 7 to 9. The nitrifying community was quantified using fluorescent in-situ hybridization and published probe sets. Fifteen separate two-stage nitrification rate expressions were evaluated consisting of different combinations of non-competitive (nc), uncompetitive (uc) and Aiba (A) type inhibition by FA and FNA coupled with either Presser two-way (P2), Cardinal three-way (C3) or Cardinal extended three-way (CE3) pH response models [5]. The system model consisted of a series of ordinary differential equations covering FA volatilization, urea hydrolysis, total ammoniacal nitrogen (TAN) oxidation (FA as substrate) and total nitrite nitrogen (TNN) oxidation with up to 19 parameters for estimation. Parameter estimation used parallel time-series estimation in the COPASI modelling package. Fitted models were validated against an independent batch experiment with uncontrolled pH. Best model selection considered

both the average relative standard deviation (ARSD) of individual parameters across the 18 parallel batch tests and combined absolute error of TAN+TNN+NO_3 predictions for the validation file.

3. Results and discussion

Ammonia oxidizing bacteria (AOB) *Nitrosomonas* (Probe Nso1225) comprised 23.6 ± 0.3 % of the microbial community while *Nitrobacter* was the only nitrite oxidizing bacteria (NOB) detected (probe NIT3) at 1.0 ± 0.1 %. Treatment was stable throughout this period with full conversion of ammonia to nitrate. Evolution strategy was found to be the most successful optimization strategy for the relatively noisy experimental data. nc-FA, nc-FNA inhibition with CE3 pH gave the lowest parameter optimization objective value, while un-FA, nc-FNA with CE3 pH gave the lowest ARSD of 0.22. However, neither showed good fit to the validation data. Rather nc-FA, uc-FNA P2 pH and uc-FA, uc-FNA P2 pH gave the best fits to the experimental data with similar absolute errors across the predictions of TAN, TNN and NO_3 with the former model performing slightly better. Both also showed relatively low parameter optimization objective values and ARSD confirming them as suitable models for high strength nitrification. Both ammonia and nitrite oxidation were relatively insensitive directly to pH. Ammonia oxidation inhibition constants $K_{i,NH3}$ and $K_{i,HNO2}$ were 464 mg-N.L^{-1} and 0.055 mg-N.L^{-1} while for nitrite oxidation they were 9.64 mg-N.L^{-1} and 0.027 mg-N.L^{-1}.This indicates AOB were highly acclimated to high FA concentrations, as expected since the reactor was fed with roughly 2000 mg-TAN/L feed with pH 9.2, while NOB were sensitive to FA in the system. Similar inhibition was experienced by both organisms from FNA.

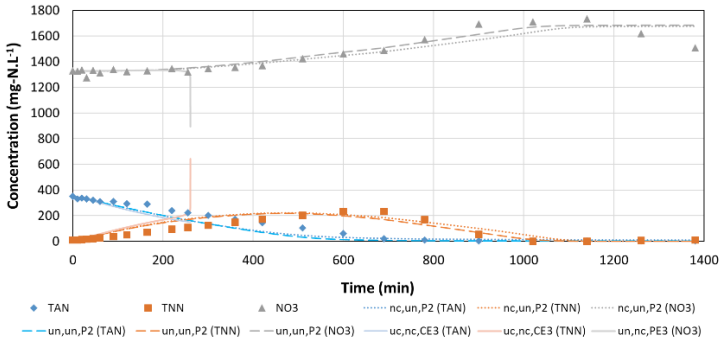

Figure 1. Fit for three models described in text against validation data where X,Y,Z stands for FA,FNA and pH inhibition model. The ODE was unstable for un-FA,nc-FNA,PE3 pH but fit was poor before instability.

4. Conclusions

These results are in contrast to Park and Bae [1] who found un-FA, nc-FNA, and Carerra et al [4] who found Aiba-FA, Haldane-FNA models were best respectively. This highlights the need for large-scale parallel testing and parameter optimization and consideration of pH to unravel interactions between FA, FNA and pH.

Highlights

- Bacterial cells immobilized in sol-gel coatings were able to degrade formaldehyde.
- Sol-gel coatings containing PEG enhanced the enzymatic degradation of formaldehyde.
- Formaldehyde was efficiently degraded by coatings kept at room temperature during 5 weeks.
- Coatings storage at 37°C decreased formaldehyde degradation ability.

1. Introduction

After the energy crisis of the 90's, new energy conservation measures were adopted in peoples's lifestyles at home and work places. Energy-efficient housing rapidly brought new building materials, interior decoration and consumer products, such as composite wood, foams and plastics, synthetic carpets and households products. These changes have increased the diversity and concentration of pollutants in the indoor air [1], mainly the volatile organic compounds (VOCs) [2]. Formaldehyde is an oxygenated-VOCs, widely used in construction materials, wood processing, furniture, textiles, carpeting, and chemical industries. It is classified as a human carcinogen and it has been given more attention in particular of its adverse effect in health [3], and so, its removal is of widespread interest. The development of bioactive coatings incorporating biomolecules able to capture and degrade this toxic compound is of major interest. It is herein presented the study of the efficiency of hydrophilic sol-gel coatings, easily prepared at low-temperature, incorporating PEG in the formulation to retain a large content of water, and so, improve cells viability and maintain enzymes activities [4]. The conservation of enzymes stability throughout time is of great importance for industrial application of the bioactive coatings.

2. Methods

Hydrophilic sol-gel coatings were prepared using a mixture of 3-glycidoxypropyltrimethoxysilane (GPTMS) and tetraethoxysilane (TEOS) and freeze-dried bacterial cells of *Pseudomonas putida* ATCC 47054. Different ratios of precursors and cells were tested in the presence or absence of the hydrogel polymer polyethylene glycol (PEG) in the coating. Eight coatings formulations were prepared (Table 1). Coatings were applied by spraying to a surface of a thin-layer chromatography (TLC) paper. After 24 h the paper was stored at room temperature and 37°C to evaluate

formaldehyde efficiency throughout storage time. Every week, during 5 weeks, the coated paper was put in contact with the reactional mixture in aqueous solution containing formaldehyde and a co-factor NAD^+. Formaldehyde degradation was quantified by a colorimetric method using the NASH reagent during 48 h.

3. Results and discussion

After 48 h of reaction with the formaldehyde, bacterial cells incorporated in the sol-gel matrices were able to degrade formaldehyde in the surface (Figure 1). Series 1, 2, 7 and 8 obtained the best degradation yields (85, 80, 78 and 85%, respectively) after 24 h of deposition, compared to the others (30%, in average). After 5 weeks of storage at room temperature, formaldehyde degradation yields for the same series were 94, 53, 75 and 45% and the remaining series obtained 13.5% in average. A small decrease was generally verified, except for serie 1 that kept the highest degradation yield. The presence of PEG in serie 1 allowed the retention of large contents of water that improved the activity of formaldehyde-degrading enzymes, which were present in high concentration (40% ($w.w^{-1}$) of cells). After 5 weeks of storage at 37°C, formaldehyde degradation yield was about 10% in average for all the series. Storage temperature decreased the enzymatic activity needed for the transformation of formaldehyde.

Table 1. Sol-gel coatings formulations

	Sol-gel	PEG (g)	Cells conc. (% $w.w^{-1}$)
Serie 1	90-3	8	40
Serie 2	90-3	0	40
Serie 3	90-1	8	30
Serie 4	90-1	0	30
Serie 5	90-3	0	30
Serie 6	90-1	0	40
Serie 7	90-3	8	30
Serie 8	90-1	8	40

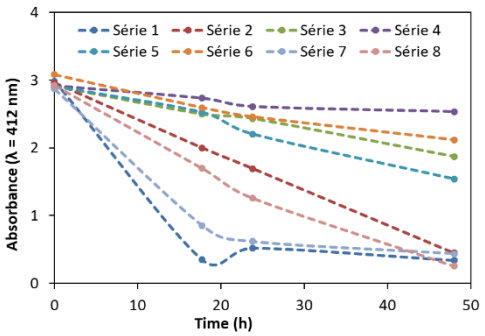

Figure 1. Enzymatic degradation of formaldehyde by coated paper.

4. Conclusions

Bioactive coatings containing freeze-dried bacterial cells were efficient in formaldehyde degradation in solution. The presence of PEG in the sol-gel improves the enzymatic degradation of the pollutant. Formaldehyde degradation efficiency can be kept by storing sol-gel coatings at room temperature.

Highlights

- Microbial consortia capable to degrade imidacloprid were isolated
- Cross degradation of other neonicotinoid insecticides was achieved
- Reactor scale treatment (STBR) removed binary and ternary mixtures of neonicotinoids
- The treatment partially detoxified the matrix towards honeybees and other biomarkers

1. Introduction

Neonicotinoid insecticides are widely applied for crop protection, hence their presence in the environment is common, where they exhibit high persistence, particularly in soil. Of particular current concern is the negative effect exerted by neonicotinoid residues on honey bees, causing the decline in their populations [1,2,3], which has led to an European Union decree that banned since the end of 2018 the use of three compounds (clothianidin, thiamethoxam and imidacloprid) on crops pollinated by bees. Biological approaches such as biopurification systems used in the removal of pesticide-containing wastewaters have shown mostly inefficient removal of such compounds, reason why the liquid-phase systems with specialized degrading consortia are explored. This work aimed to isolate and employ degrading-consortia to remove several neonicotinoid insecticides simultaneously at reactor scale, and to monitor the ecotoxicological changes during the treatment.

2. Methods

A selective enrichment approach was employed to isolate microbial degrading consortia with the ability to transform imidacloprid; members of the relevant consortia were identified by sequencing of 16S rRNA or ITS genes. The elimination of imidacloprid and the cross-degrading ability to remove the neonicotinoid insecticides acetamiprid and thiamethoxam was determined at flask scale and monitored by LC-MS/MS. The removal process was scaled-up in a stirred tank bioreactor (STBR) using the consortium exhibiting the best performance to treat mixtures of neonicotinoids. Detoxification in the reactors was monitored by ecotoxicological tests including: seed germination (*Lactuca sativa*), bioluminescence inhibition (Microtox ®) and acute oral test on honeybees.

3. Results and discussion

The selective enrichment using soil pre-exposed to imidacloprid permitted to obtain cometabolic imidacloprid-degrading consortia. The consortia were composed by eight bacterial and one yeast strains, capable of degrading not only this compound, but also thiamethoxam and acetamiprid, as demonstrated in cross-degradation assays. The scaling-up of the process in batch STBR was able to simultaneously remove mixtures of imidacloprid+thiamethoxam or imidacloprid+thiamethoxam+acetamiprid, reaching elimination of 95.8% and 94.4% of total neonicotinoids respectively after 30 d. Removal rates in the bioreactors followed the pattern imidacloprid>acetamiprid>thiamethoxam, including >99% elimination of imidacloprid in 6 d and 17 d (binary and ternary mixtures, respectively). Ecotoxicological evaluation in the STBR revealed partial detoxification of the matrix, with clearer detoxification patterns in the binary mixture compared to the ternary mixture.

4. Conclusions

Considering that the residual ecotoxicity of the synthetic wastewater was partially decreased by the reactor treatment, the liquid-phase approach here described seems a promising strategy to remove the highly toxic and persistent neonicotinoids from agricultural wastewaters. Further research should be focused on optimizing the process to achieve higher detoxification levels, and to adapt it to feasible conditions for farms of different sizes and devoted to the production of diverse crops.

Highlights

- Phosphorus removal with limited aeration
- Photosynthetic microorganisms as O_2 suppliers
- Phototrophic system for wastewater treatment

1. Introduction

P is an element with vast applications in agriculture and industry but that can negatively impact the environment when released to water streams. One of the options for treatment of P-rich wastewater streams is the enhanced biological phosphorus removal (EBPR) system, that requires intensive aeration and thus increased operational costs [1]. With the aim of reducing the aeration dependence of EBPR processes, a new phototrophic-enhanced biological phosphorus removal (photo-EBPR) process was recently proposed [2]. The photo-EBPR system is composed of a consortium of polyphosphate (poly-P) accumulating organisms (PAOs) and photosynthetic microorganisms (algae, cyanobacteria) operated under dark/light cycles. During the dark anaerobic period, glycogen is hydrolyzed and poly-P is degraded, producing the necessary energy for volatile fatty acids consumption and accumulation as polyhydroxyalkanoates (PHA). During the light phase, photosynthetic microorganisms produce the necessary oxygen and, consequently, PHA is consumed, providing energy and carbon for the regeneration of poly-P and glycogen pools [2].
The first results obtained showed that it is possible to obtain a photo-EBPR system, capable of treating streams with high P concentration (60 mg/L) without need of external aeration, using as inoculum a sludge already enriched in *Candidatus Accumulibacter phosphatis* – well-known organisms for their capacity for high P uptake in conventional EBPR systems [2]. The aim of this study was to determine if it is possible to select a photo-EBPR system using conventional activated sludge from a conventional WWTP as seed sludge and to compare the results to the previous ones.

2. Methods

A sequencing batch reactor was seeded with activated sludge from a wastewater treatment plant in Lisbon and operated in 8 hour cycles (3 h dark, 4 h light and 1 h idle period), with a light intensity of 328 W/m^2 provided by an internal halogen lamp. The sludge retention time was 20 days, hydraulic retention time was 16 hours, with temperature control at 20ºC and pH at 7.5. The reactor was fed with a solution (75%-25%) of acetate and propionate. COD in the feed was adjusted during the experiments, from 60 to 160mg/L, and the P concentration in the feed was 60 mg/L. Air was supplied in the last 2 h of the light phase to ensure that the culture was not limited by O_2. Phylogenetic analysis of the bacterial community was done through Fluorescence in situ hybridization (FISH).

3. Results and discussion

Results show that in the first cycle with 60 mg/L of COD, the culture could not carry out EBPR despite VFAs being totally consumed during the dark phase (Figure 1-A). This suggests that the sludge from the WWTP was not enriched in PAOs and therefore not capable of immediately performing P release/uptake cycles. However, since VFAs were completely consumed in the dark period, COD in the feed was gradually increased along the SBR operation and P uptake in the light phase without aeration increased up to 13 ± 1 mg-P/L (Figure 1-B), a feature that may have resulted from the O_2 availability from algae or direct P uptake by algae. Also, the higher carbon availability in the dark phase enabled more PHA accumulation and with more PHA available, more P can be taken up by PAOs. Although the culture selection process was slower in comparison with cultures already enriched in PAOs (table 1), activated sludge is widely available and a photo-EBPR system can be readily implemented without the need of a seed sludge previously enriched in PAOs.

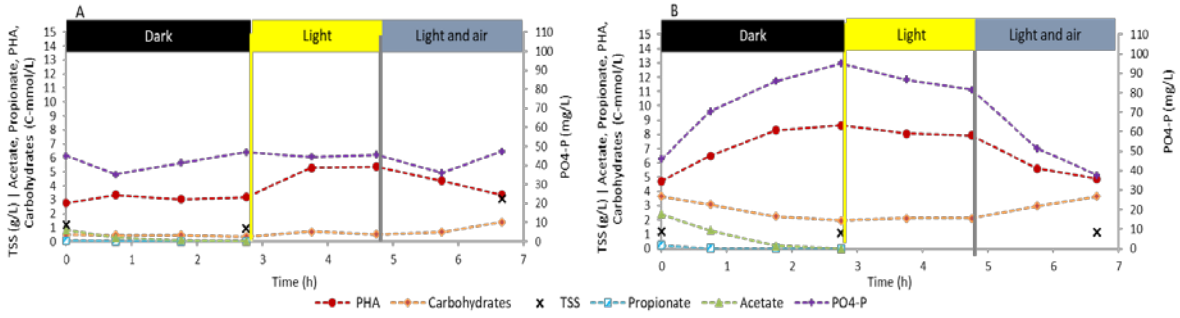

Fig. 1 **-** Profile of P and carbon transformation during SBR operation: A – COD_{feed}= 60 mg/L; B – 160 mg/L

Table 1 - Comparison of the results obtained in the present work with the results obtained in Carvalho et al. (2018).

	P release (mg-P/L)	P uptake (mg-P/L)			Pnet (mg-P/L)	Chlorophyle (mgChlo/gVSS)		FISH		Selection time (days)
	Dark	Light	Light and air	Total		Inicial	Final	PAOmix	CPB_654	
Present work: Seed sludge from a WWTP	47 ± 4	13 ± 1	47 ± 4	60 ± 2	14 ± 7	0.50	7.3	++	++	29
Carvalho et al. (2018) Seed sludge enriched in Accumulibacter phosphatis	34 ± 2	16 ± 6	49 ± 8	65 ± 1	31 ± 0	0.20	4.6	+++	++	14

4. Conclusions

The present study indicates that conventional activated sludge can be enriched in PAOs and photosynthetic organisms capable of performing photosynthetic EBPR. Selecting a photo-EBPR culture directly from activated sludge could simplify the start-up and facilitate the implementation of photo-EBPR systems in wastewater treatment plants. In addition, the implementation of photo-EBPR systems will allow energy savings by eliminating the intensive aeration that increases operation costs in conventional EBPR.

BIOCOMPATIBLE EXTRACTION OF β-CAROTENE FROM *DUNALIELLA SALINA* – NEW CONTRIBUTION

Guillaume Tanguy*[1,2], Olivier Goncalves[1], Benoît Schoefs[2], Luc Marchal[1]

1 Process engineering, environment and food processing, GEPEA UMR – FR 6144 CNRS, Nantes University, Saint-Nazaire, France

2 Metabolism, bioengIneering of Molecules from Microalgae and Applications, Mer Molécules Santé, IUML - FR 3473 CNRS, Le Mans University, Le Mans, France

**Corresponding author: Guillaume.tanguy1@univ-nantes.fr*

Highlights

- The extraction is biocompatible at the culture level but not at the cell level
- The biocompatibility of the extraction follows a granulo-selective phenomenon
- The extraction kinetics were obtained using Centrifugal Partition Chromatography

1. Introduction

Biotechnological production of carotenoids from the green microalga *Dunaliella salina* involves two steps: (i) biomass growth followed by β-carotene accumulation inside the cell and (ii) carotenoid extraction. Microalgae milking was introduced for the recovery of biomolecules directly from culture broth using long-chain alkanes as solvent [1]. In this condition, photosynthesis was not highly impacted [2] and the fraction of extracted β-carotene from biomass exceeded the fraction of disrupted cells [3]. In a biocompatible extraction or in situ extraction concept, cells remain alive during extraction and the extracted molecules can be re-accumulate [1].

The aim of this study was to determine how the extraction of β-carotene from the green microalga *Dunaliella salina* was biocompatible. The solvent used was *n*-decane and two extraction parameters were investigated: (i) time of contact and (ii) interfacial area between the solvent and the microalgal culture.

2. Methods

Dunaliella salina was grown in a 1L Air-Lift flat panel Photobioreactor (PBR) [4]. To trigger β-carotene accumulation, the green biomass was stressed through a combination of nitrogen limitations and light stress (400 µE/m²/s) or, nitrogen depletion and high light stress (800 µE/m²/s). After carotenoid accumulation, the extraction was run on a Centrifugal Partition Chromatography (CPC), which allowed to control the two liquids phases hydrodynamics with centrifugal acceleration [5]. After extraction the biomass was re-inoculated within the same medium or in the growth medium. The biomass was analyzed before and after extraction and during the re-growth to access the biocompatibility and kinetics of relaxation. Analysis were focused on cell granulometry (density and size), metabolites (pigments and lipids) and dry biomass regarding the extraction parameters.

3. Results and discussion

As a first result, total cell volume decreased as a function of time of contact of the culture media and the solvent (Figure 1). Concerning the cell volume distribution before and after extraction, the biocompatibility is lower for big than for small cells ("granulo-selective" phenomenon) and the median value µ of the distribution decrease ($p < 0.05$). As a consequence, difference between population biocompatibility and individual biocompatibility appeared a key point and a new contribution. These results suggest that carotenoid and lipid extraction yields were correlated with cell destruction.

Finally, a comparison has been made between the two stress applied to the biomass and the scenarii of re-growth to determine the most productive process scheme.

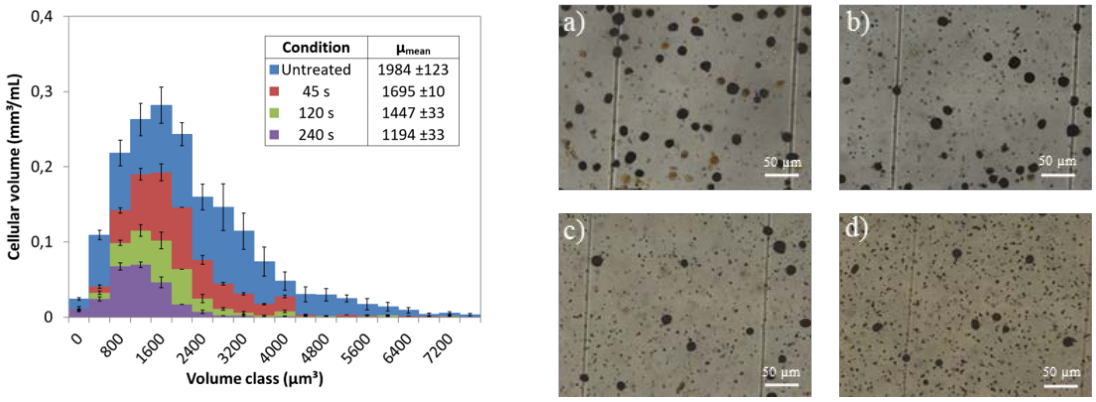

Figure 1. Cell volume distribution (Left) and light microscopy pictures for different extraction time (Right). The larger the extraction time the shorter the mean median value and the fewer cells survive. **a)** Untreated, **b)** 45 s, **c)** 120 s and **d)** 240 s of contact between the solvent and the microalgal culture. Cells were fixed with 1% lugol.

4. Conclusions

Centrifugal Partition Chromatography allowed the decoupling of biomass/metabolites production and the extraction steps giving a better understanding of the mechanism. The granulo-selective effect of the solvent extraction is an original contribution that opens the reflexion for new carotenoid production schemes. The scenarii investigated allowed to choose suitable conditions for the open-loop process with high metabolite productivity and low solvent consumption.

Using machine learning in chemometrics to check validity of existing data driven models for new data

Olivier Paquet-Durand*, Supasuda Assawajaruwan, Bernd Hitzmann

Process analytics and Cereal Science, University of Hohenheim, Garbenstr. 23, 70599 Stuttgart, Germany

**Corresponding author:* o.paquet-durand@uni-hohenheim.de

Highlights

- Online validation of chemometric models
- Evaluation of fluorescence spectra
- Prediction of glucose, ethanol and biomass
- Supervision of cultivation of baker's yeast cells

1. Introduction

A big problem in chemometrics is, that small changes in process setup or equipment or just ageing of compounds might transform existing models useless [1]. Than the chemometric models must be recalibrated. The major catch is, that it is not obvious if a recalibration is necessary or not.

2. Methods

In this contribution we will demonstrate, how machine learning can be used to check existing chemometric models for validity with new data or changing process parameters. To do so, we used an autoencoder [2] which is trained during calibration of chemometric models with the same data and the same number of hidden neurons in the code layer as the chemometric model uses principal components. The basic idea is that when new data point are presented to the chemometric model, the autoencoder error is calculated as well. If this error is significantly higher than during calibration, the used chemometric model is no longer valid and need to be recalibrated. Otherwise a recalibration is not necessary. A 2D fluorescence spectrometer, which was applied in the study, is the BioView fluorescence spectrometer. The device is equipped with 15 different filters for excitation and emission wavelengths. The measurement of one spectrum using the BioView spectrometer has 120 fluorescence intensity variables of excitation and emission wavelength combinations; scattered light is not considered here [3].

3. Results and discussion

The online validation procedure is tested during a cultivation of baker's yeast cells [4]. Here a network with 120 input neurons different hidden layers and 120 output layers are used. The ability of such an autoencoder for a validity check of data driven models will be demonstrated with the evaluation of fluorescence spectra. The data driven models are used for the prediction of glucose, ethanol and biomass. In Figure 1 the autoencoder system used here is present.

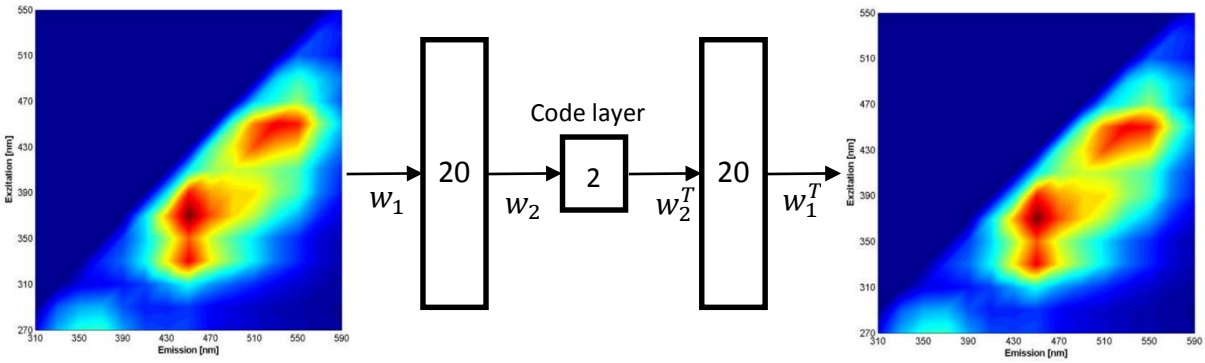

Figure 1. The *autoencoder that is trained to predict the input as output. Within the encode or compression part, the number of neurons per layer progressively decreases. The bottleneck is the code layer with the least number of neurons. Within the decode or decompression part the number neurons progressively increase up to the same dimensions as the input.*

4. Conclusions

The online validation of data driven models is still not satisfactorily resolved [4]. In this contribution autoencoders are used to test the validity of a data driven chemometric model for the prediction of glucose, ethanol and biomass during the cultivation of baker's yeast cells. Although the training of the network takes time, it is very worthwhile to obtain a tool, for the online validity check of the prediction capability of the chemometric model.

Highlights

- A lab-scale freeze-drying model is calibrated/validated
- MBDoE is proposed to design the best protocol for model re-calibration for new products
- The optimal recipe for model re-calibration lasts 10 h
- The proposed approach avoids the occurrence of critical operating conditions

1. Introduction

Over the last decades, freeze-drying (lyophilization) process has been extensively used in pharmaceutical manufacturing for the development of heat-sensitive protein-based therapeutic drugs/vaccines. Lyophilization consists in removing a solvent from a frozen solution by sublimation [1], and its characteristic low pressures/temperatures are suitable to guarantee both product stability and easy reconstitution of the dried product before use. Freeze drying is a time consuming process that is carried out through three main steps: freezing, primary drying and secondary drying. Primary drying is the most energy intensive (~36% of the total exergy input [2]) and time consuming step (up to 48h long, corresponding to over 50% of the typical total duration of a drying cycle [3]). Therefore, one way to increase process performance, guarantee product quality and run safe operations is to develop a reliable model to describe the primary drying phase for future optimization. However, once the primary drying model is calibrated for a specific product, new experimental runs are required to identify the model parameters (i.e., model re-calibration is needed) if new formulates are to be processed. In this study, model-based design of experiments (MBDoE) techniques are proposed in order to reduce the time needed for model re-calibration.

2. Methods

In primary drying, the frozen product is processed in vials placed over shelves in a high-vacuum drying chamber linked to a condenser that removes the water vapor generated by ice sublimation. The vials dynamics during the primary-drying phase has been described using a modified version of Fissore *et al*. [4] model. Namely, the original model has been augmented with a dynamic energy balance that takes into account radiation phenomena. The model has been calibrated (and validated) through industrial experimental runs conducted in a VirTis Genesis 25 EL freeze dryer at different chamber pressures and shelf temperatures, using non siliconized vials filled with 0.6 mL

of a 5% w/w sucrose solution. The measured variables are: *(i)* the vial bottom temperature (T_B) for the central zone of the shelves in the freeze-dryer chamber; *(ii)* the chamber pressure obtained using both a Pirani gauge and a capacitance manometer. After validation, the model has been used to optimally design the model identification experiment that is needed when a new formulate needs to be processed in the same freeze-dryer. The MBDoE activity [5] consists on identifying the design vector (initial conditions on measured variables, dynamic profiles of manipulated variables, experiment duration) that maximizes the information related to the mass transfer parameters to be identified.

3. Results and discussion

The optimal experiment designed by MBDoE uses the shelf temperature (T_{shelf}) and chamber pressure (P_c) as manipulated inputs. A piecewise linear profile is designed for the former input, and a piecewise constant for the latter. The maximum experiment length is set to 10 h. As shown in Figure 1a, the optimal profile for the shelf temperature shows an initial ramp lasting ~45 min, to which a stationary phase follows for almost the rest of the experiment; conversely, the optimal chamber pressure profile shows a double pulse about halfway the experiment. As shown in Figure 1b, the final part of the experiment is characterized by short time intervals where the manipulated inputs are slightly adjusted to avoid reaching the formulate collapse temperature (~240 K). By carrying out an experiment according to this schedule, it would be possible to identify all model parameters in a statistically meaningful way.

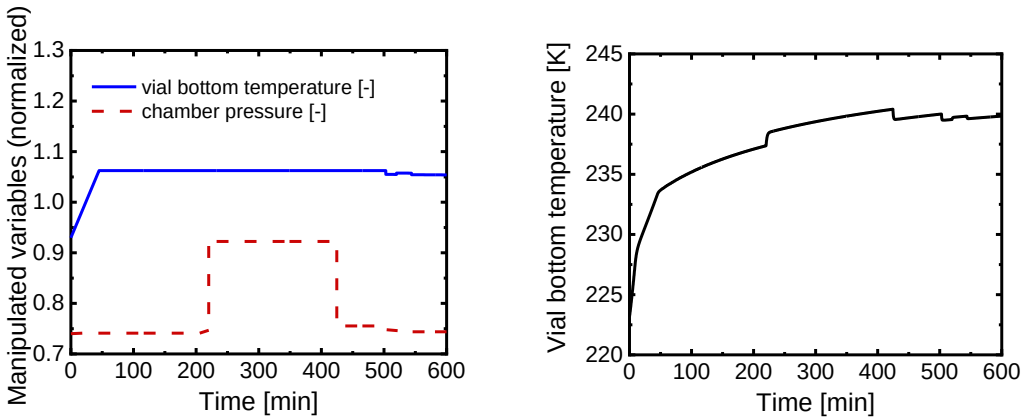

Figure 1. *Time profiles of (a) shelf temperature (blue solid line) and chamber pressure (red dashed line) in the optimally designed experiment; (b) resulting profile of the bottom temperature.*

4. Conclusions

The application of MBDoE techniques showed that one single, optimally designed experiment can be enough to allow a statistically meaningful identification of the mass transfer parameters, while maintaining a reasonable length of the experiment.

Robust design of experiments for model selection using inverse modeling.

Moritz Schulze[1,2,3], René Schenkendorf[1,2,*]

1 Institute of Energy and Process Systems Engineering (InES), TU Braunschweig, Braunschweig, Germany; Center of Pharmaceutical Engineering (PVZ), TU Braunschweig, Germany; 3 International Max Planck Research School (IMPRS) for Advanced Methods in Process and System Engineering, Magdeburg, Germany

**Corresponding author: r.schenkendorf@tu-braunschweig.de*

Highlights

- One-step model selection under consideration of parameter uncertainties.
- Inverse modeling for an efficient solution of the DoE optimization problem.
- Reliable model identification only when uncertainties are included.

1. Introduction

In terms of quality by design (QbD), the development and production of active pharmaceutical ingredients benefit from a detailed system understanding. To this end, mathematical models might be a useful tool. A crucial task in modeling of (bio)chemical reaction networks is the identification of the most suitable model candidate from a set of various model hypotheses. One possible strategy for model selection is the design of experiments (DoE) approach, where the challenge of model selection is formulated as an optimization problem. An additional consideration of model parameter uncertainties leads to robust predictions of optimal experimental conditions that are expected to provide highly informative data for a reliable model selection.

2. Methods

For an effective solution of the robust model selection problem, we aim at implementing an inverse modeling technique by utilizing the differential flatness concept [2]. With the flatness concept, we avoid simplifying assumptions as linearization and the need for solving differential equations numerically. We consider a biocatalytic step from a carboligation reaction system that forms an essential precursor in the synthesis of natural products and pharmaceuticals [2], see Figure 1.

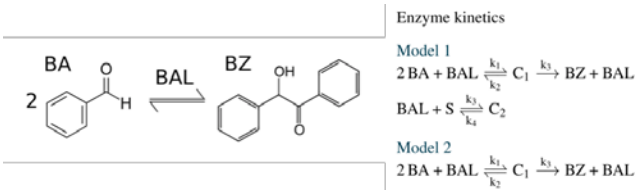

Figure 1. Model candidates of benzaldehyde lyase (BAL)-catalysed reaction network (BA: benzaldehyde, BZ: benzoine).

The two model candidates differ in the following way. Model candidate 1 suffers from a loss reaction where a second substrate (S) is inhibiting. We identify experimental conditions that maximize the differences of the model responses including the uncertain model parameters. The required statistical moments for robustifying the optimization problem are calculated with the Point Estimate Method (PEM) that guarantees low computational cost and sufficient accuracy [3].

3. Results and discussion

In Figure 2, the simulation results of a non-optimized experimental setting are shown on the left. The normalized overlap of the two models' system states is 1.0 and the expected values, i.e., the thick lines in the middle of the confidence intervals indicate that the models are not distinguishable.

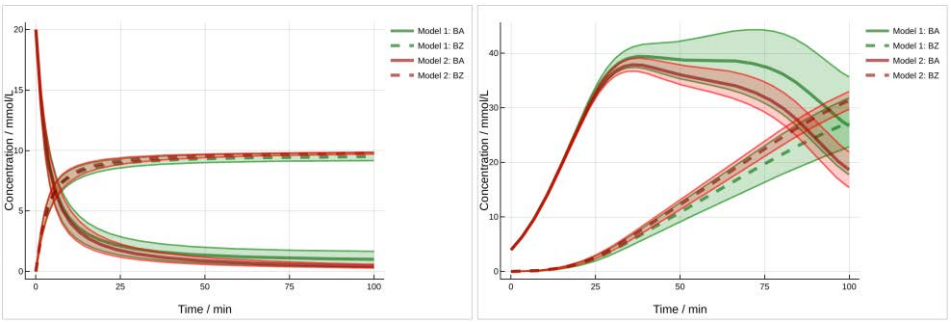

Figure 2. Prior to optimization (left) and after non-robust optimization (right).

First, non-robust optimization was performed to increase the difference in the model responses. The results are shown in Figure 2 on the right-hand side. It is visible that the expected values of the system states are driven apart. However, under consideration of the model parameter uncertainties, the normalized overlap is 1.07 and therefore worse than in the non-optimized case. Reliable identification of a particular model is problematic.

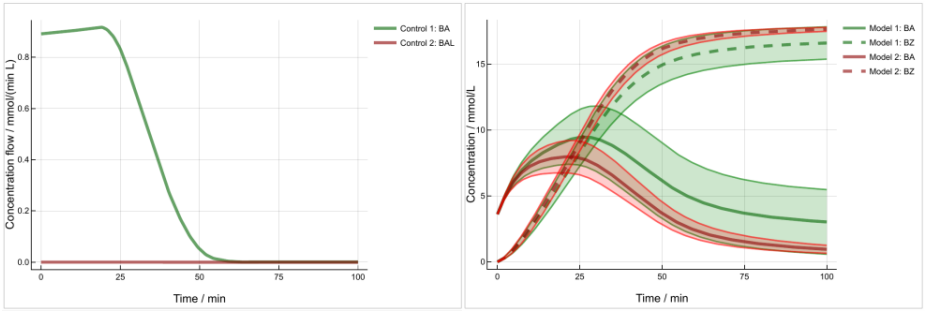

Figure 3. Robust optimized results: controls (left) and measured states (right).

Next, a robust optimization was conducted, where its results are shown in Figure 3. As before, the expected values are driven apart, but additionally, the normalized overlap could be reduced to 0.76. Here, a one-step model selection after running the experiment in the laboratory with the controls shown on the left-hand side in Figure 3 is more likely.

4. Conclusions

We successfully demonstrated how inverse modeling based on flatness could be used for a model selection problem. Furthermore, we showed that the consideration of parameter uncertainties is essential for reliable model identification.

Lipid Production With *Microchloropsis Salina* in Open Thin-Layer Cascade Reactors at Mediterranean Climate Conditions.

Torben Schädler[1,3], Thomas Brück[2,3], Dirk Weuster-Botz[1,3]

1 Technical University of Munich, Institute of Biochemical Engineering, Garching, Germany
2 Technical University of Munich, Werner Siemens-Chair of Synthetic Biotechnology, Garching, Germany
3 Technical University of Munich, AlgaeTec Center, Ottobrunn, Germany

**Corresponding author: t.schaedler@lrz.tum.de*

Highlights

- Batch production of 6 g L^{-1} lipids in open thin-layer cascade reactors
- Accumulation of up to 46 % (w/w) lipids in *M. salina*
- Continuous production of 3.5 g L^{-1} lipids in a reactor cascade

1. Introduction

The utilization of sunlight and carbon dioxide for the production of energy-rich lipids by microalgae offers a possibility to produce renewable liquid fuels. Advances in biomass and lipid productivity are needed to become an economically feasible alternative to fossil fuels. Besides efficient downstream processing and catalysis, high product concentrations are essential to reduce the costs of biomass separation and drying. Because of the increasing light absorption in dense microalgae suspensions, high biomass concentrations can only be achieved in thin fluid layers.

2. Methods

Microalgae growth and lipid production of *Microchloropsis salina* was studied in artificial sea water [1] in open thin-layer cascade photobioreactors at pilot scale (A = 8 m^2). For this purpose, the TUM AlgaeTec Center offers a realistic, dynamic simulation of light and climate conditions to evaluate microalgae processes at potentially suitable large-scale production sites [2]. The target climate of June 15, 2012 in Almería, Spain was physically simulated via an air conditioning system and a combination of natural sunlight and LED-based artificial sunlight. A nutrient limitation was used to induce the accumulation of lipids. Total lipid concentrations were measured via a Sulfo-Phospho-Vanillin assay [3].

3. Results and discussion

Biomass growth and lipid production of *M. salina* were studied in batch processes. At nutrient replete conditions a cell dry weight concentration above 40 g L^{-1} with a lipid content of 16 % was reached. At nutrient limited conditions lipids accumulated up to 46 % of dry weight while simultaneously reducing photosynthetic activity and biomass growth. Lipid concentrations of 6.6 g L^{-1} and an overall volumetric lipid productivity of 0.2 g L^{-1} d^{-1} were achieved after 30 days. Continuous production of lipids was achieved with a two-stage reactor cascade, spatially separating biomass growth and lipid accumulation. The reactor cascade reached a continuous production of up to 3.5 g L^{-1} lipids.

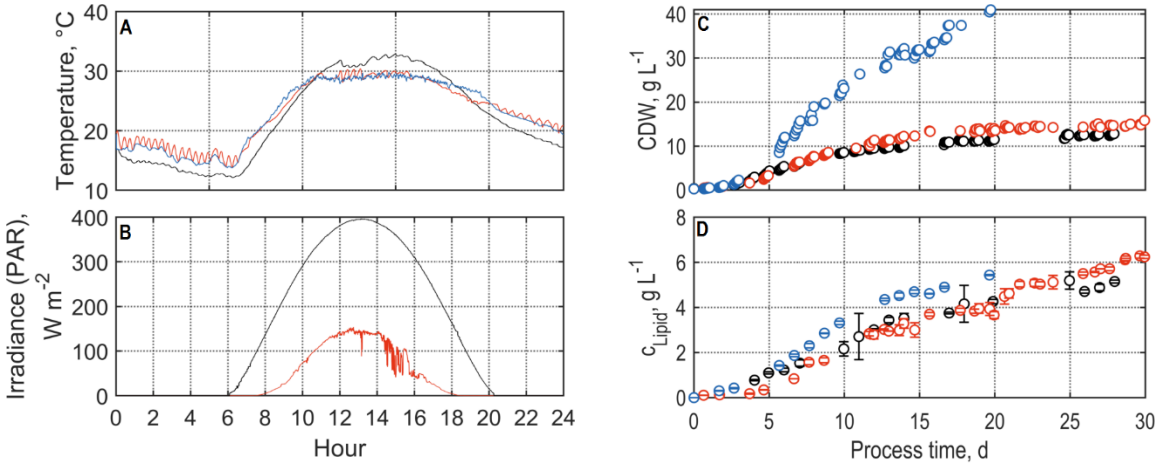

Figure 1. A: Temperature profile of June 15, Almería, Spain (blue), physically simulated temperature in the TUM AlgaeTec Center (red) and water temperature in a thin-layer cascade reactor (black). B: Natural sunlight at TUM AlgaeTec Center on October 19, 2018 (red) and combination of natural and LED-based light (black). C, D: Cell dry weight and lipid concentration in batch processes with *M. salina* in an open thin-layer cascade reactor at physically simulated Mediterranean climate conditions. Blue: Nutrient repletion. Black: Nutrient limitation. Red: Nutrient limitation, doubled initial nutrient concentration

4. Conclusions

As is shown by these results, the continuous production of commodity chemicals and fuels from microalgal biomass remains a promising alternative to fossil resources. Further advances in process engineering as well as strain selection, downstream processing and catalysis are required to compete with petrochemical pathways.

Highlights

- pH adjustment with Tris resulted in short gelation times and transparent silica hydrogels
- Investigated hydrogels exhibit a 10 times lower stiffness than those in previous reports
- Entrapped microalga *C. reinhardtii* maintained photosynthetic activity and growth
- In silica lenses entrapped cells produced hydrogen with an effectiveness of nearly 70%

1. Introduction

Immobilization of microalgae via entrapment provides protection against shear forces and contaminations. Potential applications are the continuous production of biohydrogen or secreted high-value products with a molecular tool kit [1]. In contrast to biopolymer gels, silica gels show an improved mechanical and chemical stability. Besides, they resist microbial attacks and are optically transparent which is crucial for photosynthetically active cells.

Following up on previous work [2], we developed novel biocompatible entrapment methods for sensitive hydrogen producing *Chlamydomonas reinhardtii* strains, based on three silica precursors, namely tetraethylorthosilicate, sodium silicate and tetra(*n*-propylamino)silane. Therefore, we aimed at improved viability and growth in transparent silica hydrogels by modification of the synthesis through adjustment of the pH with buffers and shortening gelation time. Furthermore, we examined if the entrapped microalgal cells produce hydrogen.

2. Methods

Silica gels and calcium alginate gels were prepared as described in [3]. Briefly, after dilution of precursors tetraethylorthosilicate (TEOS), sodium trisilicate solution and tetra(n-propylamino)silane by-products were removed via evaporation or ion exchanger. For gelation, the pH of the sol was adjusted with KOH, K_2HPO_4 or Tris. Calcium alginate gels as reference were prepared by gelling a 2 wt% sodium alginate solution with 2 wt% $CaCl_2$ solution.

Stiffness was measured from cylindrical blocks via dynamic mechanical analysis collecting the stress-strain curves at room temperature via compression.

Microalgal growth was determined in hydrogel blocks in cuvettes, overlaid with medium. Changes in the optical density at 750 nm were observed daily with a UV/vis-spectrophotometer. Hydrogen production was investigated with cells entrapped in low-sodium silica lenses and compared to free cells and cells entrapped in calcium alginate beads. Therefore, cultivation was conducted in

gas-tight vials at 30 °C and 350 µE in sulfur-depleted medium. Daily, the composition of the gas phase was measured via GC and afterwards flushed with nitrogen.

3. Results and discussion

When KOH was replaced with the buffer substance Tris, gelation times were maintained at 100-150 min for the three sols. Furthermore, absorption at 750 nm decreased by 18-72%. Elevation of precursor concentrations decreased gelation time to 2-3 min.

Stiffness differed between the silica hydrogels, namely 4.23 ± 0.72 kPa for low-ethanol, 0.90 ± 0.19 kPa for low-sodium and 0.04 ± 0.002 kPa for low-propylamine silica hydrogels. In comparison, calcium alginate displayed a stiffness of 0.64 ± 0.17 kPa.

Growth in gel blocks was observed with rates of 0.39 ± 0.02 d^{-1}, 0.25 ± 0.03 d^{-1} and 0.23 ± 0.01 d^{-1} for free cells, cells entrapped in calcium alginate and in all silica hydrogels, respectively (figure 1 A). Increased growth rates in silica gels may be attributed to the low stiffness.

Based on further investigations on growth and photosynthetic activity of cells entrapped in silica lenses (data not shown), the low-sodium gel was selected for examination of hydrogen production. The biocatalyst reached an operative effectiveness factor of 69.20 ± 6.35% when compared to a suspension culture with the same OD of 0.8 (figure 1 B).

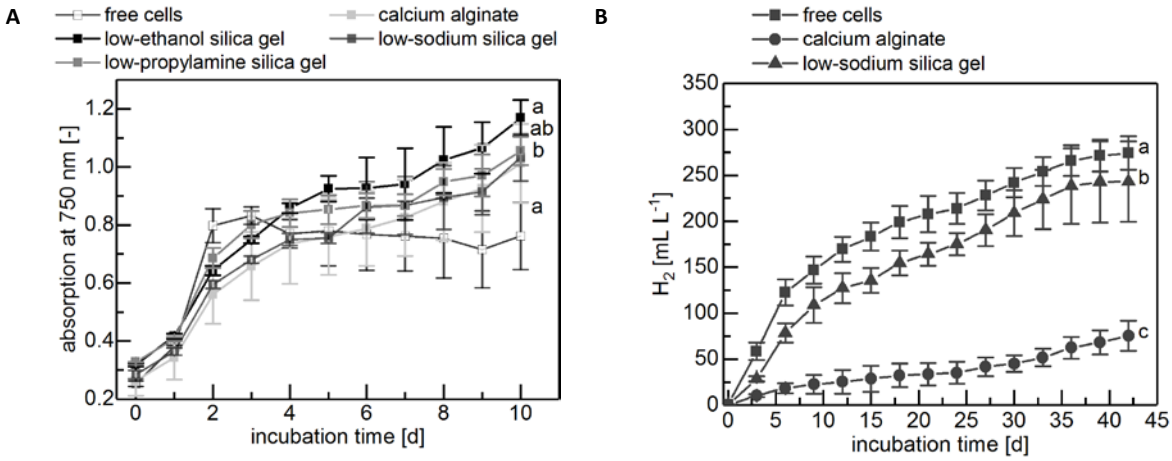

Figure 1. (A) Growth and (B) hydrogen yield of free and entrapped cells (n=5; mean±SD).

4. Conclusions

To the best of our knowledge, this is the first report of entrapment in silica gels that allow cell growth. Furthermore, we reported hydrogen production in lens-shaped particles for the first time. This entrapment method paves the way for transparent silica-gel based biocatalysts that support cell growth and protection against harmful mechanical, biological and/or chemical influences in continuous processes.

Highlights

- O_2 producing *Synechocystis* was combined with O_2 respiring *Pseudomonas* using proto-cooperation to achieve HCDs of up to 51.8 g_{BDW} L^{-1}.
- This concept was coupled to the challenging C-H oxyfunctionalization of cyclohexane to cyclohexanol with a remarkable conversion of >98% and selectivity of 100 % (KA oil).
- HCD of the photoautotrophic biocatalyst were established and resulted in a productivity of 3.76 $g_{cyclohexanol}$ m^{-2} day^{-1}, which was maintained for at least one month.

1. Introduction

In Nature, almost 385 billion tons of CO_2 are fixed annually by photosynthesis. This power of photosynthesis will be key to make inorganic carbon available for the production of value-added chemicals and fuels and reduce future dependency on fossil resources. Despite photo-biocatalysis developing remarkably and the huge potential of photoautotrophic microorganisms for eco-efficient production scenarios, photo-biotechnology is still in its infancy. The lack of scalable photobioreactors that provide efficient light transmission, CO_2 supply, and O_2 degassing and thus enable high cell densities (HCD), constitutes a key bottleneck, especially if cost-sensitive bulk chemicals are the product of choice. Commercialized tubular photobioreactors with 100 to 600 mm inner diameter offer a surface area to volume ratio (SA/V) of over 100 m^2 m^{-3} enabling the efficient capturing of incident solar radiation.[1] Here we introduce a new generation of photobioreactors based on capillary biofilm reactors. They have a high surface to volume ratio, and thus enhanced light availability, enabling HCDs of photo-autotrophic microorganisms.

2. Methods

For biomass determination mixed-trophies as well as single species *Synechocystis* sp. PCC 6803 biofilms were cultivated for 5 weeks in the biofilm format, either supplied with or without air segments and with or without citrate. Finally dissolved oxygen in the aqueous phase as well as the oxygen content in the gas phase was measured and the biomass removed and quantified.

For the biotransformation the mixed-trophies biofilms were cultivated without citrate and under segmented flow conditions. After 5 weeks of biofilm cultivation the biotransformation was induced and product concentrations as well as oxygen in the gas phase were measured.

3. Results and discussion

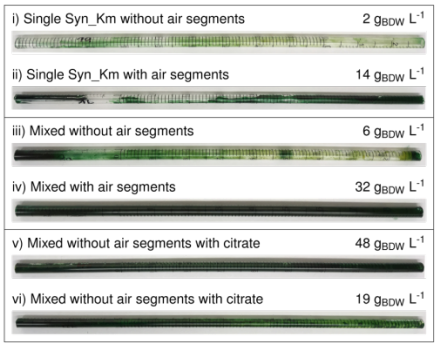

Figure 1. Images of the biofilm capillary reactors 5 weeks after inoculation. i) and ii) Syn_Km: monoseptic biofilm cultures of *Synechocystis* sp. PCC 6803 (pAH032) without and with air segments, respectively. iii) and iv) Dual species biofilm cultures of Syn_Km and *P. taiwanensis* VLB120 (pAH032) operated iii) without and iv) with air segments. v) and vi) correspond to iii) and iv) with citrate in the aqueous medium feed. Final biomass concentrations are given on the right of the respective image. BDW, biomass dry weight.

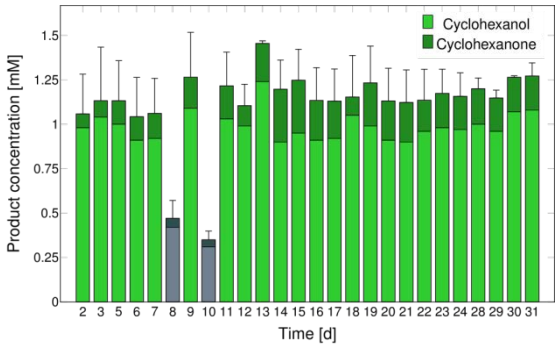

Figure 2. Biocatalytic cyclohexane oxyfunctionalization reaction performed by a dual-species mixed trophies biofilm consisting of recombinant *Synechocystis* sp. PCC 6803 (pAH050) and *P. taiwanensis* VLB120 (pAH050). Biotransformation (started day 0 in Fig.2) was initiated after 5 weeks of biofilm cultivation. The light was switched off for 24 hours during days 8 and 10, respectively. Green and gray bars represent product formation under light and dark conditions, respectively. Light and dark colors refer to the formation of cyclohexanol and cyclohexanone, respectively.

The flow reactor concept for phototrophic biofilm cultivation was coupled to the challenging C-H oxyfunctionalization of cyclohexane to cyclohexanol with a remarkable conversion of >98% and selectivity of 100 % (KA oil). High photoautotrophic biocatalyst concentrations were established and resulted in a productivity of 3.76 gcyclohexanol m^{-2} day^{-1}, which was maintained for at least one month.[3]

4. Conclusions

This work demonstrates prototrophy as a biological strategy for the cultivation of photobiocatalysts in a stable and high cell density format up to 51.8 g_{BDW} L^{-1}, thereby overcoming a key-bottleneck in photo-biotechnology. The crucial problem of O_2 accumulation and thus toxification/inhibition of the photoautotrophic biocatalyst was overcome by utilizing O_2 respiring *P. taiwanensis* VLB120, O_2 extracting air segments and by O_2 dependent biotransformation. Mixed trophies biofilms in capillary reactors were able to produce 3.76 g m^{-2} day^{-1} cyclohexanol for over a month with conversion, and KA oil selectivity values of 98% and 100%, respectively, a milestone in cyclohexane-based chemistry.

Study of starch accumulation dynamic in nitrogen starved *Chlamydomonas reinhardtii* using controlled torus photobioreactor

Fernando FERREL BALLESTAS[1*], Mariana TITICA[2], Guillaume COGNE[3], Jack LEGRAND[4]

[1,2,3,4]*University of Nantes,* Oniris, CNRS, GEPEA, UMR 6144, 44602 Saint-Nazaire Cedex, France

Highlights

- High starch accumulation by microalgae
- Controlled torus PBR with dissolved oxygen and pH regulation
- Physiological adaptation to nitrogen deficiency

1. Introduction

Chlamydomonas reinhardtii is a green microalgae known to accumulate large amounts of starch in nitrogen-limited conditions, up to 50% of its mass content expressed in dry weight of cells (%DW) that could be used as a feedstock for next generation of biofuels production [1]. In autotrophic nitrogen-starved cultures of *C. reinhardtii*, several physiological changes take place in order to adapt their mass content in pigment content and accumulate starch [2]. Starch accumulation in nitrogen starved cells can be affected by other factors such as anoxic conditions [3], light energy availability [1] and inoculum physiological state. The objective of this work is study of starch accumulation dynamic in nitrogen-starved *C. reinhardtii* in controlled O_2 dissolved (OD), pH and light availability conditions, prior to a modelling study with a view to develop an optimized starch production protocol in nitrogen-limiting conditions.

2. Methods

A wild type strain of *C. reinhardtii* (137H) has been cultivated in autotrophic nitrogen-limited conditions, using Suoeka medium with NH_4Cl concentration of 1,87mM, in a torus-shaped PBR, equipped with a pH-temperature and DO sensor, as well as mass spectrometer for gas analyses. The pH of the microalgae culture was regulated at 7.5 with gaseous CO_2 injection. DO has been regulated with 4.5% O_2 - 95.5% N_2 gas mixture injection flowrate. Limited-growth cultures were performed in batch and at different incident light intensities. Inoculum has been cultivated in 1L air-lift PBR in non-limiting autotropic conditions and pH was regulated by CO_2 injection. The local fluence rate was calculated along batch cultures using the 2-flux model and the radiative properties of culture were determined experimentally using the methodology developed by Pilon *et al*. [4]. Biotic and abiotic phases have been analyzed measuring the dynamic evolution of key nutriments and intermediate metabolites, as well as the analysis of the produced gas .

3. Results and discussion

For nitrogen-limited growth cultures of *C.reinhardtii*, an NH_4Cl initial load of 1.87mM was used to sustain biosynthesis up to 0.25g/L of biomass under standard growth conditions, according to the known stoichiometry. This amount is close to the value obtained during the first 20 hours of culture in concordance with the depletion of NH_4^+ measured (Fig 1A). After that point, an increase in the starch content was observed and a maximum accumulation of 53% was finally obtained after 70 hours of cultivation (Fig. 1A). A stop of cell growth seems to occur at 32 h of culture, once the number of cells remained relatively constant. In contrast, the nitrogen depletion in the medium lead to a remobilization of the total proteins, while reducing their content to 20% (Fig 1A). In the other hand, the pigments content decreased once the NH_4^+ vanished. The total pigments content was stabilized around 1%. This results in a change within the pigment distribution compared to a standard growth culture without any mineral deprivation. The radiative properties were estimated leading to the calculation the energy light profile within the cultivation system during the starch accumulation phase (70h). This assessment showed that light was not a limiting factor since a fluence value was estimated at 21umol/m^2s at the bottom of the PBR (Fig 1B). Throughout the experiment, the dissolved O_2 was regulated to 130% in oxygen saturation in the air, in order to avoid anoxic conditions. Nonetheless, after 63 hours the dissolved oxygen falls as a consequence of low photosynthetic activity (Fig 1C).

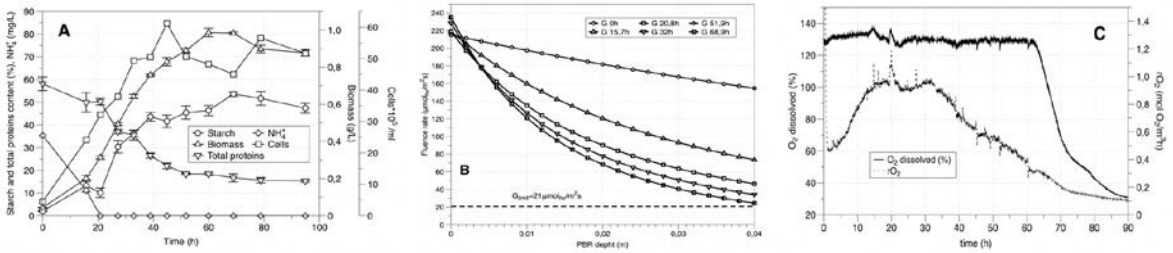

Figure 1. A. physiology response to nitrogen starvation, B. Fluence rate in batch culture q_0= 200umol/m^2s, C. Dissolved oxygen and rO_2 evolution.

4. Conclusions

The use of a controlled torus PBR allowed the study of starch accumulation dynamic after a nitrogen deficiency, where neither light transfer nor dissolved gases (CO_2, DO) influenced the storage of starch. A maximum starch content of 53% was obtained after 70 hours of cultivation. The physiological impact of nitrogen deficiency also led to the remobilization of 30% of the total protein content and to the adaptation in the content and distribution of pigments. This work will lead to the development of a biochemically structured model for starch storage in *C. reinhardtii*.

Increasing Photoautotrophic Growth and Carotenoid Production with *Dunaliella Salina* .

Lara Wolf*, Dirk Weuster-Botz
Institute of Biochemical Engineering, Technical University of Munich
Boltzmannstraße 15, 85748 Garching, Germany

**Corresponding author: l.wolf@lrz.tum.de*

Highlights:

- Up to sevenfold increase of so far reported maximum biomass concentrations (5 g_{CDW} L^{-1})
- Sixfold increase of β-carotene concentration with nutrient limitation at 18 % salinity (w/v)

1. Introduction

The photoautotrophic production of high-value products from CO_2 with microalgae is of increasing interest. *Dunaliella salina* is a halotolerant microalgae that can survive up to 30 % (w/v) NaCl thereby accumulating increasing amounts of β-carotene in the cells. Thus, *D. salina* is a highly interesting microalgae for outdoor cultivations in open photobioreactors with seawater as the salt content permanently increases due to the continuous evaporation of water. Unfortunately, the final biomass concentrations reported so far with *D. salina* are low compared to other microalgae.

2. Methods

Growth and product formation of *D. salina* was studied in fully-controlled LED illuminated flat-plate gas-lift photobioreactors [1-3] with diurnal light (0 – 1900 µmol m^{-2} s^{-1}) and temperature profiles (15 – 30 °C) according to [4] using CO_2 for pH-control. Additionally, the salt content was increased from 3.5 % (w/v) up to 30 % (w/v) in order to get comparable data to outdoor cultivations with evaporation. Growth and β-carotene formation was studied independently. First, batch processes were performed using a growth medium. Second, *D. salina* was harvested and the cells were resuspended in a medium with reduced nutrient concentration. The salt content in this production phase was kept constant. Optical density, cell dry weight, carotenoid content and transmission were monitored in the batch processes.

3. Results and discussion

Growth of *D. salina* in salt accumulating batch processes was comparable to the growth in batch processes with a constant salt concentration of 7.5 % NaCl. The final cell dry weight of 5 g L^{-1} (40 million cells mL^{-1}) after 7.7 days was increased up to sevenfold compared to so far reported data [5–7]. Neither the variation of pH in a range of pH 7.5 – pH 8.5 nor an increase in temperature from 15 – 30 °C to 20 – 35 °C showed significant changes in biomass formation demonstrating robustness of *D. salina*. A maximum lutein concentration of 8.8 mg L^{-1} (2.0 mg g^{-1} cell dry weight) and a maximum β-carotene concentration of 5 mg L^{-1} (1.1 mg g^{-1} cell dry weight) were measured during growth with increasing salt concentrations. After transferring *D. salina* into a nutrient limited

medium, highest β-carotene concentration could be observed in a batch process with a salinity of 18 % (w/v). The β-carotene concentration was increased sixfold from around 2 mg L^{-1} up to 12 mg L^{-1} (3.2 mg g^{-1} cell dry weight).

4. Conclusion and outlook

The drawback of photoautotrophic processes with *D. salina* (low biomass concentrations) can be solved by changing the cultivation system from shaking flasks, tubular reactors or column reactors to fully-controlled LED illuminated flat-plate gas-lift photobioreactors which resulted in an enhancement of the final dry cell mass concentration by a factor of 7 compared to literature [5–7]. Applying nutrient limitation after growth resulted in an increase of the β-carotene concentration by a factor of 6. Scale-up of microalgae processes from lab-scale flat-plate gas-lift photobioreactors to open thin-layer cascade reactors with physical climate simulation [4] was already shown for several microalgae and will be approved for β-carotene production with *D. salina* in the future.

Scenedesmus Obliquus Growth in Semi-Batch Microphotobioreactor under Non-Limiting CO_2 Supply

Christopher Castaldello[1,2], Eleonora Sforza[2], Fabrizio Bezzo[1,*]

1 CAPE-Lab -- Computer-Aided Process Engineering Laboratory, Department of Industrial Engineering DII, University of Padova, via Marzolo 9, 35131 Padova, Italy

**Corresponding author: fabrizio.bezzo@unipd.it*

Highlights

- Microalgae growth monitoring assessed with fluorescence measurements.
- Semi-batch microphotobioreactor for non-limiting nutrients condition.
- The system is effective in CO_2 supply.
- It will be possible to assess different light conditions simultaneously.

1. Introduction

Microalgae are nowadays widely used as a source for different chemicals and products of interest. However, the industrial optimization of biomass production is hard to achieve since many factors contribute to their growth, such as nutrients availability and light intensity and many experiments are needed to characterize their impact. A microscale platform would strongly aid with this purpose, allowing the simplification and the parallelization of the reactors [1].

One of the main challenge in micro-photobioreactor (mPBR) technologies is linked to CO2 supply, as it is the main nutrient required for photosynthesis and, even if the mPBR materials are somewhat permeable with gases, the CO_2 concentration in air is far to be non-limiting for microalgal growth. Accordingly, there is the need to provide CO_2 directly into the solution, through an absorption step in a sodium carbonate enriched medium [2].

In this work, a new device with non-limiting CO_2 supply was proposed. Here *Scenedesmus obliquus* was cultivated at constant light intensity by monitoring growth through in vivo chlorophyll fluorescence measurements [3] with the aim to assess the efficiency of CO_2 supply.

2. Methods

The device is made in polydimethylsiloxane (PDMS) which is a polymer with high compatibility with biological application and is transparent to light. The device has been designed to allow up to three different channel, each channel has 8 independent wells (non-mixed photobioreactors). A CFD simulation has been performed in order to ensure homogeneous fluid pattern at the entrance of each well. Since here velocity is almost zero, nutrients enter continuously via molecular diffusion only, avoiding limiting conditions. This device allow up to 24 parallel experiments. A syringe pump is needed to guarantee low and constant flowrates of fresh medium.

To efficiently absorb CO_2 in the liquid phase, the equilibrium of carbonate was exploited [2]. A sensitivity analysis (performed on Aspen Plus using ELECNRTL activity coefficient model), was carried out to select the carbonate concentration needed in order to obtain a suitable pH value in

a liquid which is bubbled whit 100% CO_2. This means that by slightly increasing pH in a buffered solution, is possible to shift equilibrium to increase carbon capture. Enriched medium are loaded into 50 mL syringe that allow to run 5-days long experiments.

S. obliquus was pre-cultured in agitated flask at illumination of 40 µmol photons $m^{-2}s^{-1}$ at 24±1 °C in BG11 medium, cells were then collected in the middle of exponential phase. A correlation line between biomass concentration and F_0 has been set. Measurements were performed with Open FluorCam FC800 (Photon System Instruments, Czech Republic). Microalgae growth has been carried out at ambient temperature with a constant incident light of 40 µmol photons $m^{-2}s^{-1}$. Growth rate was obtained as the slope of logarithmic variation of the concentration over time.

3. Results and discussion

Using a 2.5 g L^{-1} carbonate-enriched BG11, microalgae growth has been evaluated in two cases, with and without CO_2 in Figure 1 (left). The corresponding growth rates, calculated from eight wells replicates each, lead to a µ=0.14±0.12 day^{-1} without CO_2 and µ=0.53±0.03 day^{-1} in the opposite case. These results are statistically different by 1-way ANOVA and a Tukey-Kramer significant difference criterion since p-value<0.05. In the latter case, µ is comparable to traditional cultures where no CO_2 limitation is observed [4].

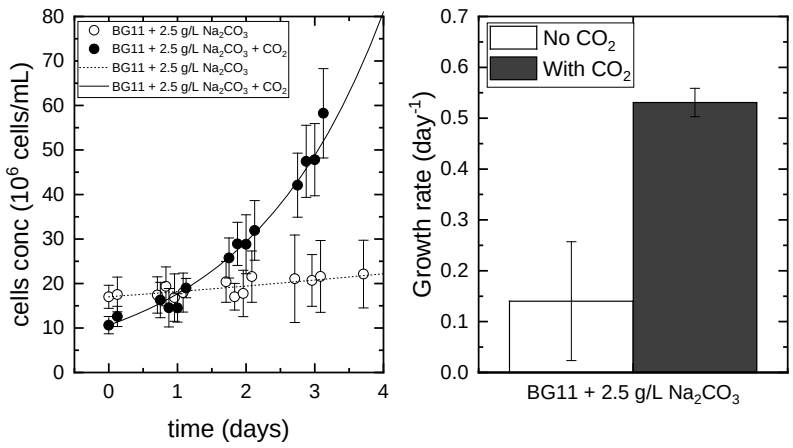

Figure 1. *S. obliquus* growth in mPBR, the lines represent the trend of the exponential phase (left). *S. obliquus* growth rate comparisons (right).

4. Conclusions

A new method to supply CO_2 efficiently in mPBR for photosynthetic organisms was proposed. Microalga *S. obliquus* cultivated in this device showed an increased growth rate of more than three times with respect to air diffusion condition. As the carbon is not limiting, this mPBR can be used in future to assess the effect of other variables such as light intensity.

Implementation of Moving Bed Bioreactor (MBBR) Technology for Phototrophic Cultivation of Terrestrial Cyanobacteria.

Jakob Walther[1], Michael Stoffel[1], Dorina Strieth[1], Roland Ulber[1]*

1 Institute for Bioprocess Engineering, Kaiserslautern, Germany

**Corresponding author: ulber@mv.uni-kl.de*

Highlights

- Growth of cells without additives on HDPE carriers
- Increase of STY by 34%
- Basis for continuous operation.

1. Introduction

Terrestrial cyanobacteria grow relatively poorly in suspension culture, which is why they have not yet been considered as producers of interesting metabolites such as antibacterial substances. Previous work in our group have shown that surface-associated growth can significantly increase productivity [1]. Moving-bed bioreactor technology, which is already established in wastewater treatment [2], offers a possibility to carry out such growth on a larger scale. The bacteria grow on a solid substrate, which is continuously kept in suspension by gassing or stirring. Integrated cell retention on the substrate allows a continuous process, which can potentially significantly improve the production of secondary metabolites.

2. Methods

The terrestrial cyanobacterium *Trichocoleus sociatus* was investigated, which has shown promising antibacterial properties in previous experiments [1]. The substrate were 1.4x1.4 cm hollow HDPE cylinders with internal fins (Figure 1, right). The initial adhesion of the biomass to the substrate took place for one week in 0.5 L shaking flasks at 100 rpm. For optimization the volume of the culture-media and the amount of substrate was investigated. Then the substrate with the biomass was transferred to a glass cylinder of 9 cm diameter and 30 cm height filled with culture-media which was illuminated from the outside. In these the substrate was either suspended by gassing or operated as a fixed bed by using a pump. Filling degrees of 0.086-0.258 $m^3_{Substrate}/m^3_{Medium}$ and protected surfaces of 0.087-0.259 $m^2_{Substrate}/L_{Medium}$ were investigated as moving beds.

3. Results and discussion

The intial adhesion of cyanobacteria to the substrate directly in the MBBR was not successful. Therefore, an upstream adhesion step was investigated for one week in a shaking flask. The optimal parameters were 30 substrate particles in 50 mL medium at 100 rpm. This immobilized over 90% of the biomass in the substrate, which is considered sufficient. Different cultivations have been carried out in glass cylinders to maximize biomass production.

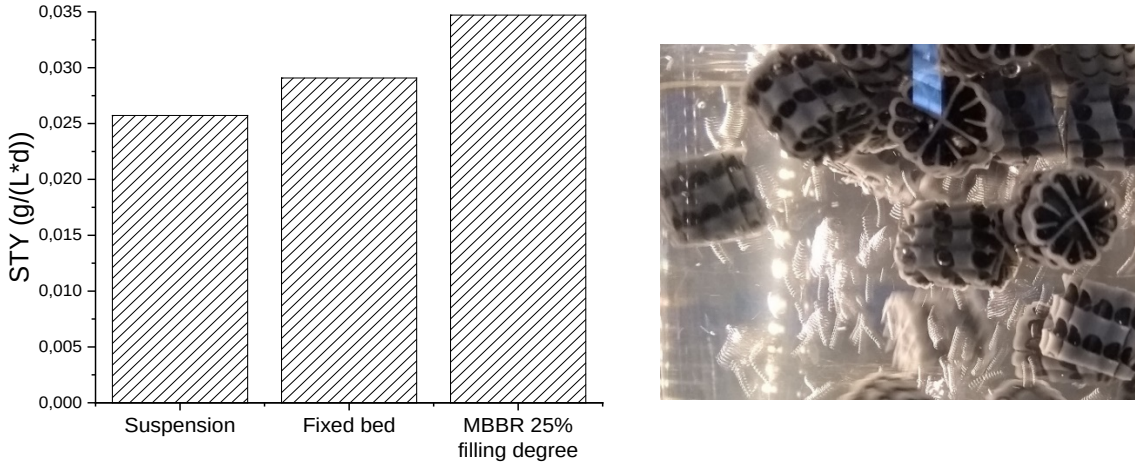

Figure 1. (left) Space-Time-Yield (STY) of different cultivations of *T. sociatus* in a glass cylinder: a.)Moving Bed Bioreactor (MBBR) with 120 substrate particles in one liter medium (corresponds to 25% filling degree); b.) fixed bed with one liter substrate and external circulation with a pump; c.) suspension culture. Cultivation time 25 days, 24°C.(right) *T. sociatus* (dark) on cylindrical growth bodies (white) within a moving bed reactor

In the control without substrate, a space-time yield (STY) of 0.025 $g_{bio\text{-}dry\text{-}mass}$/(L·day) was met. In the fixed bed, a STY of 0.029 g/(L·day) was reached, which corresponds to an increase of 13%. In the MBBR with 25% filling degree even a STY of 0.034 g/(L·day) was achieved, which corresponds to an increase of 34% for control without substrate. Over 92% of the biomass was attached to the substrate. The next step in process development is the implementation of a long-term stable culture for the production of secreted valuable compounds such as antibacterial substances.

According to our knowledge, this is the first time that microalgae have been cultivated on a solid substrate, and not on cloth [3], in a moving bed or fluidized bed. Cyanobacteria have so far only been successfully immobilized in fixed beds on sponges [4] or on cloths [5].

4. Conclusions

A proof of concept for the cultivation of cyanobacteria on a solid substrate within a MBBR was provided. Biomass productivity is significantly higher compared to a suspension culture. Further challenges are the establishment of a long-term stable culture for continuous production and an up-scale, especially with regard to illumination.

The project is financially supported by the DFG (Project number UL 170/16-1)

Effect of a double stress Light-Salinity, on the polysaccharides compartmentalization of *Porphyridium cruentum*

Antoine Decamp[1], Olivier Gonçalves[2], Dominique Grizeau[3], Jérémy Pruvost[4]

1,2,3,4 University of Nantes, CNRS, Laboratoire GEPEA, UMR 6144, 37 Boulevard de l'Université, CRTT-BP 406, 44602 Saint-Nazaire Cedex, France, https://www.gepea.fr/

*antoine.decamp@univ-nantes.fr

Highlights

- Identification of the critical light stress for polysaccharide accumulation
- Identification of the optimal osmotic/light stress combination for floridoside accumulation
- Optimization of the added value of the biomass of *Porphyridium cruentum*

1. Introduction

Porphyridium cruentum is a photosynthetic micro-organism which could produce many valuable metabolites depending on the growing conditions. In the present work, the effect of the salinity and light on the carbohydrates biosynthesis has been particularly investigated. Floridoside is the major glycoside produced by *Porphyridium* (S. Y. Li *et al.*, 2001). This osmoregulator has been identified as a potential precursor for exopolysaccharide (S. Li & Arad, 2002; S. Y. Li *et al.,* 2001) and it is also an interesting molecule for pharmaceutics and cosmetics application like Antiviral/Antitumoral (Bessie & Magne, 2007), anticomplementary agent focus in therapeutic complement depletion (Courtois, Simon-colin, Boisset, & Berthou, 2008), bone formation promoter (Gyu, 2015) or for other application like biofouling (Taylor et al., 2010). In a previous study, salinity has been identified has the major parameter which interfers in floridoside accumulation and light stress has been identified has the most effective parameter to induce polysaccharide production (bound polysaccharide and released polysaccharides). The aim of this study is to define a treatment post harvesting for polysaccharide and floridoside accumulation.

2. Methods

For that purpose an original approach was developed, combining small scale screening photobioreactors for the testing of the various environmental conditions (EOSS 2), to an original rapid quantification method of the main carbohydrate fractions impacted by the tested cultivation parameters (the starch, the intracellular low weight carbohydrates - LWC, the EPS, BPS, etc…). In this presentation, salt and light stress have been combined, the objective was to accumulate floridoside after an osmotic stress then apply a light stress to produce valuable polysaccharides. Furthermore another protocole has been tried, light stress before the osmotic stress, the objective

was to accumulate both molecule in order to add value to the final biomass. For the first protocol, salinities have been studied from 22, 50 and 72 g $NaCl.L^{-1}$ for two MRPA (Mean Rate of Photon Absorption) respectively 0 and 5,3 µmoles $photon.g^{-1}.s^{-1}$ light stress was applied after 6 hours of osmotic stress for 12 hours. For the second protocol, different MRPA have been applied (from 2 to 25 µmoles $photon.g^{-1}.s^{-1}$) and after 24 hours salinity has been increase to 50 g $NaCl.L^{-1}$ in order to identify the effect of osmotic stress on a starch-rich biomass (Floridoside and starch has a common precursor).

3. Results and discussion

Experimental design identified a relation between light and salinity for floridoside accumulation. Indeed, during the osmotic stress, *Porphyridium* accumulate floridoside for MRPA=0 (from 1,60 mg $Floridoside.10^{-6}$ cells to 2,60 mg $Floridoside.10^{-6}$ cells, so +39% in 3 hours) and more for MRPA= 5,3 (from 1,60 mg $Floridoside.10^{-6}$ cells to 3,41 mg $Floridoside.10^{-6}$ cells so +53% in 3 hours). BPS (bound polysaccharides) accumulation is highly affected by the osmotic stress. Indeed, osmotic pressure block the carbohydrate metabolism. After the light stress, only lower salt concentration cultures have produced a large amount of BPS (+59 % polysaccharide after 14h of light stress). A significant relation appears between salinity concentration and BPS accumulation rate, indeed, BPS accumulation rate is inversely proportional to the salt concentration.

4. Conclusions

These experimentations leads to the determination of the critical light stress (measured by evaluation of the mean rate of photon absorption in µ$mole.g^{-1}.s^{-1}$) and the critical salt concentration for polysaccharides and floridoside accumulation by *Porphyridium cruentum*. *Porphyridium cruentum* has a particular behavior in chemostat and could not produce a large amount of floridoside and bps. This treatment could be applied after harvesting in order to produce floridoside and BPS in the same time which will add value to the final biomass.

Castor Oil a new renewable source of biomass for green diesel production.

Giacomo Rispoli[1]

1 Eni S.p.A. Refining and Marketing, Via Giorgio Ribotta, 51 – 00144 Rome - Italy

**Corresponding author: giacomo.rispoli@eni.com*

Highlights

- The cultivation of castor, in semi-desert or degraded land, is of great interest for the production of more sustainable bio-fuels.
- Eni started an experimental crop of an autochthonous castor genotype in pre-desert lands in North Africa, demonstrating that castor can grow well under harsh climate conditions and with low agronomic inputs.
- The oil extracted from castor seeds of the trial plantation shows a high content of ricinoleic acid and is suitable for processing with Ecofining technology, providing a high quality Green Diesel.

1. Introduction

Castor oil is a vegetable oil obtained from the castor plant (Ricinus communis), widely found in tropical and sub-tropical regions of the planet.

Castor oil is composed of triglycerides of different fatty acids and about 10% of glycerine. It has a high oxidation stability and an excellent lubricating capacity. The high content of ricinoleic acid entails a great versatility of use of the oil. Furthermore, the presence of toxic substances such as ricin and ricinine does not make it suitable for food consumption.

The risk of changing the land use, directly or indirectly, from food crops to energy crops is at the base of the problem concerning the sustainability of biofuel production. This aspect is particularly important, as the EU legislation, through the ILUC and RED II directives, intends to limit the use of unsustainable and in competition with food feedstock.

The cultivation of castor is of great interest for the production of bio-fuels as a promising crop for all the tropical and subtropical climate regions. Thanks to its rusticity, in fact, it is a species able to provide high production yields even in conditions of low agronomic and energy inputs in uncultivated and degraded lands. Furthermore, as a no-edible oil, it is not subject to the caps imposed by EU legislation.

In 2018, Eni started an experimental cultivation of an autochthonous castor genotype in pre-desert lands in North Africa. The project aims to prove the feasibility of the crop under harsh climatic conditions and to collect a series of agronomic data, as well as to demonstrate the sustainability of the feedstock. The extraction of castor oil also generates two important by-products, the extraction panel and the residues of the capsules and racemes, which could be used as a soil improver in the plantation itself and for the production of advanced bio-ethanol.

In a second phase a large-scale cultivation will be started which, given the geographical proximity, will allow to feed the bio-refinery of Gela with a more sustainable short supply chain.

The Ecofining technology, jointly developed by Eni and UOP and implemented in the Eni bio-refineries of Venice and Gela, will allow the processing of castor oil obtaining a high quality Green Diesel compared to standard biodiesel. Castor oil has also proved to be an excellent feedstock for the production of jet fuel, given the outstanding cold characteristics of the oil.

2. Methods

The trial cultivation started in the pre-desert areas of Tunisia in Tatouine and Gafsa in mid-2018. The soils of the experimental crop are characterized by a very high sand content, a very low value of organic matter and high macro-porosity with low water retention. The cultivated area, divided into different plots, amounts to 140 hectares with a plant density of 2000 plants/ha (spaced 2,5 m between lines and 2 m on the line). The irrigation system adopted is a drip system with highly saline water extracted from in-situ drilled wells. The seeds for sowing were selected from an autochthonous genotype. The agricultural works included plowing of the terrains, fertilization and routine irrigation. Plants germinated after 3-5 days. After a couple of months, the plants were approximately 50 cm tall.

3. Results and discussion

After about six months from sowing, it was possible to make a first experimental collection of castor seeds from which the oil was extracted. The characterization of the oil has shown that the content of ricinoleic acid reaches values of 90%. Castor oil proved to be suitable for processing with Ecofining technology, providing a high quality Green Diesel compared to standard biodiesel.

A further objective will be to demonstrate the environmental sustainability of cultivation once in possession of all agronomic data related to the crop, which will reach full maturity after two years. In this case, the cultivation of castor could be scaled-up to obtain a stream of sustainable feedstock for Eni bio-refineries.

4. Conclusions

The results of the present study indicate that castor grows well under semi-arid climate conditions in the pre-desert areas of Tunisia, with irrigation input of high salinity water extracted from in-situ excavated wells, even in the presence of poor soils. The oil extracted from collected seeds proved to be a good feedstock for the Ecofining process providing a high quality Green Diesel.

Controlled release of capsanthin using alginate/κ-carrageenan beads

Tomoya Mizushima[1], Ryoichi Nakayama[1]*, Norikazu Namiki[1], Masanao Imai[2]

1 Applied Chemistry and Chemical Enginnering Program, Graduate School of Engineering,

Kogakuin University, 2665-1 Nakano-machi, Hachioji, Tokyo, 192-0015, JAPAN

2 Course in Bioresource Utilization Sciences, Graduate School of Bioresource Sciences, Nihon University, 1866 Kameino, Fujisawa, Kanagawa, 252-0880, JAPAN

**Corresponding author: bionakayama.ryo@cc.kogakuin.ac.jp*

Highlights

- Biopolymer composite beads were successfully prepared.
- The amount of released capsanthin from alginate/κ-carrageenan composite beads was decreased
- The initial release rate of capsanthin of alginate/κ-carrageenan beads prepared with KCl solution was slow down.

1. Introduction

Biopolymers of marine algae origin are ubiquitous in surface waters and attracted to their potentialities. They present an enormous variety of structures, such as alginate, carrageenan, and chitosan. Sodium alginate is a hydrophilic polysaccharide. It consist of a linear copolymer composed two monomeric units β-D-mannuronic acid and α-L-guluronic acid. It conveniently forms into a gel structure in the presence of divalent cations such as Ca^{2+}. κ-carrageenan is a naturally occurring sulfated polysaccharide extracted from red marine algae. It is a linear polyanionic polysaccharides composed of sulfated galactose and 3,6-anhydrogalactose copolymers, linked by alternating α-1,3 and β-1,4 glycosides. It selects K^+ to stabilize the junction zones within the characteristically firm.

The aim of this study is to develop a biopolymer composite beads for the oral delivery of hydrophobic physiological functions.

2. Methods

2. 1 Preparation of alginate/κ-carrageenan composite beads

Sodium alginate (1g) and κ-carrageenan (1g) was dissolved in DI water (98g) under magnetic stirring at 298K for 12h. Heptane contained capsanthin and Span 85 was added to the sodium alginate/κ-carrageenan solution (20mL), and then it was stirred at 10000 min^{-1} for 5 min. The mixed solution was extruded dropwise through a syringe (inner diameter= 2 mm) into a $CaCl_2$ solution or KCl solution (1mol/L, 200mL) under magnetic string (450 min^{-1}) at 298 K for 10 min.

2. 2 Release of capsanthin from alginate/κ-carrageenan composite beads

The hydrogel beads (thirty units) loaded into an ethanol solution (100mL) under magnetic string (600 min^{-1}) at 298 K. A sample (1mL) was taken from the ethanol solution at desired time. The concentration of capsanthin was measured a spectrophotometer (472 nm).

3. Results and discussion

Fig.1 shows the time course of the concentration of released capsanthin from alginate beads and alginate/κ-carrageenan composite beads. At increasing κ-carrageenan concentration, the amount of released capsanthin from alginate/κ-carrageenan beads was decreased. The improved retention of capsanthin within the alginate/κ-carrageenan composited beads formed at a high concentration of κ-carrageenan.

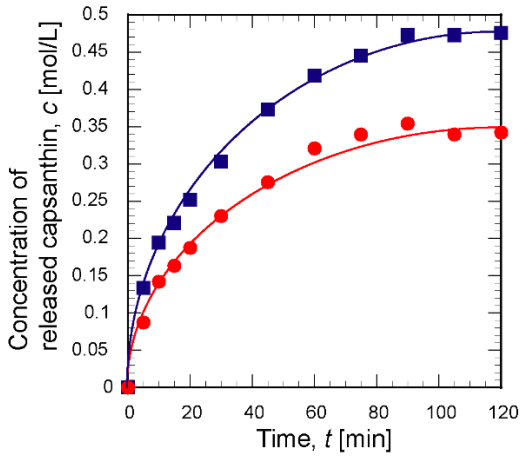

Figure 1. Time course of concentration of capsanthin from alginate beads (■) and alginate/κ-carrageenan composite beads (●) . (1mol/L $CaCl_2$ sol.)

Fig.2 shows the effect of the different cations on the initial release rate from alginate/κ-carrageenan beads. The release rate of capsanthin of alginate/κ-carrageenan beads prepared with Ca^{2+} was 1.7-fold greater than that of the beads prepare with K^+. Alginate/κ-carrageenan composite beads effectively stabilized by slowing down the release of capsanthin by K^+ which cross-linked the κ-carrageenan

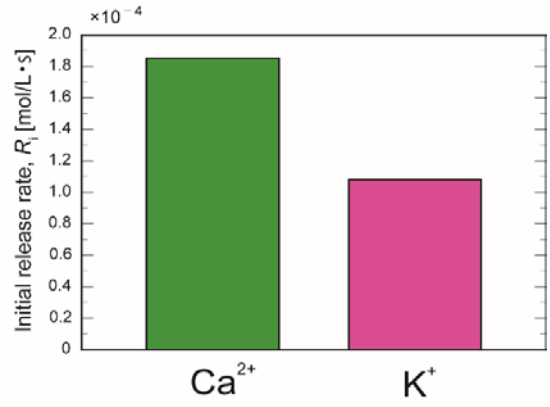

Figure 2. Effect of the different cations on the initial release rate of capsanthin from alginate beads (1mol/L $CaCl_2$ sol., 1mol/L KCl sol.)

4. Conclusions

This work successfully demonstrated that the incorporation of κ-carrageenan in the alginate beads decreased the amount of released capsanthin

Enzymatic Membrane Reactors: a Critical Analysis of Their Interest Through the Coupling of Experiments and Modelling.

Jose Sanchez-Marcano*, Ricardo Abejon, Marie Pierre Belleville.

Institut Européen des Membranes, IEM, UMR-5635, Université de Montpellier, ENSCM, CNRS, Place Eugène Bataillon, 34095 Montpellier, France.

**Corresponding author: jose.sanchez-marcano@umontpellier.fr*

Highlights

- Model of enzymatic membrane reactors (EMRs) analyzing the influence of parameters.
- Reaction kinetics is the most influent parameter on performance of EMRs.
- Model to simulate large-scale EMRs.

1. Introduction

Enzymatic reactors using immobilized enzymes reactors are usually stirred-tank or packed-bed reactors. However in such reactors the yields can be limited by mass transfer phenomena. In enzymatic membrane reactors (EMRs), the biocatalyst can be located on the surface or within the porosity of the membrane; in this last case the reaction takes place during the transfer of substrates through membrane pores using a “flow through membrane reactor concept”. This configuration results in avoiding mass transfer limitations while enhancing the contact between the biocatalyst and the substrates. Indeed, higher yields can be expected [1, 2]. The objective of this work is to carry out a fine analysis of the advantages or drawbacks of EMRs through a multi-scale modelling from the study of local mass transfers coupled with enzymatic kinetics and hydrodynamics up to the optimization of a bundle configuration for two model reactions: the hydrolysis of butyl acetate (HBA) and the degradation of tetracycline (DTC) (as model micro-pollutant) from aqueous solutions with respectively lipase or laccase grafted membranes.

2. Methods

2.1 Experimental. The active membranes (EMs) were prepared according to a method which involves the coating of porous ceramic supports with a gelatin solution, the activation with glutaraldehyde and enzyme grafting [1, 2]. Different ceramic membranes were used (mean pore size from 0.2 µm to 1.4 µm, lengths from 0.13 to 1.1 m and with 1, 7 or 39 channels). The HBA and DTC were used to test respectively EMs prepared with a Lipozyme CALB L from *Candida antarctica* and a Laccase from *Trametes versicolor* in batch reactors or in a pilot unit with a continuous recycling of permeate and retentate.

2.2 Modelling. 3D models were built with COMSOL Multiphysics™ by coupling the experimental reaction kinetics described through the Michaelis-Menten equation together with permeability, Navier-Stokes, Brinkman and continuity equations [2, 3]. The models were validated by comparison of the theoretical and experimental EMRs productivities.

3. Results and discussion.

The experimental results of productivity for HBA with lipase grafted membranes were almost identical (1.2 10^{-4} mol.s^{-1}.m^{-2}) when compared with values obtained by the model (1.1 10^{-4} mol.s^{-1}.m^{-2}), we can then conclude that the model matches well the experimental results. In order to generalize the model to all types of EMRs simulations considering different kinetics and mass transport properties were carried out. As example, in the Figure 1 is shown the evolution of the conversion in function of the membrane permeability (tangential configuration) expressed as permeate (Xperm), retentate (Xret) and global conversions (Xglobal) for (a): a relatively fast reaction kinetics (vMAX = 3.6 10^{-2} mol.s^{-1} m^{-2} and KM = 0.5 mol.m^{-3}) and (b): low reaction kinetics (vMAX = 1.6 10^{-4} mol.s^{-1} m^{-2} and KM = 20 mol.m^{-3}).

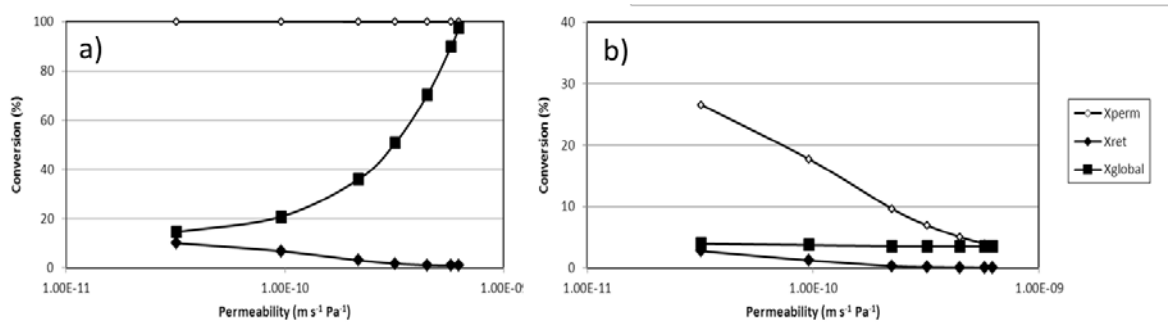

Figure 1. Evolution of the conversion in function of the membrane permeability (tangential configuration) expressed as permeate, retentate and global conversions for (a) fast reaction kinetics (b): low reaction kinetics.

In the case (a), the high reaction rate allows a complete conversion of the permeate stream within the full proposed permeability. Differing to the case of a low reaction rate (b), the global performance of this reactor is strongly influenced by the membrane permeability: while very permeable membranes lead to very high total conversion, less permeable membranes improve the retentate conversion at the expense of the moderate global conversion.

4. Conclusions

An experimentally validated model was developed coupling the measured reaction kinetics with mass transfer. The model allowed the determination of the hydrodynamics and 3D concentration profiles in EMRs. It has been demonstrated that reaction kinetics has the greatest influence among all the analyzed variables. Almost total conversion in the permeate stream can be attained for the fastest reactions, while slow reactions suffer from irrelevant conversions. When the model was applied to the scale-up of EMRs for the DTC it has been demonstrated that EMRs are not really efficient for actual systems presenting relatively low reaction kinetics.

Co-Culture Fermentation Strategy for Bioethanol Production from Mixed Sugars.

Daniele Farias[1*], Francisco Maugeri Filho[1]

[1]School of Food Engineering, University of Campinas, UNICAMP, Campinas, São Paulo, Brazil

*Corresponding author: danielefarias_@hotmail.com

Highlights

- A mixed sugar composition (C5 and C6) from sugarcane bagasse hydrolysate diluted with molasses was evaluated.
- Hexoses and xylose-fermenting yeast were cultivated together in a single batch fermentation.
- Co-culture strategy was related to upper xylose consumption and bioethanol productivity.
- Maximum productivity was achieved during co-culture with *S. cerevisiae* and *S. passalidarum*.

1. Introduction

Techniques for fermenting mixed sugar in a single process have practical significance since they could improve process economics by shortening fermentation times, and make it possible to improve ethanol yield through complete sugar utilization from sugarcane biomass. In this context, the co-culture strategy could be an alternative process, where *S. cerevisiae* effectively ferments glucose, and the remaining xylose can be fermented by xylose-fermenting species, such as *Scheffersomyces stipitis* and/or *Spathaspora passalidarum* [1,2]. The conceptual idea is the use of first generation (1G) ethanol plants as the host for second generation (2G) ethanol technologies, since these mills have a surplus of electricity, steam, water, bagasse and others facilities. Once proved technically and economically feasible, the proposed fermentation strategy will offer a sustainable and enhanced business opportunity for the sugarcane industry.

2. Methods

2.1. Yeast strains and agro industrial raw materials

Xyloses-fermenting yeasts: *Scheffersomyces stipitis* Y-7124 (SS) and *Spathaspora passalidarum* Y-27907 (SP) were obtained from the ARS Culture Collection. Hexoses-fermenting yeasts: *Saccharomyces cerevisiae* (SA), wild-type, provided by Santa Adélia Sugar Mill, (SP, Brazil) and *Saccharomyces cerevisiae* (acB11) (respiratory-deficient mutant) (SpC), kindly provided by Dr. Mario Barros (State University of São Paulo, São Paulo, Brazil).

Sugarcane molasses ($g.L^{-1}$): 414.31 sucrose (65%), 143.41 glucose (22.5%), and 79.68 fructose (12.5%), corresponding to 637.41 of total reducing sugars (TRS). Sugarcane bagasse (hemicellulosic hydrolysate): obtained after diluted sulfuric acid pretreatment (145 °C, 12 min, 0.5% (v/v) H_2SO_4, 1:10 (w/v)) and evaporation step (to provide partial detoxification and sugar concentration). The

final composition was ($g.L^{-1}$): 94.4 xylose, 12.2 glucose, 8.0 arabinose, regarding reducing sugar; and 5.5 acetic acid, 0.3 formic acid, 0.07 HMF, 0.05 furfural, regarding inhibitors.

2.2. Co-culture fermentation strategy

Co-cultures experiments were performed using hexoses and xyloses-fermenting yeasts in a single process (cell ratio 1:1, 20% of inoculum size). Batch runs were carried out (150 rpm, 28°C, pH 6.0, until sugar exhaustion) using a ratio of mixed sugars of 50:50 (w:w) from each carbon source (hemicellulosic hydrolysate and sugarcane molasses), ranging from 50 to 100 $g.L^{-1}$. The mixture with molasses was proposed in order to improve the medium composition and reduce inhibitors concentrations. Experiments were carried out in duplicate. Periodic monitoring was carried out to assess fermentation performances (cell density by OD; sugar, alcohols and organic acids analyses using HPLC and Dionex apparatus) [3].

3. Results and discussion

The results are shown on Table 1. In all experiments, hexoses content was firstly utilized. Xylose utilization was slower, probably because of O_2 competition and faster ethanol accumulation by *Saccharomyces* species. In order to investigate the O_2 supply, co-cultures with a respiratory-deficient mutant of *S. cerevisiae* (ScP) were performed. During co-culture with SS+ScP, maximum ethanol titer and yield were achieved, even with high acetic acid concentrations (major inhibitor release after bagasse pretreatment). On the other hand, sugar uptake for mutant species were lower compared to wild-types, which led to reduced ethanol productivity.

Table 1. Co-culture fermentation with hexoses and xylose-fermenting yeast using a mixed sugar composition.

Co-culture	$S_{initial}$ ($g.L^{-1}$)	P_{max} ($g.L^{-1}$)	Y_{ps} ($g.g^{-1}$)	Q_{pmax} ($g.L^{-1}.h^{-1}$)	Acetic acid ($g.L^{-1}$)	E (%)
SS + SA	50	24.3	0.486	1.10	1.26	100
	75	27.0	0.411	1.21	1.75	84.7
	100	24.3	0.458	1.37	2.21	94.4
SS + ScP	50	17.8	0.311	1.06	1.42	64.1
	75	31.1	0.391	0.84	2.25	80.6
	100	49.3	0.472	0.60	3.26	97.3
SP + SA	50	24.8	0.491	3.75	1.15	100.0
	75	27.9	0.381	4.05	1.72	78.6
	100	30.2	0.296	4.44	2.26	61.0
SP + ScP	50	16.7	0.338	1.01	1.23	69.7
	75	23.1	0.304	0.94	1.89	62.7
	100	37.2	0.371	0.79	2.26	76.5

4. Conclusions

The co-culture combinations evaluated here were able to consume all reducing sugars. Considering the co-culture strategy (SS+ScP) a significant increase in ethanol concentration (49.2 $g.L^{-1}$) was achieved, obtained when a mutant strain of *S. cerevisiae* (respiratory deficient) and *S. stipitis* were cultivated together. Furthermore, co-culture fermentation using wild-types strains (*S. cerevisiae*, *S. passalidarum*) showed the highest ethanol productivity (Q_p = 4.44 $g.L^{-1}.h^{-1}$), which could be a good strategy to accelerate bioethanol production from lignocellulosic biomass.

Influence in the Mixing Energy and Volumetric O_2 Mass Transfer Coefficient of Exopolysaccharide Production by *Gluconacetobacter Diazotrophicus*.

Sebastián Pineda[1], Carlos Cardona[2], Juan Higuita[3]

[1] spinedap@unal.edu.co; [2]ccardonaal@unal.edu.co; [3] jchiguitav@unal.edu.co

[1 2 3] Universidad Nacional de Colombia sede Manizales

Research group in Chemical, Catalytic and Biotechnological processes.

*Corresponding author: jchiguitav@unal.edu.co

Highlights

- *G. diazotrophicus* is able to produce an exopolysaccharide.
- Exopolysaccharide produced by *G. diazotrophicus changes the properties of medium.*
- Power required for mixing is directly affected by exopolysaccharide production.
- Oxygen transfer decreases in function of exopolysaccharide accumulation.

1. Introduction

Gluconacetobacter diazotrophicus is an endophytic nitrogen fixing bacterium and was the first isolated from sugarcane [1]; genus Gluconacetobacter is able to produce large amounts of exopolysaccharides (EPS) and lipopolysaccharides (LPS) [2]. One of the proposed roles for EPS is the molecular communication between plants and microbes during plant-microbes association [3]. The aim of this article was to grow Gluconacetobacter diazotrophicus using sucrose as carbon source in order to obtain an exopolysaccharide. In addition, the investigation was focused in the production of EPS and its influence in the mixing energy and oxygen consumption.

2. Methods

The strain was grown in a Biorreactor with 14 L of liquid LGI-P fresh medium with sucrose 100gL^{-1} at pH 8. Inoculum was 1.60 liters, which corresponds to 10.25% v/v. Culture was kept at 30°C under constant agitation of 150 rpm for 277 hours. Measurement of G. diazotrophicus growth were performed using the dry weight technique and the EPS was precipitated with cold ethanol (1:1 v/v, -20°C) and recovered by centrifugation at -20°C and 10000 rpm [4]. Quantification was made using a gravimetric analysis.

The Kendall-Monroe equation was used to calculate the blend viscosity as the cubic-root average of the component viscosities. Biomass viscosity can be predicted using the Vand equation and the rest of products have no significant influence on the viscosity. The required mixing power depends on the stirrer speed (N), the impeller shape and size (D_i), the tank geometry, the density (ρ) and viscosity (μ_{mix}) of the fluid [5]. The relationship between these variables is usually expressed using the impeller Reynolds number. Finally, the statistical analysis was performed using descriptive analysis of Microsoft Excel®.

2. Results and discussion

Results show that this microorganism is able to grow in LGI-P medium with sucrose 100gL-1, with a maximum cell concentration of 3.75 +/- 0.13 gL-1 (Figure 1). *G. diazotrophicus* is also able to produce an exopolysaccharide that was quantified by cold precipitation with ethanol with a maximum concentration of 9.20 +/- 0.23 gL-1 (Figure 2).

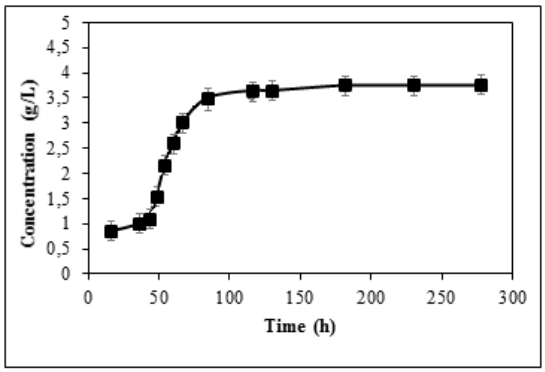

Figure 1. Biomass profile.

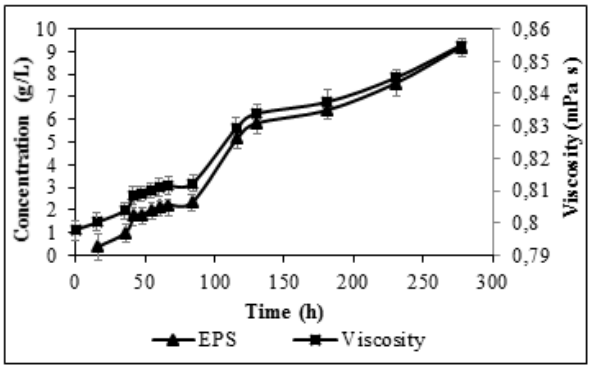

Figure 2. Calculated viscosity in comparison with EPS concentration.

It was also observed that both the mixing energy and the effort of the agitator (torque) were increased. This phenomenon may be due to the fact that exopolysaccharide production changes the rheological properties of the medium since it is a compound with a high viscosity (35 mPa-s). A reduction of 1.32% in $k_L a$ was noticed during fermentation.

3. Conclusions

The results demonstrated that the EPS produced by G. diazotrophicus is a relevant factor in the rheological properties of the medium, which is then related with the increase in power requirement. In addition, this study aims to relate the volumetric oxygen mass transfer coefficient of the microorganism with changes in fluid properties.

Dynamic Laser Speckle Technique to Monitor Biological Tissues Under Magnetic Field.

Roberto Azevedo[1], Roberto Braga[2], Renato Guimaraes[2], Caio Salgado[3], Leandro Reis[2]

1 IFSULDEMINAS, Campus Machado, Rod. Machado-Paraguaçu km 3, Machado MG, Brazil; 2 UFLA, CP 3037 Lavras MG, Brazil, 3 Klabin, Av. Brasil, 26 Telêmaco Borba PR, Brazil

**Corresponding author: robertobraga@deg.ufla.br, robbraga@gmail.com*

Highlights

- Dynamic laser speckle is sensitive to biological changes in tissues.
- Magnetic field enhance activity in seeds.
- Magnetic field can enhance germination.
- Dynamic laser speckle can identify the increase of activity in seeds after magnetization.

1. Introduction

We live in a permanent magnetic field of low intensity (30 to 60μT), however the increase of the field intensity can influence biological activities. In seeds, the application of a magnetic field around mT can improve their germination [1], while it is also possible to enhance plant growth [2] and some other characteristics in plants [3-7]. Despite the successful results reported, still remains issues about the best level of the magnetic field and its time of application in each biological material. Thus, to test the optimum procedure one needs to validate it using time consuming tests. In order to overcome the time limitations presented by the traditional tests, this work aimed to evaluate a well known optical method dedicated to monitor biological activity named dynamic laser speckle [ ]. This technique could provide faster analysis than the traditional ones as well as provide additional information such as a map of activity.

2. Methods

Seeds of coffee (*Coffea arabica* L.) were submitted to a magnetic field of 28mT during 6 days in a germinator. The field was from a permanent magnet and the seeds were placed inside the magnets associated to create the desired level. The seeds were placed in a germination paper imbibed in water and within the magnets. After 6 days in the germinator, the seeds, divided in control and magnetized, were illuminated by the laser and analyzed using a dynamic laser speckle index, the Absolute Value of the Differences AVD [9], to create a map of activity of the seed.

3. Results and discussion

Figure 2 presents the activity maps of a seed submitted to a magnetic field and another used as a control. In the maps (AVD index) it is possible to observe the higher activity in the embryo region when the 28mT field was applied. In the graphical outcome of the speckle images the pseudo-colors present the level of activity from low activity in blue to high activity in red. The same result was observed with replications. The usage of dynamic laser speckle to access the activity of the coffee's

embryo after 6 days was proved to be reliable if compared to the traditional test that usually demands 30 days in the germinator [8]. With this achievement the dynamic laser speckle can forecast the germination process and reduce significantly the time to test the result of magnetization in seeds with different combinations of time and level of magnetic field.

(a) (b)

Figure 1. Maps of activity of a coffee seed using the dynamic laser speckle index, AVD, where in (a) the embryo presented high activity in red and in (b) the embryo in the bottom left did not presented the same activity in the early protusion

4. Conclusions

The dynamic laser speckle was able to identify the change caused by the magnetization in a coffee seed after 6 days of magnetization and before 24 days of the germination test.

Highlights

- Fractionation of BSG by microwave using water and diluted sulfuric acid as solvents
- Higher sugar recoveries for microwave pretreatment assisted by diluted sulfuric acid
- Hemicellulosic sugar recovery of 71% for microwave assisted sulfuric acid (150 ºC, 10 min)
- Enzymatic hydrolysis yield of 41% for microwave assisted sulfuric acid (150 ºC, 10 min)

1. Introduction

Brewer's spent grain (BSG), which is a low cost lignocellulosic industrial waste obtained from brewing industry, has traditionally been used as cattle feed due to its high content in carbohydrates and proteins. However, the high moisture content of BSG makes it susceptible to fast spoilage. The high content of cellulose and hemicellulose in BSG makes it attractive from the point of view of a biorefinery, being able to produce different products like biofuels, chemicals and high value added compounds [1].

Nevertheless, a pretreatment results essential, as BSG structure must be disrupted in order to fractionate it into its main components (cellulose, hemicellulose and lignin). As a result, the microwave assisted pretreatment has currently gained increasing interest in comparison with conventional heating. The basis of the microwave is the ability to apply an electromagnetic field directly about the heated object. Microwave pretreatment offers a great number of advantages, such as short reaction times, uniform and direct heating, simplicity of the process, higher removal of acetyl groups in hemicellulose and lower generation of inhibitory compounds (such as acetic and formic acids, furfural, 5- hydroxymethylfurfural and phenolic compounds). Moreover, the most important aspect is that microwave assisted pretreatment is an energetically efficient method, which does not cause environmental problems while also having a small capital cost [2,3]. What is more, microwave pretreatment can be assisted by acid catalysts. The use of dilute acid is considered as a powerful and effective pretreatment of lignocellulosic biomass [4]. Nevertheless, it is necessary the use of a corrosion resistant materials, and it is generated a hydrolysate whose pH must be adjusted to a value suitable for enzymatic hydrolysis. Therefore, in this work, a hydrothermal pretreatment is also used, which is less expensive and non-corrosive in comparison with acid or

alkaline catalysts. The objective of this work was to fractionate BSG, removing the hemicellulose present and reaching in this way a cellulose-enriched solid. This study addresses the influence of extraction solvent (water and dilute sulfuric acid) on the recovery of sugars by microwave pretreatment.

2. Methods

Hydrothermal or dilute sulfuric acid pretreatment was performed in a Multiwave PRO SOLV reactor 50 Hz (Anton Paar GmbH, Austria, Europe). The solid concentration was 5% (w/v). Temperature and process time were selected as experimental factors. The temperature was set at 150 ºC and 170 ºC whereas the process time was set at 2.5, 5 and 10 min for each temperature. When dilute sulfuric acid pretreatment was employed, the sulfuric acid concentration was kept at 1% (w/v). Afterwards, the liquid fractions (or prehydrolysates) were separated from pretreated solids by vacuum filtration. Pretreated solids were subjected to enzymatic hydrolysis to compare the influence of extraction solvent. The contents in sugars (glucose, xylose, and arabinose) and potential fermentation inhibitors (acetic acid, formic acid, furfural and hydroxymethylfurfural (HMF) were determined by HPLC [1].

3. Results and discussion

When the hydrothermal pretreatment was used, high oligomeric sugars content (87-95%) was observed in the prehydrolysates whereas moderate hemicellulosic sugar recoveries, between 8 and 31%, were achieved. The maximum hemicellulosic sugar recoveries were observed at the most severe pretreatment conditions tested (170ºC, 10 min), being the influence of temperature more significant. Moreover, a maximum enzymatic hydrolysis yield of 20%, referred to glucose in the raw material (BSG), was reached under these pretreatment conditions.

Nevertheless, for the dilute sulfuric acid pretreatment, oligomeric sugar concentrations in the prehydrolysates were very low (< 3% of total sugars). Hemicellulosic sugar recoveries and enzymatic hydrolysis yields ranged between 62-71% and 35-41%, respectively, reaching the maximum value at 150ºC and 10 min.

4. Conclusions

In comparison with the microwave assisted hydrothermal pretreatment, the microwave assisted dilute sulfuric acid pretreatment is able to obtain higher hemicellulosic sugar recoveries (71 vs 31%) and enzymatic hydrolysis yield (20 vs 41%), referred to glucose in the raw material (BSG) under the experimental conditions analyzed. Further research will be focused on the optimization of pretreatment conditions of microwave assisted diluted sulfuric acid, in order to increase sugar recoveries.

Highlights

- Fast and reliable method to characterize biomass agglomerates via flow cytometry
- Insights into morphology and viability of biomass agglomerates
- Method successfully tested on filamentous fungi and yeast

1. Introduction

Process performance, process control strategies and productivity in bioprocesses highly depend on morphological elements of the biomass and therefore calls for a segregated view of biomass. This especially concerns filamentous bioreactor cultivations, where the morphology of the fungi is dependent on process conditions and tightly interlinked with productivity. Filamentous fungi show a large variety of morphological forms in submerged cultures, from dispersed hyphae to denser hyphal aggregates, the so-called pellets. Certain characteristics of morphology are favourable and need to be quantified. However, most common methods to characterise morphology are time consuming and mainly involve some form of image analysis based on microscopy.

In my talk, I will introduce an alternative, reliable and fast method based on flow cytometry for at-line and/or future on-line application. New insights into fungal morphology and viability enable at-line use in production environments, where timely assessment of viable biomass characteristics is of prime importance. Finally, I will show that our measurement principles are also applicable to other agglomeration forming organisms such as yeast, making our method a powerful and versatile tool to characterize biomass agglomerates.

2. Methods

This at-line method employs fluorescent staining of biomass and a high-end flow cytometer equipped with an image-in-flow camera feature. So far, *Pichia pastoris* biomass agglomerates and filamentous fungi were extensively characterised.

3. Results and discussion

Distinction between morphological classes is based on Flow Cytometry forward-scatter signals (FWS) and sample length, verifiable via microscopy and an integrated camera.

The use of fluorescent stains enables determination of viability in complex biomass agglomerates. Fluorescein diacetate (FDA) measures enzymatic activity producing green fluorescence. Thereby viable cells are detected. Propidium iodide (PI) is a DNA stain not permeant to live cells, dead cells are detected via red fluorescence. As an example, detailed morphological characterization as well as estimation of viability in yeast agglomerates are depicted in Figure 1.

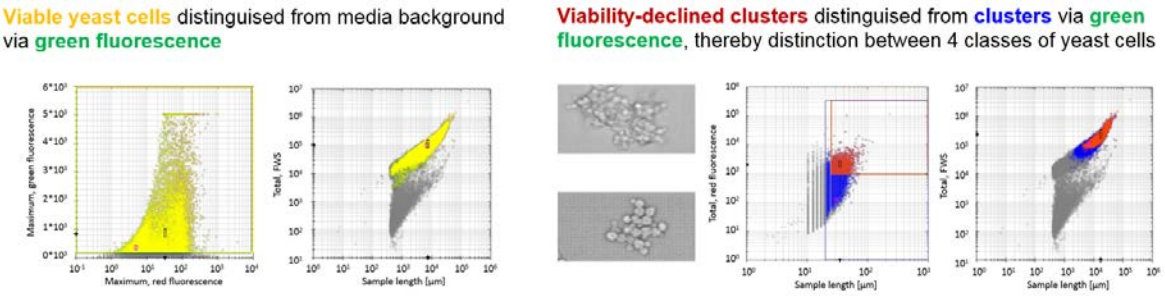

Figure 1. Distinction of yeast cells through employment of fluorescent staining, detection of media background (left) and viability-declined clusters (right)

4. Conclusions

The method's capabilities encompass discrimination of cells in turbid media and further analysis of biomass morphology. Furthermore, viability of various morphological classes can be determined including identification of viable biomass sections within agglomerates.

Analysis of agglomerates in different organisms presently includes agglomerates in glycol-engineered *P. pastoris* strains, viability-declined *P. pastoris* clusters distinguished from viable agglomerates and morphological classification of filamentous fungi.

Xylitol Production From Rice Straw Hemicellulosic Hydrolysate Using Cells of *Candida Guilliermondii* Permeabilized With Triton X-100.

Mariana A.G Tiburcio[1] and Inês C. Roberto[1]

[1] *Departamento de Biotecnologia, Escola de Engenharia de Lorena, Universidade de São Paulo, 12602-810 Lorena, SP, Brazil*

**Corresponding author: ines@debiq.eel.usp.br*

Highlights

- The cellular permeabilization medium affects xylitol production in hydrolysate.
- Permeabilized cells increases xylitol productivity by 40 % and yield by 32 %.
- High xylitol productivity (2.0 g/L.h) was obtained with permeabilized cells.
- Permeabilized cells can be reused for at least 4 cycles with preserved viability.

1. Introduction

Xylitol is a five-carbon sugar alcohol with notable applications in the food, medical and pharmaceutical areas. The production of xylitol by biotechnological route is based on the use of whole cells of microorganisms (fermentation process) or by its isolated enzymes (enzymatic technology). The fermentation process has shown significant advances but finds commercial constraints due to low productivities. On the other hand, costs of isolation/purification of enzymes has been pointed as the major barriers to the enzymatic technology. Therefore, it is important to develop an alternative method (biotransformation process) to make the biotechnology route more attractive. In our previous study [1] was demonstrated that under selected process conditions, resting cells of *Candida guilliermondii* permeabilized with Triton X-100 is able to efficiently produce xylitol from a medium composed only by D-xylose, potassium phosphate buffer and $MgCl_2.6H_2O$. In the present study, the potential use of the rice straw hemicellulosic hydrolysate (RSHH) as xylose source to produce xylitol from *C. guilliermondii* permeabilized with Triton X-100 was evaluated. The effects of permeabilization medium (semi-defined medium or hemicellulosic hydrolysate), as well as the addition of potassium phosphate buffer and/or $MgCl_2.6H_2O$ on the RSHH biotransformation was evaluated as an attempt to improve the results of this biotransformation process. The reuse of the biocatalyst in repeated batch was also assessed.

2. Methods

The rice straw hemicellulosic hydrolysate (RSHH) was obtained under conditions previously optimized by our research group. Initially, rice straw was treated with 80 mg NaOH/g of biomass, at 70 °C for 45 min. Then, the solids recovered were hydrolyzed with 85 mgH_2SO_4/g solid, at 150 °C for 10 min. Both treatments were performed in a batch reactor with liquid to solid ratio of 10:1. Cells of *C. guilliermondii* ATCC 201935 were permeabilized by adding Triton X-100 directly to the growth medium at cell to surfactant ratio of 1:0.9 g/g [1]. In this step, two different growth media were assessed: (1) semi-defined medium (SDM), containing in g/L: 30.0 xylose, 1.0 $MgCl_2{\cdot}6H_2O$, 3.0 $(NH_4)_2SO_4$, 0.1 $CaCl_2.2H_2O$, 20 % (v/v) rice bran extract and 0.1 M potassium phosphate buffer (pH 6.5); and (2) rice straw hydrolysate hemicellulosic (RSHH) containing 30 g/L xylose without any supplementation. After defining the best permeabilization medium, assays of biotransformation were carried out. For this, hemicellulosic hydrolysate (56.0 g/L D-xylose, pH 6.8) and permeabilized

cells in MSD (10-12 g/L) were added to a 50-mL Erlenmeyer flask to a final volume of 25 mL. The flasks were incubated in a rotary shaker at 200 rpm, 35°C for 21 h. In this step, the effect of potassium phosphate buffer and $MgCl_2$.$6H_2O$ on biotransformation parameter, as well as the reusability of the permeabilized cells were also assessed. The reusability of the permeabilized cells was evaluated in RSHH without any salt addition. At each 15 h, cells were collected by centrifugation (5600g, 10 °C, 20min), washed twice with 0.1 M potassium phosphate buffer pH 6.5, and then recycled for new reaction medium. Xylose, xylitol and sub-products concentrations were measured using HPLC.

3. Results and discussion

As shown in Table 2, the growth medium used for cellular permeabilization significantly affects the biotransformation parameters of rice straw hemicellulosic hydrolysate (RSHH). The highest Q_P values (2.10 g/L.h) was achieved with permeabilized cells in semi-defined medium (SDM), corresponding to increse of 34.8% in relation to permeabilized cells in RSHH. It can be noted also that the biocatalysts efficiency was not influenced by permeabilization medium showing similar $Y_{P/S}$ values (about 0.57 g/g. These results suggest that affinity of the detergent to the cell wall/membrane was reduced in hemicellulosic hydrolysate.

Table1. Effect of permeabilization medium of *C. guilliermondii* on biotransformation parameters of RSHH, after 15 h.

Biotransformation Parameters	Permeabilization medium	
	MSD	RSHH
Xylitol production (g/L)	30.8±2.05 (21.94±0.60)	23.7±0.11
Xylose utilized (%)	93±1.7 (85±0.5)	75
$Y_{P/S}$ (g/g)	0.57±0.03 (0.43±0.01)	0.56±0.01
Q_P (g.L.h)	2.10±0.13 (1.47±0.04)	1.38±0.01

Values between parentheses correspond to data from non-permeabilized cells.

In this study, was also verified that the addition of potassium phosphate buffer and $MgCl_2.6H_2O$ to the RSHH did not affect the biotransformation parameters, being observed a average production of xylitol of 29 g/L and 92 % of xylose utilized. As compared to the non-permeabilized cells, the impact of using permeabilized cells on xylitol production from RSHH was an increase of 40 and 32 % on Q_P and $Y_{P/S}$, respectively. Besides, permeabilized cells remained viable during 4 cycles of 15 h in repeated batch maintaining its catalytic activity (Q_P~1.93 g/L.h and $Y_{P/S}$~0.59 g/g).

4. Conclusions

The yeast *C. guilliermondii* permeabilized with Triton X-100 proved to be an effective biocatalyst for xylitol production from rice straw hemicellulosic hydrolysate. Moreover, the permeabilized cells may be reused up to 4 consecutive reaction cycles without reducing production rates and yields. This approach may allow the future development of xylitol production from xylose present in lignocellulosic biomass, with additional potential for implementation in biorefinery.

Highlights

- Bioleaching efficiencies up to 80% within 20 days.
- Heap bioleaching shows high potential for Cu and Zn.
- Leaching efficiencies are highly dependent from loading rates.

1. Introduction

Companies in the field of automotive and residual waste usually crush materials in big shredders in order to increase the surface area for further processing. During the shredding process, the so called light shred fraction, containing mainly plastics and other synthetic polymers, is discharged and deposited. However, these fractions still contain reasonable amounts of metals such as Fe, Cu, Ni and Zn, making them an interesting substrate for bioleaching. Within the last six decades, the use of microbes for metal recovery, known as bioleaching, raised the interest of scientists and industry, mainly due to their higher efficiency as well as the milder and environmental friendly process conditions[1]. The extremely acidophilic, metal-sulphide-dissolving bacterium *Acidithiobacillus ferrooxidans* is one of the most prominent and well-studied bioleaching organism which leaches metals either indirect *via* the production of sulfuric acid or direct by enzymatic oxidation[2].

2. Methods

In order to develop a bioleaching process for the metal recovery from shredded fractions, two different approaches including a heap and a continuous-stirred-tank reactor were tested. In stirred tank reactor experiments, a 25 L glass reactor was inoculated with a culture of *A. ferrooxidans* and stirred continuously at 150 rpm. At regular intervals, the concentration of the shredded fraction was increased (up to 100 $g*L^{-1}$) and parameters such as pH and redox potential were measured. In a second approach a heap bioleaching system for metal recovery was

investigated. The system consisted of a 20 L glass reactor with a sieve plate at the bottom, a pump for circulation of the leachate and a sprinkling system at the top. The leachate was inoculated with *A. ferrooxidans* and pumped in a circular way to rinse the substrate from the top of the heap. In both experiments the temperature was kept constant at 30°C and the pH was regulated automatically via dosage of 1 M sulfuric acid. For calculation of the leaching efficiency, the metal concentrations in solid substrate and leachate were measured *via* Inductively Coupled Plasma-Mass Spectrometry (ICP-MS).

3. Results and discussion

Metal recovery from shredded light fractions in the continuous stirred tank bioleaching system showed promising results after 20 days with leaching efficiencies of up to 80% for Cu, Ni and Zn, respectively (Fig.1-A). In the heap reactor, bioleaching with *A. ferrooxidans* resulted in leaching efficiencies of 15–35% after 33 days. By comparing the metal recovery of chemical leaching and bioleaching in the heap reactor, it is clearly visible that Cu and Zn were only leached in the presence of microorganism indicating the high potential of biological leaching (Fig. 1–B).

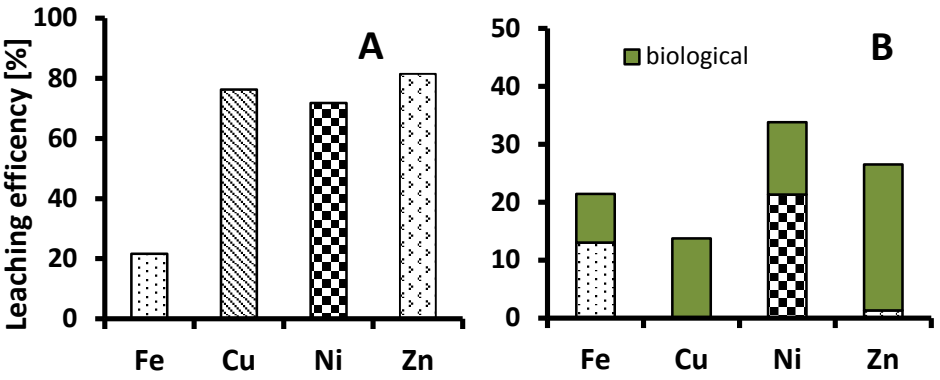

Figure 1. Bioleaching efficiencies of Fe, Cu, Ni and Zn in stirred tank (A) and heap reactor (B). Green bars indicate the biological leaching by *A. ferrooxidans.*

4. Conclusions

Two different bioleaching processes were tested according their ability for metal recovery of Fe, Cu, Ni and Zn from light shred fractions. The stirred tank reactor was operated with loading rates from 10-100 $g*L^{-1}$ showing high leaching efficiencies for all metals. The operation of the heap bioleaching reactor was more difficult but showed high potential in the biological leaching of Cu and Zn. This makes both processes interesting for further investigations and applications in industry and especially metal recovery.

Highlights

- Sericin improves the proliferation of the cells in serum-free culture.
- Sericin prevents the cell from apoptosis induced by heating.
- Sericin induced the proliferation of the cells via not only EGF-signaling pathway.
- Sericin induced the proliferation via but also pathway different from EGF-signaling.

1. Introduction

Mammalian cells are extensively cultured for using in tissue engineering and for producing biotherapeutics production. Although mammal-derived factors are supplemented into the culture media, these mammal-derived factors have the risk of zoonotic disease and so must be replaced by non-mammal factors.

Previously, we reported that sericin hydrolysate obtained from cocoon of silkworms successfully induced the proliferation of various cells and significantly improved the cellular survival under stressful conditions.

In this study, we aimed to elucidate the mechanism how sericin promotes the proliferation of mammalian cells. For the purpose, we focused on a human keratinocyte cell line, highly depend on sericin, as well as on EGF. Using this cell line, the proliferation signal pathway from sericin was compared with that of EGF.

2. Methods

Human keratinocyte PHK16-0b cells were sub-cultured in Keratinocyte-SFM medium supplemented with EGF and BPE. One day later, the medium was replaced into that without both EGF and BPE in order to reset the cells. After additional 24 hours for reset, the medium was replaced to fresh one containing EGF or sericin and/or any of signal inhibitors. Then the cells were cultured for three days and the cell number was counted.

The activation or phosphorylation of signal factors including EGF-Receptor and ERK is confirmed by immunoblotting against lysates from the cells treated with sericin or EGF using anti-phosphorylated tyrosine antibodies.

3. Results and discussion

Both EGF-Receptor inhibitor and EGF-Receptor-neutralizing antibody inhibited the proliferation of the cells treated with sericin and EGF, implying that sericin promotes the proliferation through EGF-Receptor as well as EGF.

MAPK pathway inhibitor and JAK/STAT pathway inhibitor inhibited the proliferation of the cells treated with both factors, whereas PI3K pathway inhibitor inhibited the proliferation of the cells treated with sericin only, and failed to inhibited those with EGF; implying that sericin promotes the proliferation of the cells partly through other pathways different from EGF.

Immunoblot analysis found that phosphorylation/activation of EGF-Receptor and ERK in the cells treated with EGF and sericin were suppressed by EGF-Receptor inhibitor and EGF-Receptor-neutralizing antibody.

4. Conclusions

We found that sericin promotes the cell proliferation through EGFR-MAPK and EGFR-JAK/STAT signaling, as well as PI3K signaling independent of EGF.

Highlights

- Separation of surfactant in drug using ODS Shim Pack MAYI ODS Column
- Characterize the separate surfactant using analytical orthogonal tools (HPLC, HPLC MS and GC MS)
- Observed the major changes in polysorbate structure and identified saturated and unsaturated fatty acids and the estimated levels may cause the stability in the biotherapeutics (mAb) shelf life.
- Identified critical attribute helps to optimize the level of surfactant (polysorbate) in biotherapeutics (mAb) stability.

Introduction

Polysorbates are the most widely used non-ionic surfactants to stabilize protein pharmaceuticals against interface- induced aggregation and surface adsorption. They are effective against various stresses such as agitation (for example, shaking or stirring), freeze/thawing and lyophilization. Nevertheless, some of their characteristics need to be carefully considered and monitored. Commercially avail- able polysorbates (PS) 20 and 80 are chemically diverse mixtures containing mainly sorbitan POE fatty acid esters. Additionally, substantial amounts of POE, sorbitan POE and isosorbide POE fatty acid esters are present. This leads to a significant degree of lot-to-lot variability requiring a close scrutiny of each lot in order to ensure uniform behavior. The presence of residual levels of peroxide in bulk polysorbate is also a concern. There have been reports of a buildup of peroxides in bulk as well as in aqueous solutions of polysorbate, when exposed to ambient oxygen and light. Depending on handling and storage conditions and supplier lot, varying concentrations of peroxides (9 ppm– 250 ppm) were noted among different lots of polysorbates . The buildup of peroxides can be detrimental not only to the stability of polysorbate itself but also to the protein therapeutic, which it stabilizes. Based on this consideration, Harmon et al. have also developed an oxidation stress test relying on peroxides formed in PS80 in the presence of Fe (III). polysorbate or by spiking degradation products resulting from oxidation such as fatty acids and fatty acid esters into protein formulations were investigated.

Methods

1. Surfactant separation using Shim-pack MAYI Column.

Shim-pack MAYI (5 mm L. × 2.0 mm I.D., 50 µm)column in this macromolecular proteins are blocked and cannot enter the pores, smaller molecules infiltrate the chemically modified pores to be retained on the column. By incorporating this column with another column by switching HPLC flow lines, proteins introduced into the pre-treatment (C18 Reverse phase, 100 mm L. × 2.1 mm I.D., 5 µm) column from the autosampler are directly discharged out of the system after passing through the column and using a UV detector (wavelength 280 nm) to monitor an mAb molecule. For details

Table No.1

column	Shim-pack MAYI-ODS (5 mm L. × 2.0 mm I.D., 50 µm)	Zorbax 5u C18 100 Å, (100 mm L. × 2.1 mm I.D., 5 µm)
Mobile phase	A: 10 mmol/L Ammonium Formate in Water B: 2-Propanol	C: 10 mmol/L Ammonium Formate in Water D: 2-Propanol
Time program	Solvent switching, A (0 - 1.5 min) → B (1.5 - 3.5 min) → A (3.5 - 9 min)	D.Conc. 5 % (0 - 1 min) → 100 % (6 - 7 min) → 5 % (7.01 - 9 min)
Flowrate	0.6 mL/min	0.3 mL/min
Extraction time	1 min	-
Injection Vol	10 ul	-
Column Temp	40˚C	40˚C
Detection	UV 280	3200 QTRAP (LC MS), ESI Positive Mode, 50 to 1750 M/Z Scan Mode

Due to the weak UV absorption of polysorbate, a mass spectrometer was used for detection in the analytical flow line. Generally, polysorbate includes a large number of by-products, and because some of these are very strongly retained, 2-propanol was used as the final mobile phase.

2. Analysis of extracted surfactant (polysorbate) using Gas chromatography mass spectrometry (GC MS)

Gas Chromatography Mass spectrometry (GC MS) analysis of extracted (polysorbate) samples were performed using Agilent 7890A series GC system equipped with a Supelco Omega wax column (30m*0.25mm ID, 0.25um thickness, Sigma) coupled with a Agilent 7000 QQQ MS. Omega wax column was used for good separation and for gas chromatography mass spectroscopic detection. Electron ionization system with ionization energy of 70eV was used, 99.99 % pure helium gas was used as a carrier gas at a constant flow rate of 1.1 ml/min. mass transfer line and injector temperature were set at 220˚C and 250˚C respectively, and the oven temperature was programmed, initial temperature was 150 °C for 1 min then 10 °C/min to 240 °C for 15 min with total 25 min run. 1 ul of sample injected in the split mode 10:1. the signals were recorded in full scan mode (m/z 20-600, 250 scan/milli seconds). All components were identified by comparison of theirs mass spectra with those obtained from authentic samples and/or the NIST mass spectral database using AMDIS and mass hunter software.

	9-Octadecenoic acid (Z)-, methyl ester / 9-Octadecenoic acid, methyl ester, (E)- (C18:1)	9.504	22.66	10.76	8.06	0.65	7.68
Nonadecanoic acid, methyl ester (C19:0)		10.151					
	Methyl 9-cis,11-trans-octadecadienoate (C18:2n-7,9 trans,cis)	10.664	6.90				
	Linoleic acid, methyl ester (C18:2)	10.773	6.52			1.15	
Eicosanoic acid, methyl ester (C20:0)		11.101					
	8,11-Octadecadienoic acid, methyl ester (C18:2n-7,10)	11.244	5.26			0.80	
Docosanoic acid, methyl ester (C22:0)		13.518					
	13-Docosenoic acid, methyl ester, (Z)- (C22:1n-9)	13.862				0.90	13.81
Tetracosanoic acid, methyl ester (C24:0)		17.191				1.65	
Hexacosanoic acid, methyl ester (C26:0)		22.966					

Other than stable fatty acids from PS 80 cause reduce the surfactant concentration for stability and it cause the effect on shelf life of the protein and destabilization of protein. saturated fatty acids are less effect to compare to the unsaturated fatty acids levels on stability.

Effect of polyunsaturated fatty acids (PUFA) (C16:1; C18:1; (C18:2n-7,9 trans,cis) ; (C18:2) ; (C18:2n-7,10) ; (C22:1n-9) occurs on mAbs lifetimes and this binding effect on decreasing immunoreactivity with monoclonal antibodies spanning amino acid residues. and this may cause the precipitation and visible particles in PS 80 degradation and this effects instability to the mAb. Interaction propensity of the carboxylate moiety of the fatty acid with the mAb coupled with the low solubility of the fatty acid leading to destabilizing effects. the level of degradant fatty acid reduces the concentration of surfactant and may lead to destabilizing the mAb.

Conclusions

The formulations for biopharmaceuticals invariably comprise of Polysorbates to prevent aggregation and surface adsorption. However, polysorbates consist of trace levels of peroxides as impurities that could catalyze target product degradation via oxidation. In this work, we used HPLC-UV and mass spectrometry to catalogue the polysorbate 80 and its derivatives in commercial biosimilar products. Spiked samples with varying levels of the polysorbate 80 impurities were studied for their impact on the structure and function of the target product. The study reveals that polysorbates in the marketed products vary considerably and the implicate the quality of the product, in several instances. Future work proceeding to Simulations and molecular docking studies provide insights for engineering the product so that the ensuing structural and functional changes are minimized.

Influence of Fluid-Dynamic Conditions in STBR on *S.Blattae* (P424ibpso) Cultures for Isobutanol Production.

Miguel G. Acedos, Victoria E. Santos and Felix Garcia-Ochoa*

Chemical and Material Engineering Department, Chemical Sciences Faculty, Universidad Complutense de Madrid (Madrid, Spain)

**Corresponding author: fgochoa@ucm.es*

Highlights

- Hydrodynamic stress was detected for high stirrer speeds in STBR cultures
- Metabolite distribution as function of OTR-OUR variations is shown
- The oxygen conditions have effects over bacterial growth and metabolism

1. Introduction

Nowadays, there are a growing interest in obtaining alternatives for bioethanol as biofuel, among them isobutanol is a good alternative [1]. Isobutanol can be used as additive improving gasoline properties and also as chemical platform, to produce solvents or plasticizers agents [2]. It is well known that the fluid-dynamic conditions could critical in bacteria cultures [3], affecting culture performance. The objective of this work is to study the effect of fluid-dynamic conditions in STBR on *S. blattae* (p424IbPSO) cultures for the production of isobutanol.

2. Methods

Seven STBR cultures of S.blattae (p424IbPSO)[4] strain were carried out under different fluid-dynamic conditions, changing the stirrer speed from 100 to 1200 rpm and remaining constant the air flow (1vvm). The bacteria growth were measured by spectrophotometer analysis and the cell viability evaluated by total viable count technique. The cell morphology was also evaluated by electron microscope observations. During the growth, the time course of glucose, isobutanol and by-products were measured by HPLC analysis. The k_La values were estimated for the seven experiments under different conditions, and OTR, OUR_{max} and qO_2 were also calculated from k_La values and the DO concentration measurements with time. The isobutanol production in resting cells state was also studied employing cells collected from cultures under different fluid-dynamic conditions and growth times.

3. Results and discussion

The biomass growth rate increases in the runs carried out employing stirrer speeds between 100 and 600 rpm, and remain constant in the runs performed from 600 to 1000 rpm. However, the biomass growth rate decreases in the runs using stirrer speeds higher than 1000 rpm. The cell viability decreases for high agitation speeds, in the runs conducted at agitation greater than 800 rpm. Cells aggregates, cell damage and cell elongation were also detected, all these phenomena appearing for high agitation speeds. The increases of stirrer speeds produces an increase in the OTR values, and, depending of the conditions, also in the OUR values. When OTR < OUR maximum

value, the DO concentration quickly falls to zero, and the culture produces more lactic acid, ethanol and isobutanol. On the other hand, when OTR > OUR maximum, the culture produces more acetic acid and biomass. In Figure 1, It can be seen the yield of each compound.

The same carbon flux distribution is maintained when the cultures are performed on resting cells with cells cultured under different oxygen conditions.

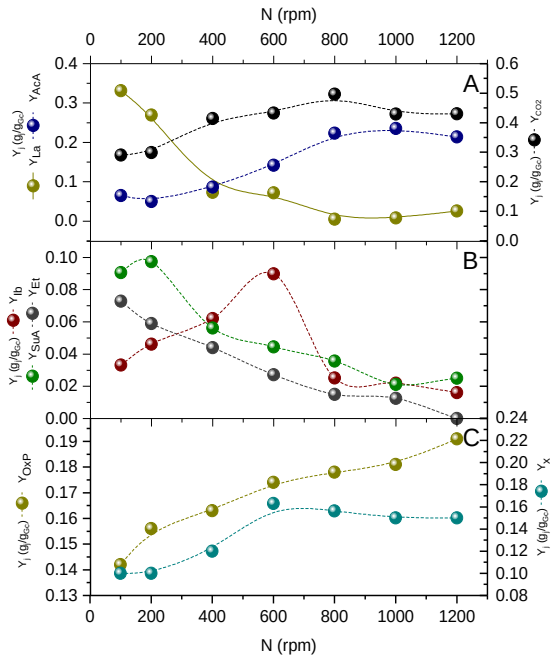

Figure 1. *Yield value on biomass and the main compounds referred to consumed glucose vs stirrer speed in STBR culture. The yield on lactate (La), acetate (Ac) and CO_2 can be seen in graphic A. The yield on isobutanol (Ib), ethanol (Et) and succinate (SuA) for each agitation (N) can be seen in the graphic B. The yield on high oxidation products (OxP) and biomass (X) it can be observed in graphic C.*

4. Conclusions

The hydrodynamic stress appears when high stirrer speeds were employed in STBR. The metabolite distribution is clearly affected by DO concentration, as a consequence of the relative values of OTR and OUR maximum values. It is relevant that these effects are maintained when the culture is carried out in resting cells, in these assays under the same conditions.

Production of a fungal fermented product as a meat substitute

Rebecca Gmoser[1]*, Mohammad J. Taherzadeh, Patrik R. Lennartsson

[1]Swedish Centre for Resource Recovery, University of Borås, 50190 Borås. Sweden

*Corresponding author: Rebecca.gmoser@hb.se

Highlights

- Food residues is converted by an edible fungi into a high protein meat replacer.
- The fungal product contain 29 % protein and 0.8 mg/g carotenoids.
- The product showed textural similarities with hamburgers and non-meat products.

1. Introduction

By 2050 world population is set to increase to over 9 billion. In order to feed this larger and wealthier population, food production foresees to rise by 70%. Access to a healthy and sustainable diet will become more important than ever as the planet accommodates for increased population. In this context, the present study presents a way to biotransform food residues into a valuable food product with promising attributes to substitute meat products. The edible filamentous fungi *N. intermedia* was used to create a fungal burger with stale bread and brewers spent grain as substrate. Since more than one billion people worldwide is unable to meet their daily protein requirement [1, 2] and texture is one of the biggest barrier to widespread acceptance for meat alternatives [3], the product was mainly evaluated based on its protein and texture attributes.

2. Methods

Fungal fermentation of the edible food grade filamentous fungi *Neurospora intermedia* CBS 131.92 (Centraalbureau voor Schimmelcultures, The Netherlands) was carried out in sterile petri dishes with bread crumbs alone or addition of brewers spent grain were used as substrate. Total 15 g substrate was inoculated with 1 ml spore suspension of *N. intermedia* separately for each petri dish and initial moisture content was adjusted to 40% (on a dry basis (w/w, db). Solid state fermentation was carried out batch wise for 6 days in a climatic test cabinet (NUVE test cabinet TK 120, Turkey) at 90-95% Rh at 35 °C under light. All the cultivation experiments were conducted in duplicate except for texture analysis where six replicates were made, and the mean values are presented with standard deviations. The textural profile analysis (TPA) of the samples was assessed with a TVT 6700 texture analyser (Perten Instruments, Sweden with software TexCalc version 4.0.2.50). To simulate a bite force through the burgers, a heavy Duty Stand, a knife blade probe with holder and blade set was attached. The maximum force required to break the sample was compared between samples. Instrumental texture measurement of the fermented fungal burgers was investigated after frozen samples for 24 h followed by frying at 100°C in 2 g of canola oil for 10 minutes.

3. Results and discussion

Bite force was measured by shearing with a knife blade to simulate a human bite and ease of chewing through the sample. As expected, the maximum force increased overall with increasing

BSG concentration in the substrate. Texture analysis on *N. intermedia* fungal burgers produced from stale sourdough bread with 0 % addition of BSG revealed a similar bite force response when fried as hamburger whereas addition of 10 % BSG was needed to reach a similar bite force response as a commercial soy burger, Figure 1. The objective textural data contribute to important knowledge about the products quality attributes. The stale bread with 10 % BSG used as substrate was converted into a high protein and nutritional fungal burger where mostly carbohydrates were converted into protein by *N. intermedia*. This fungal burger resulted in a protein increase by 152 % by *N. intermedia*. The increase in protein content is largely explained by a decrease in dry weight content of the fermented material [4]. Moreover, the fungal burger contained 0.95 mg carotenoids/g total material.

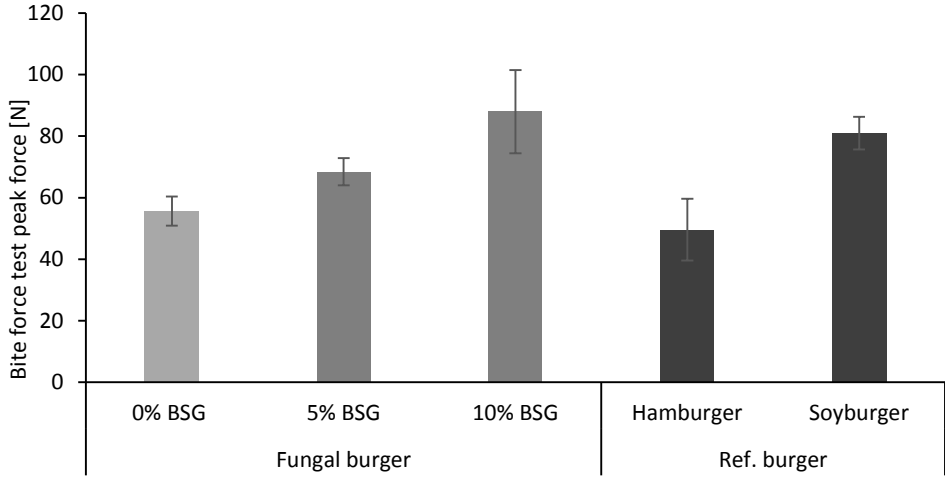

Figure 1. Bite force test of pre-frozen and fried fungal burgers and reference hamburger and soy burger available on the market. Fungal burgers are made from stale sourdough bread + 0, 5 or 10 % brewers spent grain using *N. intermedia* after 6 days solid state fermentation under light at 35 °C, 90 % Rh, and 40 % initial moisture content. Results are expressed as the mean value ± standard deviation.

4. Conclusions

The fermented fungal burger made from stale bread and up to 10 % brewers spent grains present an opportunity for an meat substitute. With up to 36 % protein and similar texture attributes to commercial products on the market, the product present a great addition to a modern diet without over-exploiting natural resources. The additional pigments produced (0.95 mg carotenoids/g total material) in the final product further adds value to the protein-rich fermented product.

D-Lactic Acid Fermentation from Orange Peel Waste: Effect of Initial Hydrolysate Concentration.

Isabel de la Torre, Felix Garcia-Ochoa*, Miguel Ladero and Victoria E. Santos

Chemical and Materials Engineering Department, Chemical Sciences Faculty, Universidad Complutense de Madrid (Madrid, Spain)

**Corresponding author: fgochoa@ucm.es*

Highlights

- D-Lactic acid production is carried out from cheaper carbon and nitrogen source
- 83.16 g/L of D-LA are obtained at highest OPW hydrolysate concentration
- 2.35 g/Lh of productivity is attained at the lowest OPW hydrolysate concentration
- A high OPW concentration improves D-LA final titer but worsens its productivity

1. Introduction

D-lactic acid (D-LA) is an organic acid produced mainly by lactic acid bacteria that has gained interest due to its application in the synthesis of poly-lactic acids (PLAs), a biodegradable and environmentally friendly polymer [1, 2]. The main obstacle to produce PLAs is the manufacturing costs caused largely by its monomer production (D-LA). This makes it necessary the use of cheaper carbon source like orange peel waste (OPW) [1]. The OPW is considered an optimum candidate for this applications due to: its high content in free sugars easily extracted (about 10 % in glucose, fructose and sucrose), its high content in polymers (37 % of cellulose and 11 % hemicellulose), which, after hydrolysis, release fermentable carbohydrates, and its low content in lignin (7.5 %), which inhibits enzyme action during hydrolysis and microbial activity in fermentation process. These residues are also notable for its high percentage of humidity [3].

2. Methods

OPW was milled down to 1–2-mm particle size, with a subsequent enzymatic hydrolysis carried out in batch run at 10.1% w/w of dry solid, 50 °C, 300 rpm, and initial pH of 5.2. Fed- batch saccharification was performed with 4 charges (initial + 3) of OPW partially dried by air convection, reducing the humidity from 80 to 60 % and 10.1% w/w of dry solid at initial time, 50 °C, 300 rpm and pH adjusted after added a charge to 5.2. The enzymes employed were Celluclast 1.5L, Novozyme 188 and Pectinex Ultra-SP. The hydrolysate was filtered through 0.2 µm size pore membranes of cellulose acetate for sterilization.

Lactobacillus delbrueckii ssp delbrueckii CECT 286 was employed as the biocatalyst to carry out D-Lactic acid production. Fermentation experiments were performed in 1L stirred tank bioreactor (STBR) BIOSTAT B-Plus with a volume broth of 0.5L and initial biomass concentration of 0.1g/L (5%v/v). The conditions were maintained at 40ºC, 200rpm, pH of 5.8 by adding NaOH 10M and anaerobic atmosphere by bubbling nitrogen before inoculation. The broth employed was OPW hydrolysate supplemented with 37 g/L corn steep liquor (CSL).

3. Results and discussion

D-Lactic acid production was carried out employing cheap carbon (OPW) and nitrogen (CSL) sources. If we pay attention to sugars uptake, glucose is consumed first in all experiments, while fructose and galactose, as observed in figures 1A and 1B, were metabolized later. All sugars were used to produce D-lactic acid, as suggested in those figures. In the figure 1C, results achieved when the hydrolysate concentration is highest are displayed, and it can be observed that the strain is not able to consume all sugars in this condition. If looking at final biomass concentrations, differences are not evident, although the growth rate is slower at higher hydrolysate concentration, as expected with increased inhibition due to either the substrates themselves or polyphenols and other components present in such hydrolysates. This LAB always grows from glucose, but it is not able to grow anymore in the presence of fructose and galactose. The final D-LA concentration improves when the OPW hydrolysate concentration increases, but the productivity decreases.

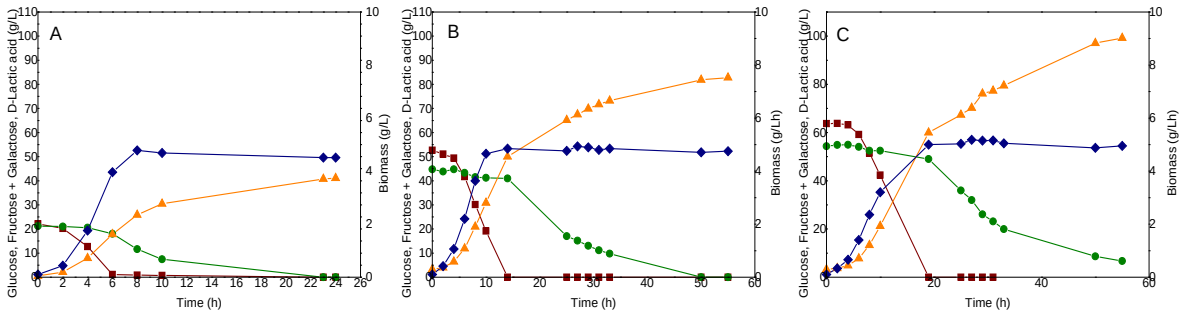

Figure 1.*D-Lactic acid production form OPW hydrolysate.* ***A.*** *Saccharification carried out in batch,* ***B.*** *Saccharification carried out in Fed Batch, hydrolysate diluted 80% and* ***C.*** *Saccharification carried out in Fed Batch, hydrolysate without dilution. Legend: Glucose, squares; fructose and galactose, circles; D-lactic acid, triangles; and biomass, diamonds.*

4. Conclusions

D-Lactic acid production is possible from cheap carbon (OPW) and nitrogen (CLS) sources. An increment in hydrolysate concentration reduces the productivity and growth rate but increases the final D-LA concentration, suggesting that inhibition due to substrates or stress due to phenolics and other chemicals plays a role in D-lactic acid production. At the highest hydrolysate concentration, 83.16 g/L of D-lactic acid were obtained at a productivity of 1.53 g/L·h.

Mitigation of Ammonia Inhibition Through Bioaugmentation in Anaerobic Digestion: Selection of Strains and Reactor Performance Evaluation.

Ziyi Yang[1], Wen Wang[1*], Chao Liu[1], Guangqing Liu[1]

1 Biomass Energy and Environmental Engineering Research Center, Beijing University of Chemical Technology, Beijing 100029, China

**Corresponding author: wangwen@mail.buct.edu.cn, anne_wangwen@163.com*

Highlights

- Bioaugmentation could achieve 71% increased methane production and 85% biodegradability.
- Bioaugmentation with *Syntrophaceticu smithii* + *Methanobrevibacter* spp. was optimum.
- Enhancement of both aceticlastic and hydrogenotrophic methanogenesis was important.
- *Methanobrevibacter* and *Methanosarcina* spp. were non-dominant but important archaea.

1. Introduction

Anaerobic digestion (AD) has gained extreme attention since producing renewable energy [1]. Ammonia is considered as a key parameter affecting AD efficiency [2]. Bioaugmentation could be a potential method to improve AD efficiency [3]. Researchers have attempted to increase methane production (MP) by strengthening the hydrogenotrophic methanogenesis bioaugmentated with certain strains [4]. However, other studies didn't indicate significant improvements [5]. Knowledge of mitigating ammonia inhibition effect with hydrogenotrophic methanogens is lacking. On the other hand, *Methanosaeta* and *Methanosarcina* were found to be dominant archaea [6]. Whether bioaugmentation with aceticlastic methanogens could achieve efficient MP remains unknown. The objectives of the present research are as follows: (1) to compare the bioaugmentation effects of different strains and (2) to develop an ammonia-tolerant environment for MP.

2. Methods

Seven pure strains were selected (Table 1). The total and working volumes were 500 and 350 mL. Glucose and NH_4Cl were applied as carbon and ammonium nitrogen sources. Organic loading rate was 1 g glucose/L/d. Hydraulic retention time was 10 days. The reactors were carried out in a 37 °C continuous stirred shaker. The ammonia level was 4 NH_4^+-N/L. Biogas production, NH_3-N, were determined as publications [7]. Specific methanogenic activity (SMA), stable isotopic analysis (based on α_c values), and 16S rRNA gene sequencing analysis were described in publications [7,8].

Table 1. Abbreviation of different strains used in this study

Pure strain	Abbreviation	Pure strain	Abbreviation
Methanosaeta harundinacea	MSH	*Methanosarcina barkeri*	MSB
Methanobacterium bryantii	MBB	*Syntrophaceticus schinkii*	SS
Methanoculleus bourgensis	MCB	*Tepidanaerobacter acetatoxydans*	TA
Methanobrevibacter smithii	MBS		

3. Results and discussion

Bioaugmentation with SS + MBS was the optimal choice (Figure 1; MP was 71.1% higher than that in Blank), the activity of hydrogenotrophic methanogenesis was greatly heightened according to SMA (Figure 2). And bioaugmentation with MSB alone was also proven efficient (MP was 59.7% higher than that in Blank), both aceticlastic and hydrogenotrophic methanogenesis were enhanced. Further evaluation with carbon isotope fractionations analysis (Figure 3) indicated that balancing the activities of the aceticlastic and hydrogenotrophic methanogenic pathways is of great importance. 16s rRNA gene sequencing results (Figure 4) showed that showed that *Methanobacterium* spp. and *Methanosaeta* spp. were the dominant archaea in all 14 reactors. Nevertheless, bioaugmentation with *Methanosaeta* spp. did not result in a positive effect on MP. On the other hand, *Methanobrevibacter* spp. and *Methanosarcina* spp. were non-dominant archaea (even after bioaugmentation with MBS or MSB, the relative abundances were still poor (< 2%)), but displayed pivotal roles in determining the overall microbial consortium and, in turn, improved the overall performance.

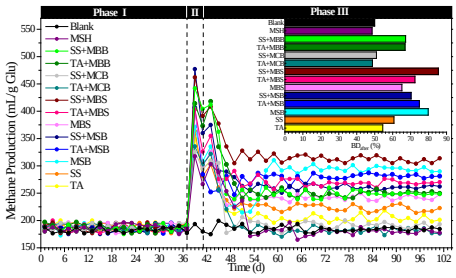

Figure 1. MP and biodegradability of different reactors

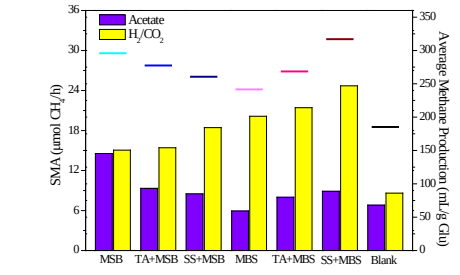

Figure 2. SMA and average MP in different reactors

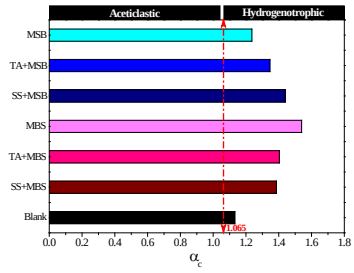

Figure 3. α_c values and pathway in different reactors

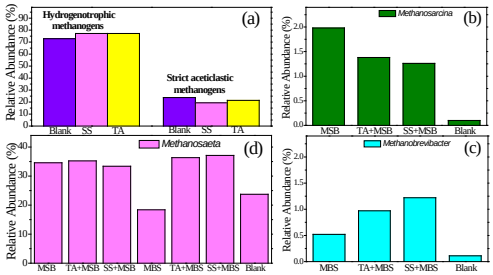

Figure 4. Relative abundance of different methanogens

4. Conclusions

Bioaugmentation could be an efficient way with over 59% increased on MP. aceticlastic and hydrogenotrophic methanogenic pathway should be both taken into account during bioaugmentation and the balance could result in a better reactor performance. Non-dominant archaea might display pivotal roles in improving AD performance.

Tolerance Improvement of Xylose-Utilizing Yeast Strains on Acetic Acid by Evolutionary Engineering.

Ja Kyong Ko[1], Soo Rin Kim[2], Youngsoon Um[1], Sun-Mi Lee[1,*]

[1] *Clean Energy Research Center, Korea Institute of Science and Technology (KIST), Wharang-ro 14 gil 5, Seongbuk-gu, Seoul 136-91, Republic of Korea;* [2] *School of Food Science and Biotechnology, Kyungpook National University, Daegu, Republic of Korea*

**Corresponding author: smlee@kist.re.kr*

Highlights

- Acetic acid derived from biomass severely inhibits xylose fermentation of yeast.
- Evolutionary engineering strategy was applied to improve acetic acid tolerance.
- Evolved yeasts could serve as platform strains for biofuel production from biomass.

1. Introduction

The presence of inhibitors in the lignocellulosic biomass hydrolysates are inevitable bottlenecks for achieving economic cellulosic ethanol production by *Saccharomyces cerevisiae*. The yeast tolerance toward acetic acid, released during the pretreatment of lignocellulose, needs to be improved for the efficient fermentation of un-detoxified biomass hydrolysates. Specifically, acetic acid stress is more severe on xylose fermentation resulting in decreased cell growth, xylose utilization rate and ethanol yield than glucose fermentation. In this study, an evolutionary engineering strategy was applied to improve fermentation performance of the engineered xylose-utilizing yeasts under acetic acid stress.

2. Methods

We attempted to evolve the two engineered strains harboring xylose isomerase (XUS-E) [1] and oxidoreductase (DY4)-based pathways using serial sub-culturing in synthetic medium with xylose as a sole carbon source in the presence of acetic acid at pH 5. After 13 rounds of exponential phase transfer, the evolved strains, XUS-AE57 and DY4-AE1, were obtained. Transcriptomic characterization of evolved strains through RNA sequencing was performed using tools from Ebiogen, Inc. (Seoul, Republic of Korea).

3. Results and discussion

The evolved strain, XUS-AE57, with xylose isomerase pathway could efficiently convert xylose to ethanol with yields of 0.43-0.47 g ethanol/g xylose even in the presence of 2-5 g/L acetic acid (Figure 1). This strategy not only achieved ~1.7 fold higher level of ethanol yields, but also improved xylose utilization rate by >2 folds. For DY4AE1 harboring an oxidoreductase pathway, the xylose utilization rate was significantly enhanced by ~2.3 fold. To understand the molecular mechanisms underlying the improvement in the acetic acid tolerant phenotypes, the global

transcript profiles of the evolved strains grown under acetic acid stress were analyzed by using RNA sequencing.

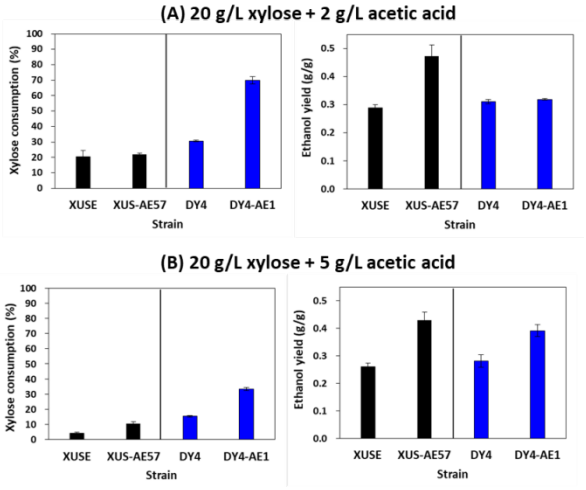

Figure 1. Xylose fermentation performance of the control (XUSE and DY4) and evolved strains (XUSAE57 and DY4AE1) under 2 and 5 g/L acetic acid stress.

4. Conclusions

XUSAE57 and DY41 strains could serve as robust platform strains of *Saccharomyces cerevisiae* for biofuels/biochemicals production from lignocellulosic biomass.

Soybean Protein: a Potential Additive to Improve the Saccharification of Lignocellulosic Biomass in Biorefineries

Mariana G. Brondi[1,2], Roberto C. Giordano[1], Cristiane S. Farinas[1,2*]

[1] *Graduate Program of Chemical Engineering, Federal University of São Carlos, São Carlos, Brazil;*

[2] *Embrapa Instrumentação, São Carlos, Brazil*

**Corresponding author: cristiane.farinas@embrapa.br*

Highlights

- Soybean protein improves biomass saccharification.
- Soybean protein can be used as cost-effective additive.
- Gain of soybean protein is comparable to BSA.

1. Introduction

The conversion of renewable lignocellulosic biomass into biofuels and other bioproducts employing the biochemical route has been considered as a sustainable alternative to implement future biorefineries. However, this process still presents several technological challenges related to the low yield of the enzymatic hydrolysis step and the high cost of the cellulolytic enzymes. Among the strategies to increase the efficiency of the enzymatic hydrolysis reactions of the biomass, the use of additives has shown very positive effects, since they decrease the unproductive adsorption of the cellulases in the lignin, thus reducing the loss of enzymes in the process [1,2,3]. However, there is a clear need to find more cost-effective additives for use in large-scale processes. Here, soybean protein was evaluated as an alternative low-cost additive in the saccharification of pretreated sugarcane bagasse using a commercial enzymatic cocktail.

2. Methods

Liquid hot water pretreated bagasse (LHW) was prepared as described in [3]. Soybean protein (soybean protein isolate with 90% protein content, from Bremil, Brazil) was used at 12% (w/w) per wt of biomass (on a dry basis). The enzymatic hydrolysis experiments were carried out in 5 mL tubes placed in a hybridization incubator operated at an agitation speed of 30 rpm. Solids loadings of 15% (w/v, dry weight basis) of biomass and enzyme loadings of 5, 10, 15 and 20 FPU/g dry biomass were used, at 50 °C, in sodium citrate buffer (50 mM and pH 4.8). Samples were withdrawn every 24, 48 and 72 h for glucose determination using a D-glucose enzymatic assay kit (Labtest, Brazil).

3. Results and discussion

The addition of soybean protein had positive effects on glucose release during the hydrolysis of LHW pretreated sugarcane bagasse, with gains up to 26% when 12% (w/w) soybean protein was used (Figure 1). These improvements were comparable to those obtained using bovine serum albumin (BSA), a much more expensive protein that has been widely reported for such an application [2]. Moreover, addition of soybean protein led to a saving of 48 hours in the hydrolysis reaction time, corresponding to a 66% decrease in the reactor operation time required. In order to achieve the same hydrolysis yield without the soybean additive, the enzyme loading would need to be increased by 50%. Similar gains were also observed when using steam exploded pretreated sugarcane bagasse [2], thus showing the potential of soybean protein for other types of pretreated biomass.

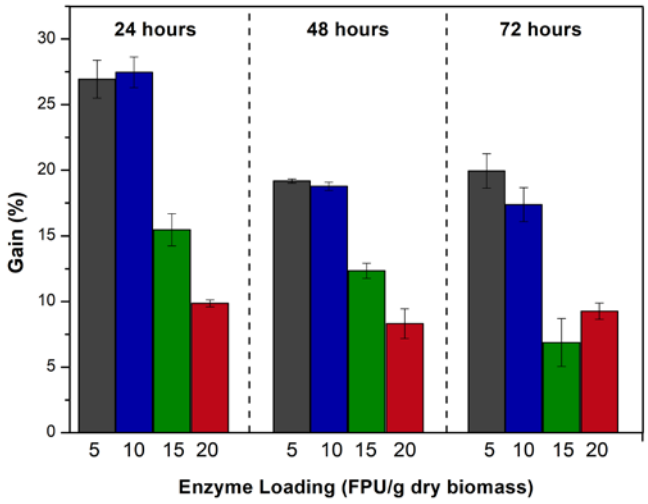

Figure 1. Increase in glucose release after the addition of soybean protein (12% w/w) compared to the bagasse hydrolysis without additive (Gain). The hydrolysis were performed with an enzyme loading of 5, 10, 15 and 20 FPU/g dry biomass, solids loading of 15% (w/v) for 24, 48 and 72 hours.

4. Conclusions

These findings suggest that soybean protein supplementation during enzymatic hydrolysis by commercially available enzymes is an effective strategy for achieving higher saccharification yields from pretreated lignocellulosic biomass, hence improving overall efficiency of future biorefineries.

Highlights

- Sugarcane bagasse is a feasible carbon source for bioprocess
- Fluidized bed reactor can be used for chemical and biochemical process
- Bioprocess conducted in Fed-batch configuration is a potential method

1. Introduction

Due to environmental and political problems regarding the imminent scarcity of fossil fuels, different approaches for biofuels production have been gained great importance in the global scenario. Thus, various agroindustry residues, such as bagasse, bark, grains, straw, among others, are used as raw material for the production of 2G ethanol. Among them, sugarcane bagasse has presented greater advantages due it is available in abundance in countries such as Brazil, India, China and others [1]. Additionally, new studies must be developed in order to produce biomolecules from lignocellulosic materials, since the processes of pretreatment, saccharification and fermentation are still stages that still needs to be optimized, aiming the scale-up and industrial production. Within this context, i.e., the use of fluidized bed reactor (FBR) in chemical and biochemical processes is a potential approach for the conduction of methods applied to scale-up. When compared to the stirred tank reactor, the most commonly used reactor, the fluidized bed reactor has advantages such as: no requirement to use mechanical impellers for agitation, ease control of homogenization by insertion of air or fluid recirculation, and hence, increase of the contact surface between the catalyst and fluid [2]. Taking this into account, we present a new development for ethanol production from lignocellulosic material in fludized bed reactor. Ethanol production was evaluated by conducting saccharification stage in fed-feed process by inserting with alkaline pre-treated sugarcane bagasse, in order to obtain fermentable sugars, followed by and subsequent fermentation, carried out in simultaneous sacharification and fermentation configuration (SSF) in all process conducted in FBR.

2. Methods

Sugarcane bagasse was conducted to alkaline hydrolysis in a fluidized bed reactor (a column reactor from Bioengineering AG - PID Fermenter AWS, Wald, Switzerland- with 540 mm x 55 mm column, with central vertical tube of 9 mm inner diameter) where 30 g of sugarcane bagasse was mixed with 700 mL of 0.5M NaOH alkaline solution at 90 ° C for 120 min in a non-pressurized fluidized bed reactor system, homogenized by insertion of air in 0.3 min^{-1}. After the hydrolysis process, the remaining solid fraction of pre-treated sugar cane bagasse was washed and used in the subsequent

saccharification step. In other similar fluidized bed reactor, homogenized by aeration of 0.3 min^{-1}, sacharification step was conducted at 50ºC by mixing of 700 ml of Citrate buffer (50 mM, pH 4.8), 0.3 ml of twin and 20 FPU of cellulase enzyme complex (Cellulase CP CONC-Dyadic) and 10g of alkaline pretreated sugarcane bagasse, obtained in last step. At every period of hours, 10g of alkaline pre-treated bagasse was added, until the total of 50g was reached. After 48 hours of saccharification, the pH of the medium was adjusted to 5.5 with addition of NaOH solution, and subsequently added 5 g/L of ammonium sulfate, 3 g/L of yeast extract and 3 g/L of extract of malt, according to nutritional medium proposed by Antunes et al. [3]. To the supplemented medium, 0.5 g/L of *Scheffersomyces shehatae* UMFG-HM 52.2 cellular solution was added (wild Brazilian sugars pentose convert yeast). The fermentations were conducted for 72 h in the same fluidized bed reactor, by the aeration of 0.3 min^{-1}, at 30 ° C. Samples were collected periodically for analysis of biomass, fermentable sugars and ethanol.

3. Results and discussion

Figure 1 shows the consumption profile of fermentable sugars (glucose and xylose) obtained by means of enzymatic hydrolysis operated in batch fed alkaline pre-treated sugar cane bagasse and followed used in the conversion of ethanol to a fluidized bed reactor using yeast *Scheffersomyces shehatae* UFMG-HM 52.2.

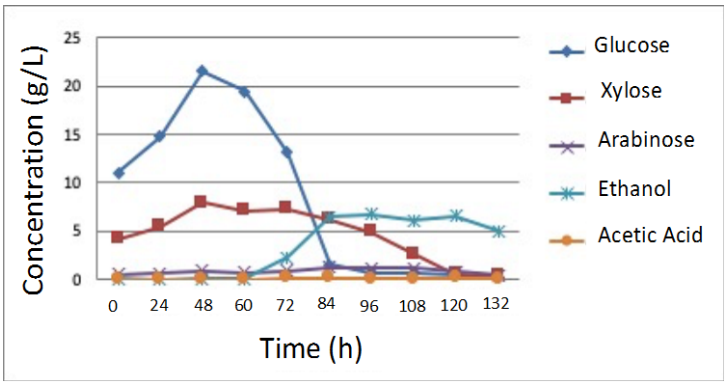

Figure 1. Ethanol production from fermentable sugars of sugarcane bagasse in fluidized by using the yeast *Scheffersomyces shehatae* UFMG-HM 52.2

After conducting 48 h of enzymatic hydrolysis carried out in fed-batch configuration, around 22 g/L and 8 g/L of xylose were observed as available fermentable sugars. From this time, with addition of the microorganism, total consumption of fermentable sugars, with the highest production of ethanol (6.775 g / L) were verified in the followed 48 hours of fermentation (96h of total process), showing ethanol yield ($Y_{P/S}$) of 0.26 g/g and volumetric productivity of 0.14 g/Lh .

4. Conclusions

The potential use of column reactors applied to the stages of pre-treatment of vegetal biomass and fermentation of fermentable sugars was norteworthy, as well as the indication for further of studies of process optimization.

Process simulators have been used in the petroleum and chemical industries for over four decades to facilitate the development of new processes and optimize the performance of existing ones. Similar benefits can be derived from the use of such tools in the industrial biotechnology arena to aid in the design, feasibility evaluation and environmental impact assessment of biorefinery systems. In this work, we demonstrate such a case for a biorefinery that utilizes mango kernels to produce energy and biochemicals such as oil, proteins and starch.

Enzymatic Recovery of Building Blocks from Textile Blends.

Felice Quartinello[1], Alessandro Pellis[2], Georg M. Gübitz[1]

Highlights

- Circular economy concept
- Textile waste recycling
- Enzymatic separation and degradation of fibres.
- Secondary value-added products

1. Introduction

In the last decades the production of textiles, especially for clothing, is exponentially increasing mostly due to the globalization phenomena [1].In Europe, 80.000 tons of textile waste are generated per year and their end-life is primarily landfilling. Together with soil pollution, this represents also a global warming challenge due the production of greenhouse-gases [2]. For example only 18% of this kind of waste in the last years was used for energy recovery. Furthermore, considering the material composition, the discarded textiles still contains valuable polymers/polymer building blocks that could be reused. In this study we present an enzyme-based strategy for the recovery of valuable building blocks from mixed textile waste and blends as a circular economy concept [3,4].

2. Methods

Textile, waste was sequentially incubated with 1) protease for the extraction of amino-acids from wool components) and 2) cellulases for the recovery of glucose from cotton and rayon constituents. The purity of the remaining poly(ethylene terephthalate) (PET) unaltered by the enzymatic treatments was assessed via Fourier-transformed infrared spectroscopy. Amino acids recovered from wool were characterized via elementary and molecular size analysis, while the glucose resulting from the cotton hydrolysis was successfully converted into ethanol by fermentation with *Saccharomyces cerevisiae*.

3. Results and discussion

The enzymatic hydrolysis of wool- and cellulose- based fibers led to yields of approximately 95% and 85%, respectively. The purity of the resulting poly(ethylene terephthalate) was comparable to the pure PET as demonstrated by FT-IR measurements, allowing recycling. Furthermore, in line with circular economy concepts, the recovered building blocks from wool and cellulose fiber components in blended textiles can be reused. The amino acids and oligopeptides (with molecular weight lower than 10 KDa) obtained from wool degradation can be used as a replacement for carbon and nitrogen sources for germination or phenolic-related compounds for resins according to previous reports. On the other hand, in this paper recovered glucose (around 0.62 g•L^{-1}) was successfully used as carbon source for yeast fermentation to produce ethanol (0.3 g•L^{-1}).

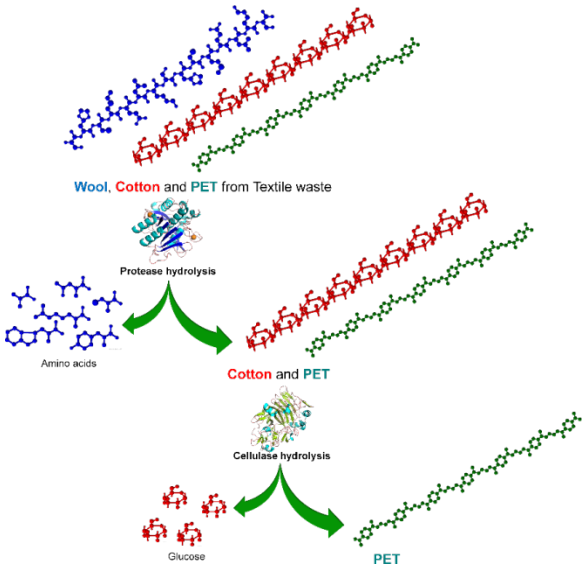

Figure 1. Scheme of enzymatic separation of textile fibers

4. Conclusions

In summary, such step-wise enzymatic process is especially attractive for the recycling of blended materials which are otherwise rather difficult to recycle with other technologies. Furthermore, this work demonstrated that the step-wise application of enzymes can be used for the recovery of pure building blocks and their further reuse, example for fermentative processes (glucose).

Highlights

- A PAT application for preparative protein chromatography was established.
- Non-parametric statistical models were complemented with parametric mechanistic models.
- Hybrid semi-parametric models show enhanced prediction quality of critical quality attributes.

1. Introduction

Regulatory agencies encourage pharmaceutical industry to implement Quality-by-Design approaches into manufacturing processes. We integrated additional online sensors, namely infrared (ATR-FTIR), fluorescence, refractive index and static light scattering detectors, into a conventional chromatography workstation. Obtained online signals were statistically correlated to offline measured parameters of quantity, purity and potency. Thereby, predictive models were generated. Hybrid semi-parametric models combine such statistical correlations with first-principles expert knowledge [1]. Hybrid models are able to balance strengths and weaknesses of different sources of knowledge considering for example extrapolation power and data availability. This has been shown among others for monitoring of bacterial fermentation processes [2]. We applied this approach to optimize loading and elution of chromatographic steps where monitoring is currently mostly done via UV/Vis absorption only.

2. Methods

Multivariate data analysis enables extraction of unknown or unidentified correlations from large amounts of data sets. Online data obtained from implemented spectroscopic sensors were pre-processed to maximize the information content and reduce unspecific noise. Boosting algorithms allowed automated variable selection. CADET was used for efficient computing of mechanistic models [3].

3. Results and discussion

Different combinations of parametric and non-parametric model parts, i.e. parallel and serial hybrid structures, were compared and the best performing identified for monitoring of product attributes. Prediction accuracy and robustness were compared to solely data-based models and differences analyzed. A major advantage of the hybrid models is that predictions can be provided based on the feed composition while non-parametric model estimates are only available retrospectively with a time delay of up to 10 seconds.

4. Conclusions

The generated hybrid models enable controlled loading and peak cutting based on defined quality settings. Time and labor intense offline analytics can therefore be reduced to a minimum for model training and final product release. The developed approach is fundamental for the implementation of real-time batch release and continuous manufacturing in biopharmaceutical industry.

Highlights

- Membrane filtration allows the concentration of lipids from disrupted microalgae.
- The rotatin disk filtration with a PAN membrane offers the best performances.
- An optimized coupling between cell disruption and filtration will enhance the biorefining.

1. Introduction

The biorefinery of renewable resources like microalgae offers great opportunities to substitute biomolecules to traditional raw materials in various industry sectors. Such strategies necessitate innovative choices of soft and energy-efficient processes to guarantee the integrity of fragile molecules and develop eco-friendly production. For large-scale production (food, energy or green chemistry), a wet processing of biomass has been proposed, that avoids expensive drying steps and reduces solvent use. However the energetically efficient extraction of biomolecules at low cost and industrial scale is not yet mature. Biomass wet treatment includes 1- the harvesting, 2- the cell disruption step to release the valuable biochemical compounds in the aqueous phase, 3- the fractionation step (extraction, concentration and purification). The integration of membrane processes into the microalgae downstream processing concerns the harvesting and the concentration of microalgae, but membrane filtration is also a promising clean separation process for the fractionation step.

In this work we focus on the recovery of lipids from *Parachlorella kessleri*, cultivated in starving conditions to enhance their lipid production. The lipid recovery from microalgae was mostly performed with supercritical CO_2 on dried matter or solvent extraction. In this study we will focus on the recovery of lipids from aqueous extracts by membrane processes. Clavijo et al. [1] demonstrated that the supernatant after bead milling and centrifugation of *Parachlorella kessleri* contains emulsified lipids in aqueous phase. The membrane separation of those valuable compounds is studied.

2. Methods

In this work a model solution was formulated, based on the analysis of ground *Parachlorella kessleri* [1].Then the performances (retention, flux, fouling, cleanability) of polyacrylonitrile (PAN), polyethersulfone (PES) and polyvinylidene fluoride (PVDF) membranes to concentrate lipids from *Parachlorella kessleri* aqueous extracts were evaluated, using the model solution. The most appropriate material and conditions (TMP) were then selected and validated on real microalgae fractions. Two modules were compared allowing the crossflow (CF) and the rotating disk (RD) filtration.

3. Results and discussion

The PAN 500kDa membrane presented the best performances (flux, lipid retention and cleanability) in crossflow and rotating disk filtrations. It was selected to test the filtration of real aqueous extracts from *Parachlorella kessleri*. The performances of the PAN membrane in CF module with the real products was similar to the one with the model solution despite the composition differences. The lipids are totally retained whereas some of the hydrophilic compounds (polysaccharides and proteins depending on the conditions) could permeate. The use of RD filtration allows reducing the membrane fouling, using a higher transmembrane pressure thus leads to higher fluxes. In the case of real aqueous extracts RD filtration, the water permeability is enhanced by the accumulation of hydrophilic compounds whereas the shear rate limits the membrane clogging by the lipids. The RD filtration using a PAN membrane presents the best performances.

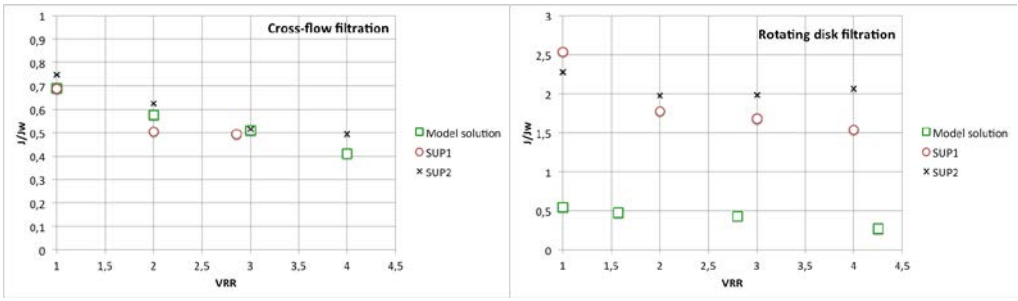

Figure 1. Crossflow and rotating-disk filtrations of an emulsion (model solution of concentrated microalgae aqueous extract) and two real aqueous extracts (SUP1 and SUP2) with a PAN membrane.

4. Conclusions

The membrane filtration is a relevant seperation process to concentrate the lipids, reduce the volume of water to treat for further purification steps and offers interesting opportunities for the fractionation of biomolecules from microalgae. An optimization of the coupling with the upstream operations (culture, cell disruption, clarification) would enhance the separation.

Highlights

- Use of anionic ion exchange resin to remove phenolic compounds
- High efficiencies on the removal of both p-coumaric and ferulic acids in the pretreatment liquid and enzymatic hydrolisates
- Low sugar losses for both the pretreatment liquid and enzymatic hydrolisates

1. Introduction

The use of lignocellulosic biomass as a feedstock for biofuels production is still challenging due to the formation of toxic products in the pretreatment that are inhibitory to fermentation and hence may affect economics. The type and concentration of inhibitors formed depend on the pretreatment technologies, being aliphatic carboxylic acids (e.g. acetic, formic, levulinic acid), phenylic compounds (benzoic acid, phenolic compounds), furans (furfural and hydroxymethylfurfural) and uronic acids (galacturonic and glucuronic acid) the main by-products formed [1]. The presence of inhibitors in the hydrolysates play a vital role in ABE fermentation as they affect negatively fermentation yield and efficiency mainly due to its toxicity to microorganisms. Phenolic compounds including ferulic acid, p-coumaric acid, 4-hydroxybenzoic acid, vanillic acid, and vanillin can cause growth inhibition of *C. beijerinkii* and no butanol production. The presence of phenolic compounds inhibited ABE fermentation at concentrations as low as 0.5 g/L for gallic acid and 0.1 g/L for catechin [2].

To overcome the problem due to the presence of inhibitors, a detoxification step before fermentation is usually carried out. Removal of phenolic compounds involves techniques such as physical methods (evaporation, membrane separations, electrochemical detoxification), chemical methods (neutralization, overliming with calcium hydroxide, addition of reducing agents), liquid-solid extraction (activated carbon treatment, ion exchange resins) and biological detoxification by enzymatic catalysis mainly with the use of laccase and peroxidase [3-5]. The use of ion-exchange resins is also a promising detoxifying technology, due to the selectivity of the resins, which are able to remove practically the totality of the phenolic compounds present with very little losses of monosaccharides

Different anionic exchange resins have been tested and operating conditions were optimized with the objective of removing the inhibitors formed during the pretreatment of brewer´s spent grain before ABE fermentation step with minimum sugar losses.

2. Methods

Model solutions were prepared simulating sugar concentrations of pretreatment liquid obtained during acid diluted pretreatment of brewer´s spent grain (15% dry matter content, 121ºC, 30 min) and enzymatic hydrolysates from pretreated solid (15% solids loadings, 15 FPU/gDM Cellic CTec 2, 48h, pH 4.8). Major phenolic compounds founded in these liquids are p-cumaric acid and ferulic acid and concentrations tested were in the range 0.5-2 g/L. Four different commercial ion-exchange resins (Lewatit Monoplus MP500, Lewatit VPOC, Lewatit S4528 and Lewatit A365) have been tested, operating in batch mode, at solid/liquid ratios of 1%, 2% and 3% w/v. Temperature was maintained at 35ºC, pH of 5.0, 200 rpm and operating time was 24 h for all the experiments. The contents in sugars (glucose, xylose, and arabinose) and phenolics inhibitors were determined by HPLC [6].

3. Results and discussion

A different behavior on the sugar losses and inhibitor´s removal have been found when the pretreatment liquid was detoxified with ion exchange resins. The highest sugar losses (17-21%) were obtained when the resin Lewatit A365 (weak anion exchange resin) was employed and sugar losses increased when resin:liquid ratio increased. On the opposite, the resin Lewatit Monoplus MP500 (strong anion exchange resin) showed the lowest sugar losses (7.8-8.0%) and no influence was observed with resin:liquid ratio. Related with the removal of phenolic compounds, weak anion resins removed almost completely p-cumaric and ferulic acids even at 1% w/v resin:liquid ratio, whereas when strong resins have been tested, it is necessary to work with a 3%w/w resin:liquid ratio to attain phenolic compounds removal higher than 90.0%.

When the enzymatic hydrolysates were detoxified with anion exchange resins, phenolic compounds were completely removed due, mainly due to the lower concentrations founded in these streams. Related with monosaccharides, significantly sugar losses up to 24% have been obtained for both weak and strong resins.

4. Conclusions

Weak anionic resins allow to remove almost completely phenolic compounds from BSG hydrolysates (pretreatment liquid and enzymatic hydrolysates) with relatively high sugar losses. On the contrary, the operation with strong anionic resins lead low sugar losses and phenolic´s removal up to 90%. Further research will be focused on the column operation and optimization of the main parameters (bed volume/h, temperature, time of cycle and regeneration conditions) will be studied.

Highlights

- Enzymatic deconstruction is performed to extract immobilized cells of *Clostridium beijerinckii* from their polymerous matrix.
- Viability analysis is achieved by flow cytometry
- Heterogeneous viability repartition within the biofilm is assessed by confocal microscopy.

1. Introduction

Butanol and isopropanol are commonly used chemicals in the industry as solvent. They can also be employed as fuels and are mainly produced from propylene coming from petrochemistry. To a lesser extent, an alternative bioproduction of Isopropanol and Butanol mixture using solventogenic Clostridium is also currently investigated .

However, this fermentation process is not used at an industrial scale because of low productivity and low solvent yield and titer due to butanol toxicity of classical batch or continuous processes. To overcome this issue, continuous fermentation using immobilized cells on a carrier is currently employed at a laboratory scale. This system allows the continuous removal of butanol, can be operated at high dilution rate without causing cell washout, and gives high productivity (4 $g.L^{-1}.h^{-1}$) [1].

During immobilized cell fermentation, bacteria adhere to the solid and form a structure called biofilm. This biofilm is composed of cells trapped into a gel-like matrix made from a mix of polysaccharides, proteins and extracellular DNA [2]. But the scale-up of an immobilized fermentation system is not easy as bacterial adhesion or biofilm growth and evolution are not well known [3]. This study focuses on cells viability assessment during IBE immobilized fermentation.

Firstly, confocal microscopy is used to show the cells repartition within the biofilm according to their viability. Then a sequential enzymatic lysis of the biofilm matrix coupled to flow cytometry analysis gave us information about physiological state of both sessile and planktonic cells during continuous fermentation.

2. Methods

Four screw scrap bottles, fill with the immobilization carrier, were used as reactors. The system was operated in continuous mode at an useful volume of 80mL. The analysis were performed by scarifying each reactor at different fermentation time.

After staining with a mix of carboxy fluorodesceine diacetate [cFDA] and propidium iodide [PI], the level of viability of the *Clostridium* cells were analysed by flow cytometry (Cyflow Space, Sysmex).

For confocal analysis, the carriers has been removed from the system and gently washed with deionized sterile water to remove planktonic cells attached to the biofilm. Then the carriers were put into staining solution containing propidium iodide and syto 9. After staining the carriers were plonged into PFA solution and then observed under a Zeiss LSM800 confocal laser microscope.

3. Results and discussion

Flow cytometry, showed that enzymatic deconstruction using sequentially Dnase and protease are able to extract cells from the biofilm without altering their viability. Using this method, the percentages of viable planktonic and sessile cells follow similar patterns during fermentation. However the amounts of viable sessile cells on the carriers are less important than the planktonic one. Using confocal microscopy, heterogeneity of viability is observed within the biofilm. Those observations also helped us to describe qualitatively the growth of the biofilm inside the foam during continuous fermentation.

4. Conclusions

In this study, two methods were validated in order to evaluate the physiological state of *C. beijerinckii* cells during continuous fermentation of immobilized cells. Other parameters of cell viability, such as membrane fluidity or polarization, may complement this analysis in the future. In addition, cell viability analysis using confocal microscopy highlight a high heterogeneity within the biofilm but need some improvement in order to better identified solvent producing cells in the biofilm.

Alkaline peroxide pretreated sugarcane bagasse as cell immobilization carrier for isopropanol-butanol-ethanol production

Carla Vieira[1*], Mateus Codogno[1], Francisco Maugeri-Filho[2], Rubens Maciel-Filho[1], Adriano P. Mariano[1]

1 School of Chemical Engineering - UNICAMP, Av. Albert Einstein, 500 - Campinas - SP - Brazil
2 School of Food Engineering - UNICAMP, R. Monteiro Lobato, 800 - Campinas - SP - Brazil
**Corresponding author: carlafsvieira90@gmail.com*

Highlights

- The proposed cell immobilization technique was successful in increasing IBE production.
- A more disorganized bagasse structure allowed the adhesion of a greater number of cells.
- Excessive production of biofilm exopolysaccharides affected the IBE yield.

1. Introduction

Cell immobilization techniques have been widely applied to ABE (acetone-butanol-ethanol) [1] and IBE (isopropanol-butanol-ethanol) [2 - 5] fermentation processes to increase productivity and decrease butanol inhibition to Clostridial species. The use of lignocellulosic materials as immobilization carrier can be an economically advantageous alternative due to their low cost and abundance. However, the adhesion of microorganisms cells can be difficult because of the poor permeability of lignocellulosic tissues [6]. Therefore, we evaluated whether the alkaline peroxide pretreatment can improve the efficiency of sugarcane bagasse as a cell immobilization carrier for IBE fermentation.

2. Methods

Sugarcane bagasse was provided by a mill located in São Paulo state, Brazil. The bagasse was pretreated with alkaline peroxide [0.5% (w/v) NaOH, 2% (w/v) H_2O_2, 10% (w/v) biomass loading] for 24 h at 200 rpm and room temperature in dark place [6]. IBE fermentations using *Clostridium beijerinckii* DSM 6423 were conducted in 250-mL flasks (triplicate) containing pretreated bagasse (1:20 liquid to solid ratio) and P2 medium [4] with 60 g/L initial glucose. The flasks were incubated in anaerobic chamber at 35 °C. Experimental controls consisted of fermentations without bagasse and with non-treated bagasse.

3. Results and discussion

Upon pretreatment, we observed a more disorganized morphological structure of the sugarcane bagasse (Figure 1), which allowed the adhesion of a greater number of cells (Figure 2). It had a positive impact on IBE concentration, IBE productivity, and sugar conversion (Table 1). Nevertheless, the decrease in the IBE yield can be attributed to an excessive production of biofilm exopolysaccharides, especially in the fermentation with pretreated bagasse.

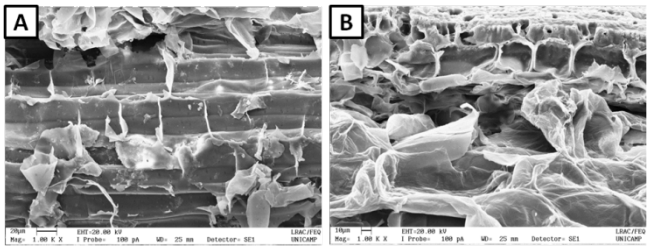

Figure 1 – Morphological structure of the sugarcane bagasse (A) before and (B) after pretreatment with alkaline peroxide.

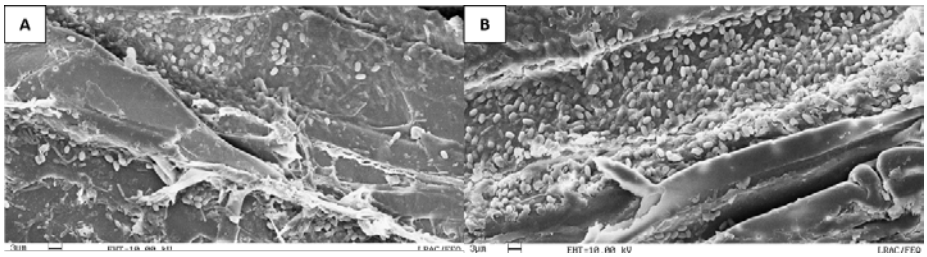

Figure 2 – *C. beijerinckii* DSM 6423 adhered to the sugarcane bagasse after the fermentation process. (A) Non- and (B) pretreated sugarcane bagasse

Table 1 – Performance of the IBE fermentation

	Without immobilization	Non-treated bagasse	Pretreated bagasse
Sugar conversion (%)	32	60	78
Final IBE concentration (g/L)	7.8	12.8	13.9
IBE productivity (g/L.h)	0.19	0.31	0.34
IBE yield (g/g)	0.40	0.34	0.29

4. Conclusions

Sugarcane bagasse as a cell carrier offered remarkable gains (78%) in IBE production. Further gains (8%) can be obtained if the bagasse is pretreated with alkaline peroxide. However, more sugar was used to produce biofilm exopolysaccharides, thereby affecting the IBE yield more intensively. Thus, future studies should focus on attenuating the production of exopolysaccharides by *C. beijerinckii* DSM 6423.

Highlights

- Conversion of food waste to biogas and eco-friendly digestate
- SBO addition enhanced biomethane production reducing the content of NH_3
- Effects of temperature and assessment of nitrogen's fate in the process

1. Introduction

Food waste (FW) is a valuable feedstock utilized as a renewable substrate for obtaining a wide variety of bio-based products [1]. However, the conversion of FW into biogas requires secondary treatment, since the process produces high contents of NH_3 in the digestate, constituting a common inhibitor in bio-waste anaerobic digestion (AD) systems. Excess NH_3 can be reduced through the use of SBO isolated from compost of gardening residues [2]. Many studies have shown promising applications of SBO as chemical auxiliary in the chemical industry and in agriculture. Some existing examples in the relevant literature comprise the use of SBO for textile dyeing [3], detergents manufacturing [3] and hydrocarbons contaminated soil washing [4].

The present study has been carried out within the LIFECAB project funded under the 2016 LIFE program. It aims to evaluate at pilot-scale a novel FW fermentation technology that involves four-steps, including: 1) use of FW as feedstock in two pilot anaerobic digesters, 2) co-composting of the digestate produced with green waste, 3) chemical hydrolysis of the compost generated to produce SBO, and 4) implementation of SBO in AD for enhanced biogas formation and production of digestate with reduced NH_3. The technology will be tested in 3 EU countries (Italy, Greece and Cyprus) through the production of eco-friendly cost-effective biogas and agricultural products. The study will assess the fate of NH_3 removed with the use of SBO in lab-scale experiments and to present preliminary data obtained from the pilot system.

2. Methods

Composting: Green waste was used for composting comprising grass clippings, dry leaves, wood sawdust, tree prunings and soil. The analytical methods applied included monitoring of the organic carbon content, pH, TS, VSS, ash, temperature, phytotoxicity, conductivity and moisture content, water holding capacity, phosphorus content and heavy metals.

AD experiments: Lab-scale experiments were conducted for FW fermentation to produce biogas and digestate with low NH_3 content. SBO was provided from Acea Pinerolese Industriale (Pinerolo, Italy). Four treatments were tested: A) Anaerobic sludge (AS) as control, B) AS with SBO, C) AS with FW, and D) AS with FW and SBO. The amount of SBO used in each treatment was 0.2% (w/w) and the temperatures applied were 30 °C and 55 °C. Gas samples were analysed for CH_4, CO_2, H_2, N_2, O_2 and N_2O using Gas Chromatography. Furthermore, the samples were passed through sorbent tubes (DRAGER tubes) for the determination of NO, NO_2 and NH_3.

3. Results and discussion

Lab-scale experiments were conducted under anaerobic conditions for evaluation of nitrogen's fate in the novel SBO-based process. Four treatments were tested as described above and the gas samples collected were analysed for CH_4, CO_2, H_2, N_2, O_2, N_2O, NO, NO_2 and NH_3. The data obtained from these experiments (Figure 1) demonstrated higher production of biogas and CH_4 in SBO assisted fermentations. Moreover, the GC analysis performed showed a small production of N_2O at the initial stages of experiments and small concentrations of N_2 at the final stages of experiments fed with FW. However, no detection of NO, NO_2 and NH_3 was observed in the gas phase, excluding the formation of the specific molecules due to the addition of SBO. Results from preliminary composting trials in three different countries will be also presented.

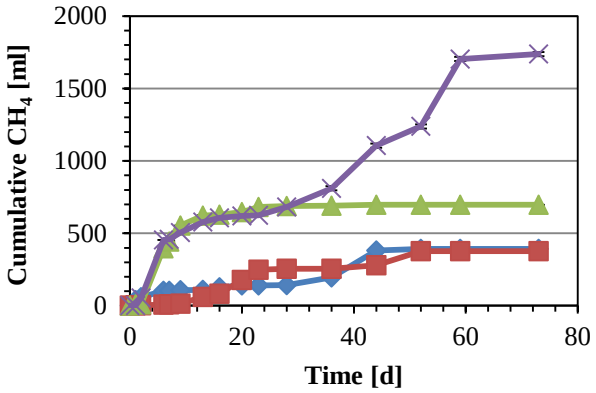

Figure 1. Cumulative volume analysis of CH_4 during lab-scale experiments. Coloured symbols correspond to: (I) control (blue), (II) AS and SBO (red), (III) AS and FW (green), and (IV) AS, FW and SBO (purple).

4. Conclusions

Based on the findings obtained, the fermentation of FW coupled to SBO is capable of significantly reducing the ammonia content of the digestate, producing elevated quantities of methane. Thus, the proposed technology improves both energy efficiency and the environmental footprint of AD.

A novel microfluidic device to investigate tumor cell extravasation

Claudia Kühlbach[1, 2], Margareta M. Mueller[1], Frank Baganz[2], and Volker C. Hass[1, 2]*,

1 Furtwangen University, Villingen-Schwenningen, D-78054, Germany; 2 University College London, London, WC1E 6BT,UK

**Corresponding author: volker.hass@hs-furtwangen.de*

Highlights

- Novel microfluidic device for cell extravasation
- Total confluency of functional area for transmigration
- Proof of tumor cell adhesion and transendothelial migration

1. Introduction

The process of metastasis of tumor cells is highly complex and includes the steps of intravasation, tumor cell distribution by blood stream and extravasation into surrounding tissues [1]. The molecular conditions and the mechanism for extravasation are still not fully understood.

To investigate the metastatic cascade, two different microfluidic approaches are frequently pursued. The hydrogel based systems, where the endothelial cells (EC) are embedded in hydrogel take advantage of the capability of the EC to self-assemble into a tubule-like vascular network, however it cannot be subjected to flow [2]. The second approach uses EC in monolayer, cultivated in matrix protein coated microfluidic channels. These devices are often hard to control for EC confluency [3].

Here we introduce a novel microfluidic device to study tumor cell extravasation and proof its functionality, under well-established confluency control as well as the extravasation process under dynamic flow conditions.

2. Methods

Methods used include culturing and seeding of the EC, the introduction of the tumor cells and immune fluorescence staining and are described in detail in Kühlbach et al., 2018 [4].

3. Results and discussion

The microfluidic device consists of three different parts. The upper channel, together with the porous membrane, represents the vessel equivalent (Figure 1A).

The upper channel and the membrane were seeded separately with EC in monolayer. This better represents the in vivo situation, in contrast to devices which work with multilayer EC, embedded in hydrogel [2]. The lower channel acts as reservoir to collect transmigrated tumor cells. In this novel device, the EC monolayer was checked for 100% confluency, before any assembly, as a confluent EC monolayer is essential to assure a tight barrier function. The EC monolayer integrity was verified, showing a regular expression and integration of VE-Cadherin into the EC cell membrane, as described for the in vivo situation in blood capillaries [5].

Additional coating of the microfluidic unit was abandoned, as the used EC secrete collagen IV and therefore establish their own basement membrane, as described before for EC cultures [6].

When adding different flow conditions to the device, the EC changed phenotype and oriented into flow direction, similar as previously described for the in vivo situation [7].
The introduced tumor cells successfully adhere to the endothelial lining under different flow conditions. The number of adherent tumor cells was not influenced when continuous flow was applied. In contrast, when pulsating flow was adopted, the number of adherent tumor cells decreased with increase of flow velocity (Figure 1B).
The successful transendothelial migration of tumor cells under static conditions could be shown.

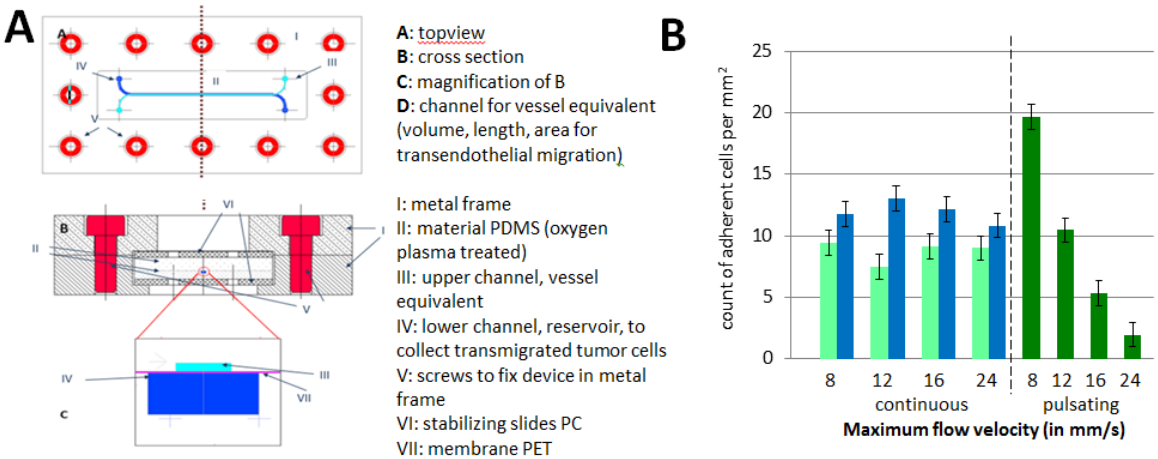

Figure 1: A: Technical drawing and measurements of the novel microfluidic device. Channel sizes: Vessel equivalent: 500 µm x 100 µm x 6.1 cm; Reservoir: 1mm x 500 µm x 6.1 cm; Membrane properties: Pore size 5 µm, pore density $6x10^4$ cm^{-2}, thickness 15 µm. **B:** Count of different tumor cells adherent to the endothelial monolayer within the vessel equivalent [4].

4. Conclusions

With our work, we introduce a novel microfluidic device overcoming problems found with other devices described in the literature. The successful functionality tests indicate that the device can be used for the in vitro research on cell extravasation. By adding adhesion inhibitors or homing factors to the system, the impact of these chemokines onto the adhesion rate and transendothelial migration could be evaluated.

Highlights

- The MW of P3HB obtained under oxygen limitation was as high as 25,000 kDa.
- MW of P3HB increased by decreasing the OTR_{max} of the culture.
- *A. vinelandii phbZ*$^-$ strain accumulated up to 93 % of intracellular P3HB.

1. Introduction

Poly-3-hydroxybutyrate (P3HB) is a biopolymer of the polyhydroxyalkanoate family; this bioplastic is produced in the form of intracellular inclusions as a carbon and energy reserve by the bacterium *Azotobacter vinelandii* [1]. P3HB has characteristics similar to those of plastics derived from the petrochemical industry [2]. Its use has been focused on the biomedicine field, because it is also a totally biodegradable and biocompatible polymer [3].

The thermomechanical properties and biodegradability of P3HB are determined by the molecular weight (MW) of the polymer [4]. It has been reported that the synthesis of the polymer is favored when *A. vinelandii* is cultured under oxygen limitation. In recent studies it has been found that, at low percentages of oxygen saturation (1 % DOT), high molecular weight polymers (between 3,500 and 5,500 kDa) are produced [5].

In this study, two mutant strains of *A. vinelandii*, with the ability to produce high molecular weight P3HB were cultured under microaerophilic conditions in bioreactor by using low agitation rates.

2. Methods

Strains of *A. vinelandii* (OP and *phbZ*$^-$) were grown in PY medium, which contains sucrose (20 g L^{-1}), yeast extract (3 g L^{-1}) and peptone (5 g L^{-1}). Batch cultures were carried out in a bioreactor using the OP strain as well as the *phbZ*$^-$ strain with a work volume of 2 L in Applikon 3 L bioreactors. Two agitation conditions were used (300 and 500 rpm) with a 1 vvm aeration, controlling pH to 7.2 and without control of the dissolved oxygen tension.

Recovery of P3HB was performed as described previously [5]. The molecular mass analysis was performed by gel permeation chromatography (GPC) using a Shodex K-800 column in an HPLC system (Waters 2695, USA) coupled with a refractive index detector (Waters 2414, USA). The mobile phase was chloroform at 30°C at a flow rate of 0.7 mL min^{-1}. A calibration curve was constructed with polystyrene standards as described in [5]. Samples were dissolved in chloroform at a concentration of 2-3 mg mL^{-1} and were filtered through a 0.45 µm membranes before being injected into the HPLC.

3. Results and discussion

Results of mean molecular weight (MMW) of P3HB obtained from the cultures performed at 300 and 500 rpm are presented in Figure 1. The MMW of P3HB increased significantly in the cultures carried out at OTR_{max} of 5 mmol L^{-1} h^{-1} (22-25,000 kDa) with both strains, with respect to the MMW reached in the cultures developed at 8 and 11 mmol L^{-1} h^{-1} obtaining a P3HB between 15,000-16,000 kDa (Figure 1).

The initial accumulation of P3HB in the cells was around 50 % with both strains, as the culture evolved, the accumulation of P3HB increased , reaching up to 93 % with respect to dry cell biomass for *phbZ*$^-$ strain and 89 % for the OP strain cultured at high OTR_{max} (8 and 11 mmol L^{-1} h^{-1}).

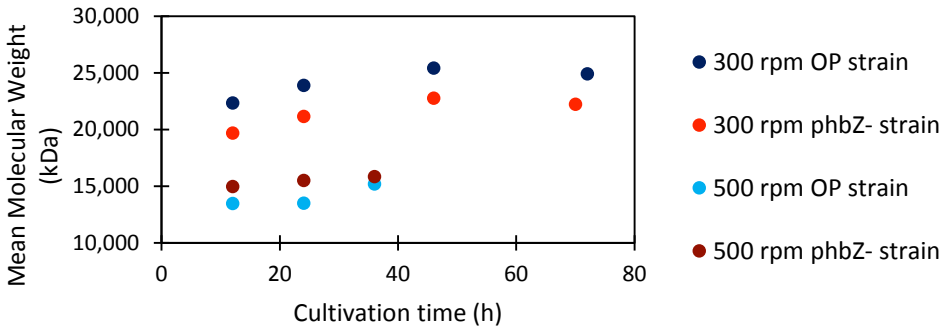

Figure 1. Mean molecular weight of P3HB produced by OP and *phbZ*$^-$ strain at 500 rpm (OTR_{max} of 8- 11 mmol L^{-1} h^{-1}) and 300 rpm (OTR_{max} of 5 mmol L^{-1} h^{-1}).

4. Conclusions

- Microaerophilic conditions promote the production of P3HB with ultra-high molecular weight in bioreactor cultures using *A. vinelandii* strains OP and *phbZ*$^-$.
- There is an inverse relationship between P3HB accumulation and the molecular weight of the polymer, finding that at high OTR_{max} both strains accumulate a high percentage of P3HB (90 %), but with a lower molecular weight (15,000 kDa) than that obtained at low OTR_{max}, where the accumulation was lower, 50 and 70 % respectively with the OP and *phbZ*$^-$ strain; however, the molecular weight reached up to 25,000 kDa with the OP strain and 22,000 kDa with the *phbZ*$^-$ strain.

Control-release of polyphenol from biodegradable sericin / chitosan/ glucomannan films

Chutimon Satirapipathkul, Nutyatip Suksawasd
Chemical Engineering Research Unit for Value Adding of Bioresource, Department of Chemical Engineering,Faculty of Engineering, Chulalongkorn University,Phyathai Road, Phatumwan, Bangkok 10330, Thailand

Ab s t r a c t

Biopolymers including chitosan, silk proteins and glucomannan have been the focal point of many research studies reporting their potential use in new biodegradable films. These films exhibit hydrophobic characteristics with controlling water and gas diffusion. They can be used to control and improve bioactive compound releases. In the present study, silk protein /chitosan/ glucomannan films were obtained by solution casting of blends of Silk protein extract (SE) from cocoons of the tropical silkworm *Antheraea mylitta* , glucomannan (GM) and chitosan (CS). Films from a SE/GM/CH blend were characterized by FTIR and SEM. The sorption properties and tensile mechanical of the films were evaluated. The films were also examined to determine the release properties of the polyphenol.

**Corresponding author: isatoshi@gifu-u.ac.jp*

Highlights

- The particle size and circularity of wild-type *Saccharomyces cerevisiae* were calculated.
- *Saccharomyces cerevisiae* could be classified as budding and non-budding by the images.
- The ratio of budding yeast caluculated from the imagies would be a benchmark in culture.

1. Introduction

Fermatation processes in food industries are one of the most important key steps to determine the quality of the food. It has been reqired to set an good parameter to moniter the fermatation processes. The growth of *Saccharomyces cerevisiae*, widely used for fermentation, which affects their shapes and sizes, depends on various conditions such as incubation time, oxygen concentration, pH, and temperature. This study aimed to evaluate the optimum growth conditions of wild-type Saccharomyces cerevisiae by using simple, easy, and rapid technique, namely Flow Particle Image Analyzer (FPIA-3000) which could provide the image of individual particle of wild-yeast in short time. In this study, the effect of incubation time, oxygen concentration and ethanol concentration in culture on the growth pattern of yeast was focused and evaluated by FPIA-3000.

2. Methods

Saccharomyces cerevisiae strain BY 4741 was grown in YPD medium (2% high polypeptone, 1% yeast extract and 2% glucose). In order to evaluate the effect of oxygen concentration on molphology of microorganisms, the wild type yeast was grown in YPD medium and incubated

under 2 different conditions described below.

Condition 1: static culture in a closed vessel with an AnaeroPack (anaerobic).

Condition2: shaking culture in an Erlenmeyer Flasks with baffles(aerobic).

After incubation, a 5.0 ml of sample was applied to FPIA to obtain image parameters of the samples. Gas chromatography was used to determined the ethanol concentration of the sample in culture (aerobic condition).

3. Results and discussion

The total number, particle size and circularity of BY 4741 in culture could be calculated from the obtained images(Figure 1). From these results, BY 4741 grew under anaerobic and aerobic condition at different incubation time showed different total number, particle size and circularity. BY 4741 under aerobic condition had a higher total population than that grown under anaerobic condition. BY 4741 could be classified as budding and non-budding by the degree of circularity calucylated from image data. The budding yeast had a low degree of circularity (< 0.95), whereas the non-budding yeast exhibited a high degree of circularity (> 0.95). The ratio of budding yeast under both conditions increased with increasing incubation time. However, BY 4741 grown under anaerobic condition showed a slower rate of budding than that grown under anaerobic condition. Concentration of ethanol was increasing rapidly just after the total number increasing in the aerobic conditions. The FPIA-3000 is an appropriate technique which can also be applied to monitor the growth pattern of wild-yeast under various growth conditions.

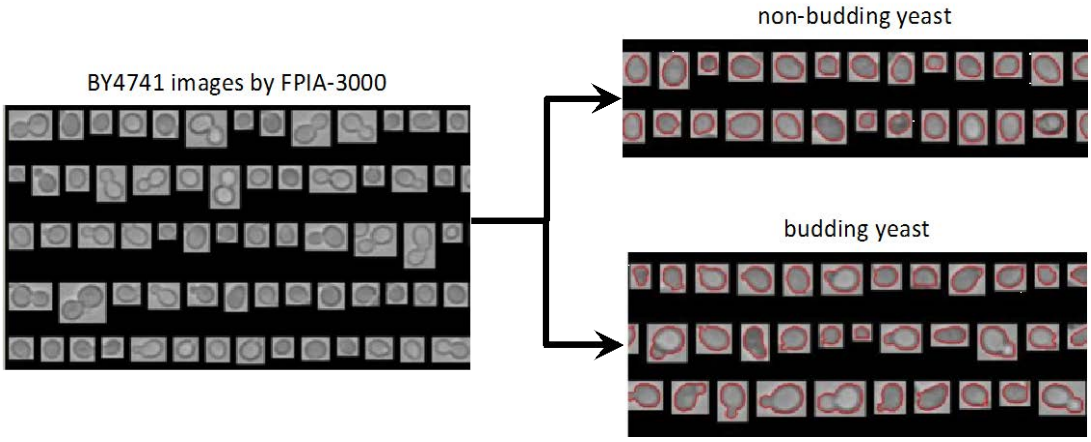

Figure 1. Morphology analysis of *Saccharomyces cerevisiae* strain BY 4741.

4. Conclusions

The particle size and circularity of *Saccharomyces cerevisiae* were calculated. *Saccharomyces cerevisiae* could be classified as budding and non-budding by the images analysis. The ratio of budding yeast caluculated from the imagies would be a benchmark in culture.

Highlights

- Sericin induces the proliferation of the cells under glucose-limitation condition.
- Sericin improves cell survival under glucose-limitation condition.
- Glucose-limitation increases monoclonal antibody productivity.
- Sericin further increases antibody productivity of the cells under glucose-limitation.

1. Introduction

In recent years, biologics production is increasing. Among the biologics, protein pharmaceuticals such as erythropoietin and antibodies are produced by mammalian cell culture. For the productions, expensive equipment and media are required and so the cost is too expensive.

In this study, we focused on cellular glucose metabolism for reducing the cost of culture medium. Although carbon sources including glucose are pivotal in the cell culture, large part of carbon sources in the medium is not efficiently consumed by the cells. Most of culture media contain abundant amount of glucose and so the cells tend to consume glucose and to produce lactate. But soon glucose concentration decreases and the cells cannot get glucose adequately. Thus, at the first stage of the culture, medium contains excessive amount of glucose that induces cells consume glucose uselessly, and it results in wasteful consumption of glucose and inefficient cell culture.

In this study, to avoid consuming nutrition wastfully, medium was diluted with PBS and at day 2 or day3, condensed medium was added. Or the culture was started with lowered glucose concentration, and then fed with glucose. Further, in order to prevent the starved cells from death and to activate the cells, sericin hydrolysate obtained from silk was added into the diluted or glucose-limiting culture. Sericin hydrolysate is potent culture supplement.

2. Methods

Murine hybridoma cells producing anti-TNP monoclonal antibody were used. Commercially available serum-free medium ASF 104 (Ajinomoto, Japan) was used for dilution culture using by phosphate buffered saline (PBS). For glucose limitation culture, we used RPMI1640 medium (Wako,

Japan). RPMI medium can be purchased with and without glucose, and so we easily prepared medium containing glucose at different concentration.

Silk protein sericin hydrolysate (Wako) and pyruvate was also added to the culture. Proliferation and antibody production of the cells were measured and the culture conditions were evaluated to find optimal condition.

3. Results and discussion

Dilution of ASF104 medium by half largely decreased the maximum cell density, but antibody production was slightly decreased. Antibody concentrations were similar, indicating that the yield of antibody production per medium powder weight was doubled (Figure 1). In addition, sericin improved the viability of the starved cells.

Limitation of glucose in RPMI1640 medium affected both cell proliferation and antibody production. On the other hand, addition of sericin hydrolysate improved glucose-limitation culture. In the presence of sericin hydrolysate, glucose concentration did not affect the cell proliferation (Figure 2).

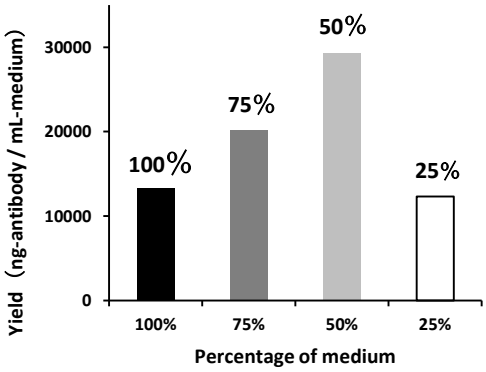

Figure 1. Antibody productivity.

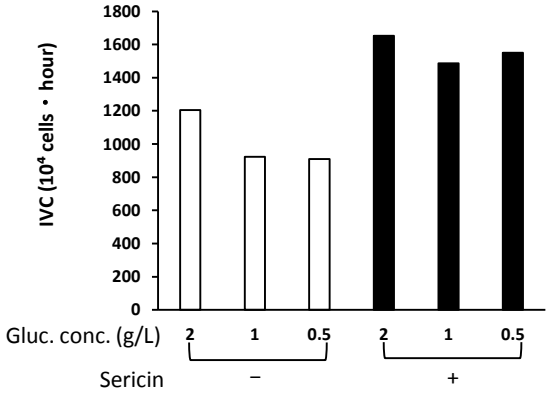

Figure 2. IVC between day 0 - 4.

4. Conclusions

Glucose- or nutrients- limitation culture are useful in cell culture. But the limitation often induce cell death and so decrease the productivity. Addition of sericin hydrolysate activates the starved cells. In this way, culture supplements such as sericin are potent tools for mammalian cell culture.

Synthesis of Cephalexin in Aqueous Two-Phase System.

Lucie Vobecka[1], Linda Ticha[1], Zdenek Slouka[1], Michal Pribyl[1]

1 University of Chemistry and Technology Prague, Technicka 3, 166 28 Prague, Czech Republic

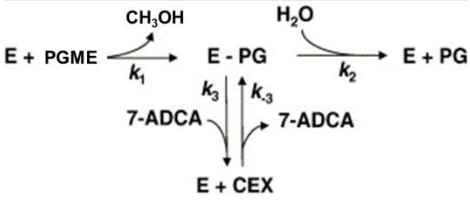
**Corresponding author: lucie.vobecka@vscht.cz*

Highlights

- Optimization of aqueous two-phase systems (ATPS) for the production of cephalexin.
- Optimal conditions for reaction kinetics (temperature, enzyme quantity)
- Extraction of cephalexin and recycling of enzyme on microscale.

1. Introduction

We focus on the possibility of efficient production of cephalexin in microfluidic devices by the enzyme penicillin acylase (E). The following simplified reaction scheme shows the mechanism of the cephalexin (CEX) synthesis:



Hydrolysis of substrate phenyl glycine methyl ester (PGME) together with consumption of product by the enzyme take place. To optimize the productivity, it is necessary to separate either the products or the enzyme from the reaction mixture to enable the enzyme recovery and prevent product disintegration. One of the possible solutions is based on the use of aqueous two-phase systems (ATPS), which are widely used in separation and purification applications. Because of high water content in both the immiscible phases, ATPS provide mild environment for proteins or even living cells in downstream processing [1].

Microreactor technologies bring important benefits if compared to classical bioreactor systems such as the reduction of transport resistances, precise control of hydrodynamic conditions, the possibility of integration of several unit operations into one device etc.

2. Methods

The first aim of these studies is to find ATPS with optimal separation efficiency, i.e. ATPS that exhibits a high difference in the partition coefficients of the enzyme and the reaction products [2]. Several ATPS based on polyethylene glycol (PEG)/phosphate are tested. The next aim is to find optimal conditions for reaction kinetics with optimal cephalexin yield, the period with maximal product yield, duration of reaction. The experiments are performed at several temperatures and

with different enzyme concentrations. Further, the extraction of cephalexin and enzyme recovery is studied. The reaction is carried out in the ATPS, then the immiscible phases are separated and the phase with enzyme content is mixed with fresh phase containing reaction substrates. Analysis of substrate and product concentrations are carried out by HPLC analysis using Agilent 1260 Infinity Series device equipped with UV-VIS detector and Waters C18 column (WAT066224). Finally, the whole system is transferred into the microfluidic environment and the process is carried out in a continuous manner with the enzyme recycle.

3. Results and discussion

We found that ATPS consisting of 15 wt % of PEG 4000, 12 wt % of phosphates, 73 wt % of water (pH = 7.0 after dissolution) provides optimal separation of cephalexin which prefers the top PEG phase unlike the free enzyme accumulated in the bottom salty phase [2].

Experiments with reaction kinetics show that higher quantity of enzyme leads to significant increase in the reaction speed but unfortunately decreases stability of synthesized cephalexin. In the same manner, higher temperature increases reaction speed, however, it decreases cephalexin stability. At the end, we found conditions with optimal reaction speed and cephalexin stability.

Figure 1 shows the cephalexin concentration synthesized and extracted to the top phase in each step of enzyme recovery. It is seen that synthesized amount of cephalexin slightly decreases in each step of enzyme recycling, but the enzyme seems to have almost the same activity also after recovery.

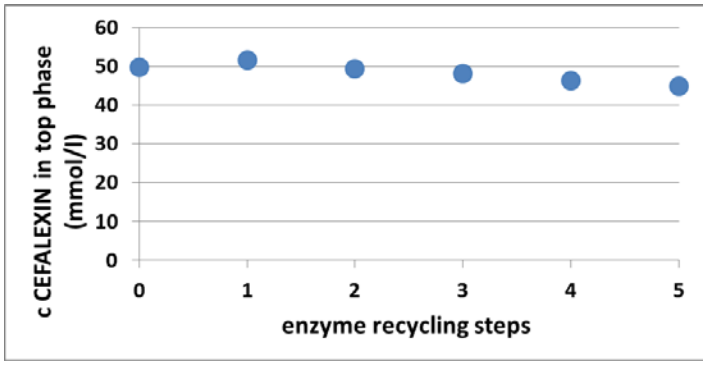


Figure 1. Concentration of Cephalexin in the top phase in the dependence on the number of cycles of the enzyme use.

4. Conclusions

We optimized conditions under which cefalexin is separated from the reaction mixture with the use of aqueous two-phase system. We experimentally determined the composition of the ATPS and also the reaction conditions at which we reach highest cefalexin yield along with reasonable time duration. We further showed that enzyme retains it stability and can be recycled n the given process. This process was adopted to the microfluidic format which allows integration of several processes and very good control of the experimental conditions.

Kinetic studies of anaerobic digestion of chicken manure with sawdust and wheat straw after fungal pre-treatmet

Andreja Goršek*, Darja Pečar

University of Maribor, Faculty of Chemistry and Chemical Engineering
Smetanova 17, SI-2000 Maribor, Slovenia

**Corresponding author: andreja.gorsek@um.si*

Highlights

- The pre-treatment was conducted with two white-rot wood decay fungi.
- Anaerobic fermentations of chicken manure with co-substrates were conducted.
- First-order and modified Gompertz kinetic models were employed.
- Kinetic parameters of the fermentation were determined.

1. Introduction

Bioenergy is an alternative, cheap and sustainable source of energy compared to non-renewable energy sources such as fossil fuels [1]. Anaerobic fermentation is one of the most promising renewable energy production processes. However, the feasibility of anaerobic fermentation depends on substrate characteristics, operating conditions and fermenter design.

With increases in poultry breeding, huge amounts of manure are produced. Anaerobic fermentation is the most suitable process to deal with this material [2]. Crops and crop residues which mainly consist of lignin, cellulose and hemicellulose are used as co-substrates in these processes. Lignocellulosic biomass pre-treatment is usually necessary to reduce structural obstacles by breaking the polymer chains of lignin and making cellulose and hemicellulose more accessible for microbial attack. Pre-treatment methods are divided into physical, chemical, and biological. Biological ones are based on fungal, microbial and enzymatic pre-treatment.

Fungal pre-treatment is usually conducted using white-rot, brown-rot and soft-rot fungi. White-rot fungi produce lignolytic enzymes (laccase and peroxidases) and they are known as the most efficient in delignification processes [1].

In this study, for wheat straw pre-treatment white-rot fungi, *Pleurotus ostreatus* (WPO) and *Trametes versicolor* (WTV), were used. Three different mass ratios (80:20, 60:40, 50:50) of chicken manure with saw dust (CMS) to pre-treated (WPO, WTV) and ordinary wheat straw (OWS) were used as substrates in anaerobic fermentations. During the fermentations, the volume of produced biogas and CH_4 concentration were measured. The main goal of our study was to determine the kinetic parameters of CH_4 production during anaerobic fermentation. First-order and modified Gompertz kinetic models were fitted to the experimental data.

2. Methods

The pre-treatment was conducted with white-rot wood decay fungi. All fermentations were carried out in thermostated batch fermenters at different temperatures, ϑ = (35, 40 and 45) ºC. The single experiment was started by loading the reactor with 5 g of pre-treated substrate, 5 g of inoculum (dry mass) and 20 mL of water. Then the fermenters were purged for 2 min with argon to remove all air and to establish anaerobic conditions. The fermenters were thermostated at the desired temperature for 21 d. During the

fermentation, the volume of the biogas produced was measured. It was determined by the water displacement method. The methane concentration was calculated using a Shimadzu GC-2010 gas chromatograph coupled to a thermal conductivity detector TCD. The kinetic data obtained from separate anaerobic digestions were checked for the fitness of first-order kinetics and modified Gompertz equation.

3. Results and discussion

First-order and Gompertz kinetic models were used to simulate anaerobic fermentation of a chicken manure with sawdust with pre-treated and ordinary wheat straw at three mass ratios of used substrates. Activation energies and pre-exponential factors for CH_4 production during the anaerobic fermentation were determined from the reaction rate constants obtained from first-order kinetic model at different temperatures (Table 1).

Table 1. Activation energies and pre-exponential factors for CH_4 production during the anaerobic fermentation.

SUBSTRATE	MASS RATIO	E_a / kJ mol^{-1}	k_0 / d^{-1}
CMS:OWS	80:20	110.8 ± 19.6	$(8.2 \pm 1.5) \cdot 10^{17}$
	60:40	88.3 ± 12.5	$(1.5 \pm 0.2) \cdot 10^{14}$
	50:50	72.1 ± 15.9	$(3.2 \pm 0.7) \cdot 10^{11}$
CMS:WPO	80:20	103.8 ± 38.7	$(5.5 \pm 2.1) \cdot 10^{16}$
	60:40	88.8 ± 19.6	$(1.9 \pm 0.4) \cdot 10^{14}$
	50:50	89.6 ± 14.1	$(2.7 \pm 0.4) \cdot 10^{14}$
CMS:WTV	80:20	109.9 ± 22.9	$(6.9 \pm 1.5) \cdot 10^{17}$
	60:40	79.0 ± 11.6	$(4.7 \pm 0.7) \cdot 10^{12}$
	50:50	65.8 ± 18.7	$(2.8 \pm 0.8) \cdot 10^{10}$

We found out from the results of model accuracies, that both models properly describe the experimental data, but it is more suitable to describe CH_4 production with the first-order kinetic model, rather than with Gompertz kinetic model. The lowest R^2 value for the first-order kinetic model was 0.9780, and for the Gompertz model, 0.9713. The difference can be explained by the instant acceleration of the CH_4 concentration at the very beginning of fermentation. Thus, the profiles of CH_4 concentration are not the typical sigmoidal curves usually described by the Gompertz kinetic model. Generally, maximum CH_4 concentrations determined with Gompertz kinetic model are lower than those determined with the first-order kinetic model.

4. Conclusions

During the fermentation of chicken manure, the amount of biogas produced and the CH_4 concentrations were measured. The volume of biogas produced was slightly lower when ordinary wheat straw was used as co-substrate, compared to the pre-treated wheat straw. The kinetic parameters of CH_4 production during anaerobic fermentation were determined. A comparison between the experimental data and the data calculated by first-order kinetic model and modified Gompertz kinetic model was made. Both models describe the experimental data very well. The kinetic parameters do not significantly differ regarding the substrate; only the activation energies are slightly higher for the pre-treated wheat straw compared to ordinary straw.

Highlights

- ID of physical adsorption immobilized derivative was 28.55%.
- ID of covalent binding immobilized derivative was 34.47%.
- Corn cob powder is a successful immobilization carrier for lipase.

1. Introduction

Lipases are glycerol ester hydrolases (EC 3.1.1.3) and are widely employed as biocatalysts in Enzymatic Biotechnology. These enzymes are commonly used for oils and fats modification in the immobilized form. When immobilized, they are easily recovered from the reaction medium. A great variety of methods are used to immobilize enzymes, of which physical adsorption and covalent binding are the most important [1]. Therefore, the objective of this work was to immobilize *Rhizopus oryzae* lipase in corn cob powder in order to apply the immobilized derivative to the synthesis of dietary triglycerides by enzymatic acidolysis of grape seed oil.

2. Methods

2.1 Immobilization of Rhizopus oryzae *lipase*

Immobilization by physical adsorption (PA) was carried out according to Costa (2015) [2]. Immobilization by covalent binding (CB) was carried out according to Bassan et al. (2016) [3].

2.2 Enzymatic acidolysis of grape seed oil

The immobilized derivatives (10% w/w) were used in acidolysis of grape seed oil with capric acid (C10:0) at molar ratio 1:3 in batch reactor (6 x 3 cm) for 24 h (45 °C, 800 rpm). The product was analysed by CG – FID. The incorporation degree (ID, %) was calculated according to equation 1:

$$ID(\%) = \left(\frac{MFA}{TFA}\right) * 100 \quad \text{(Equation 1)}$$

MFA: moles of medium fatty acids (C10:0); TFA: moles of total fatty acids.

3. Results and discussion

The results of ID (%) are presented in Table 1. The ID obtained for the immobilized derivative by PA was 28.55%. Costa et al. (2018) [4] obtained an ID of 34.8%, using a different immobilization carrier

(Eupergit) for olive oil and capric acid acidolysis. The lower ID obtained in this work can be justified by the difference in the carrier material and the substrate used.

Table 1. ID (%) of the fatty acid (C10:0) from *Rhizopus oryzae* lipase immobilized derivative

Fatty acid	Fatty acids (%)		Moles	
	PA	CB	PA	CB
C10:0	19.83	24.52	0.12	0.14
C16:0	8.03	5.68	0.03	0.02
C18:0	2.75	1.95	0.01	0.01
C18:1n9C	20.45	19.95	0.07	0.07
C18:2n6C	45.64	44.63	0.16	0.16
C18:3n3	3.31	3.28	0.01	0.01
Sum	100.00	100.00	0.40	0.41
ID (%)			**28.55**	**34.47**

For the CB immobilized biocatalyst, the ID was 34.47%. Considering that the maximum ID for 1,3 specific lipase dietary triglyceride synthesis is 66.66%, the obtained ID was satisfactory. According to Bassan et al. (2018) [5], who performed the enzymatic acidolysis of grape seed oil using a commercially immobilized lipase (Lipozyme RM IM), the ID was of 34.53%. Our results are similar to that obtained by Bassan et al., which shows the potential of the corn cob powder as a carrier for lipase immobilization.

4. Conclusions

The use of corn cob powder as a carrier for immobilization of lipases presents great potential for the application in dietary triglycerides synthesis.

Highlights

- Cell destruction is affected by day/night cycles and so TAG availability for downstream
- TAG recovery by wet-extraction was optimized with a Box-Behnken experimental design
- Optimal large scale TAG production relies on a key harvesting time during Day/Night cycles

1. Introduction

Coupling microalgae cultures at photobioreactor with cell destruction and wet-extraction has shown to be energy-efficient for recovering lipids[1]. Also, Nannochloropsis gaditana is capable to produce up to 38% triacylglycerol (TAG) during nitrogen depletion[2]. However, most of these cultures have been done only under continuous light, which means the cells have a constant energy supply for lipid synthesis. Large scale production brings to scene the challenges of maintaining high TAG yields in real day/night cycles (D/N). Notably, not all the produced lipids can be extracted mainly because of losses in downstream.

2. Methods

This approach involves four stages of analysis: I) Tracing the physiological changes and cell destruction during the culture at Subitec Flat panel 200L photobiorectors (One reactor -S2- was filled with ASW+CONWAY(3N3P) medium as a control; the second one –S1- was depleted in nitrogen source to trigger lipid accumulation), II) Bead-milling pre-optimization, III) A Box-Behnken DoE for wet-extraction optimization using a Rousselet centrifugal extractor and IV) Direct Impact of physiological changes on the final TAG recovery. The downstream process optimization has considered bead-milling duration, biomass concentration and solvent consumption.

3. Results and discussion

For a D/N of 15h/9h, it was shown that cell destruction at the end of the night is the most efficient (Figure 1). On the other hand it seems that TAG accumulation reaches its maximal level at the end of the day. Such a result may suggest an optimal harvesting time affecting the entire process which will be discussed. For cells coming from S2 (full media) it was only needed 2 or three destruction

cycles for achieving ~80% destruction while for cells coming from depleted media, it was required 4 cycles. This reveals the influence of "stress by nutrients" over lipid availability.

The Box-Behnken experimental design, also reveals the optimal conditions to get the maximal efficiency for TAG recovery.

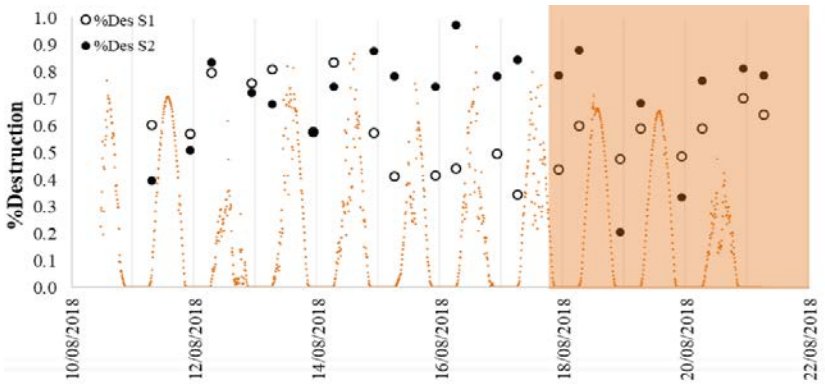

Figure 1. Destruction rate comparison for *Nannochloropsis gaditana* during day/night cycles at two different growth conditions.

4. Conclusions

At the present day, no work had considered the direct effect of the D/N over the final TAG recovery. In the present work, a global approach is proposed to elucidate how D/N affects the cell destruction during nitrogen starvation coupled with the subsequent wet-extraction. Further studies will aim at proposing an optimal coupling between the production and downstream processing stage. This will take into account the dynamic of lipid production/consumption during D/N and changes in cell destruction during nitrogen starvation.

Highlights

- Treatment of groundwater contaminated by a mix of chlorinated hydrocarbons
- Isolation of biodegrading aerobic strains
- Trial of treatment of the remaining pollutants under anaerobic conditions
- Monitoring of the treatment

1. Introduction

Halogenated solvent-contaminated sites are a worldwide problem in industrialized countries. Chlorinated ethenes are among the most diffused pollutants in groundwaters; they are prevalently degraded by reductive dechlorination reactions, which take place under anaerobic conditions. In some cases, groundwater conditions does not support anaerobic respiration processes, because of redox conditions and due to the presence of not negligible oxygen concentrations. The present work illustrates a pilot trial of anaerobic treatment in a chlorinated compounds polluted aerobic groundwater, by the use of slow release amendments for the stimulation and growth of the anaerobic microflora after the total consumption of the oxygen present in the water.

2. Methods

Microcosms set up (aerobic conditions). 1L of groundwater was filtered (0,22 μm) and the particulate was used to inoculate a number of aerobic cultures (30 ml each) set up with the same sterilized groundwater additioned of ammonium chloride, potassium phosphate, sodium chloride, oligoelements and vitamins (pH 6,7).

Chemical analysis. 1,2-dichloroethane concentration was followed by Headspace GC analysis on a DB-5 Megabore column. Chemical analysis during monitoring of the pilot test were conducted by a certified laboratory.

qPCR experiments. The DNA extracted from groundwaters was amplified in qPCR experiments using the primers for *Dehalococcoides sp.* (Cocc728f aaggcggttttctaggttgtcac - Cocc944r cttcatgcatgtcaaat) or coding for dehalogenases bvcA, vcrA and tceA (bvc925F aaaagcacttggctatcaaggac – bvc1017R ccaaaagcaccaccaggtc, vcr1022F cgggcggatgcactatttt - vcr1093R cgggcggatgcactatttt, tceA1270F atccagattatgaccctggtgaa – tceA1336R gcggcatatattagggcatctt).

3. Results and discussion

The initial aerobic conditions of the groundwater showed the presence of bacteria able to degrade 1,2-dichloroethane, present in concentrations of 1 - 10 ppm. The degrading species was isolated and identified as *Ancylobacter sp.*; some species, such as *A. dichloromethanicus*, are known to metabolize 1,2-dichloromethane, in addition to other carbon sources (chlorinates alcohols, methanol, formate, succinate and formaldehyde). The species showed a good activity and resistance to 1,2-DCA, up to 800 ppm (*Fig. 2*). After a few years, the analysis of groundwater showed the almost total consumption of this pollutant, while chlorinated ethenes remained non-degraded. The injection of the selected amendment resulted in the change of redox conditions and in the consumption of the oxygen present in almost all the analyzed wells. Monitoring of the chlorinated ethenes showed the initial reduction of concentrations of perchloro- and trichloroethene (PCE – TCE) and the slight start in the increase of 1,2-cis dichloroethene (1,2-cisDCE) as the first product of the metabolic chain a few months after injection (*Fig. 2*). qPCR experiments were set up to identify the presence of species belonging to *Dehalococcoides* group and also for the confirmation of the presence of enzymes involved in PCE – TCE degradation.

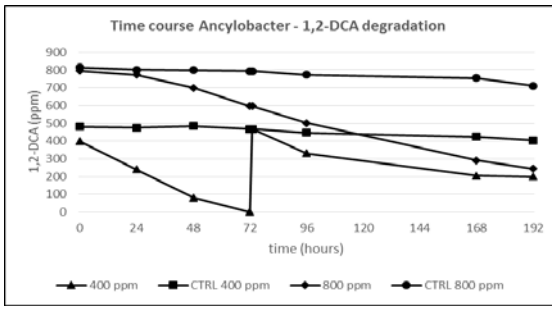

Figure 1. Time course of *Ancylobacter sp*. 1,2-DCA degradation; T=72: 400 ppm spike 1,2-DCA

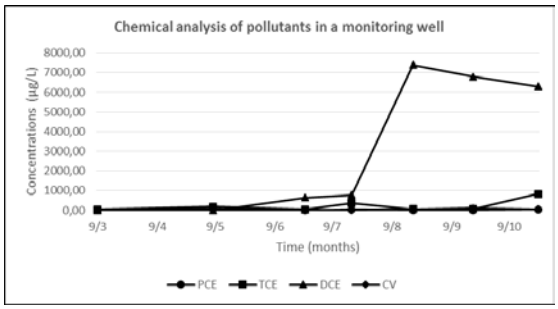

Figure 2. Chemical analysis of the chlorinated hydrocarbons after the injection of the slow-release amendment

4. Conclusions

The preliminary results of this work show the potential, for chlorinated hydrocarbons remediation, to follow natural attenuation in the groundwater conditions if the suitable microbes are present. In a second phase, it is possible to change redox/oxygen conditions shifting to anaerobic conditions and stimulating anaerobic degrading bacteria with appropriate amendments. This protocol is particularly useful in the case of mixed contamination of different chlorinated compounds.

Highlights

- Agitation mode and microcarrier distribution within the bioreactor have an important impact on MSC culture.
- Collisions between microcarriers are detrimental to MSC viability

1. Introduction

Mesenchymal stem cells extracted from the Wharton's jelly of human umbilical cords (hWJ-MSC) are of increasing interest for cell therapies due to their reduced immunogenicity, high expansion capabilities, fast growth kinetics and various growth factors synthesis capabilities. To address the problem of cell confluence on microcarriers during their culture in stirred bioreactors, it was previously shown that the addition of fresh microcarriers could maintain the cell growth and could allow reaching higher cell densities than without microcarriers feeding [1]. However, the resulting increase in the bead shocks frequency could also negatively impact cell quantity and quality. Until now, no quantitative study describing the impact of bead interactions on MSC death was reported in the literature. It is crucial to determine the respective influence of microcarrier feed strategy and microcarrier mixing characteristics on cell viability and to propose robust culture conditions of mixing and microcarrier concentrations. The objective of this study was to demonstrate the importance of the agitation mode on the expansion and the ability of cells to migrate to new fresh carriers. It appears that agitation has an important impact on the cell death and more precisely on the cell lysis in microcarrier cell cultures due to the lack of protective cell wall, high cell size and the lack of individual cell mobility [3].

2. Methods

hWJ-MSC were cultivated on Cytodex-1 microcarrier in HPL-supplemented medium, with an initial concentration of 7000 cells/cm^2. Previous studies (Loubière et al. 2018) showed that the best choice of microcarrier for hWJ-MSC adherence and expansion, in dynamic conditions, was Cytodex-1 [2]. Two types of culture systems were evaluated, shaken flaks (orbital agitation) and spinner vessels (mechanical agitation), agitated below or above particle just-suspended agitation rate (N_{js}). Glucose, glutamine, ammonium, lactate and lactate dehydrogenase concentrations were monitored every day. Moreover, cells were counted from the post-processing of DAPI-stained cells

pictures [2]. Using this method, a strategy of microcarrier feeding at an appropriate time during the culture was established to maintain a constant target value of cells per microcarrier [4].

3. Results and discussion

First, it was shown that hWJ-MSC bead-to-bead transfer appeared to be a potential way to avoid or delay cell and microcarrier aggregation, allowing an increase of the maximal total cell number in comparison with a culture with only medium feed addition. This assessment was applied to all culture systems: shaken flasks or spinner vessels. In the meantime, better performance of bead-to-bead transfer could be obtained by controlling N_{js} and the mode of agitation. The results also showed that the addition of fresh microcarriers could have a significant negative impact on cell viability, as revealed by the dead cell staining and the strong increase in LDH concentration in the liquid phase (Figure 1). However, as indicated by LDH concentration measurements, this was particularly the case in orbitally shaken flasks and below N_{js}. For these conditions, a concentration of microcarriers was observed in the lower part of the bioreactor, promoting more frequent collisions.

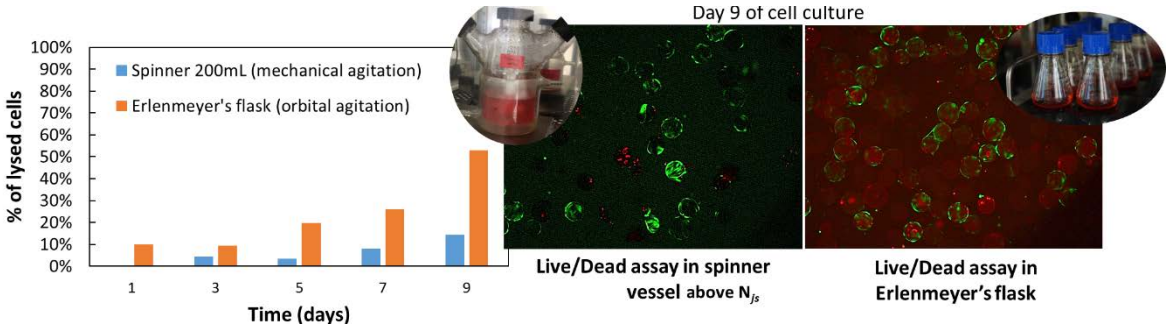

Figure 1. Impact of the cell culture system on viability and cell lysis.

Consequently, these results suggest that the collisional energy dissipation was more detrimental to cell viability than the hydromechanical stress arising from mechanical agitation. Hence, a compromise must be found between a limited concentration in microcarriers and the ability of cells to migrate towards other microcarriers, promoted by contact between them.

4. Conclusions

To conclude, this study underlined the importance of the just-suspended state determination and particle distribution in the bioreactor on the hWJ-MSC performances, notably during the bead-to-bead transfer phenomena.

Highlights

- Accelerated biological degradation of PET-like textile fibres.
- Anaerobic and aerobic degradation of PET-like fibres.
- Mathematical process models for anaerobic and aerobic degradation.

1. Introduction

Textile polyester wastes are difficult to recycle due to their composition and a large number of different dyes and additives. In 2012 about 1,5 Mio. tons of textile wastes were recycled worldwide, while 4,3 Mio. tons were burned or stored in landfills [1]. Biodegradable synthetic fiber materials can potentially be recycled to generate biogas or be disposed via a composting process. Unfortunately, due to their slow degradation rates, processing them with common biogas- or composting methods would be unprofitable [2].

In this study, the influence of different process parameters on the degradation rate of a PET-like polyester were investigated. Furthermore, enzymatic and hydrothermal pretreatment methods were employed to improve the biodegradability of this polyester. Kinetic process models were developed to systematically plan and evaluate the experiments.

2. Methods

Alkaline and neutral thermal hydrolysis was performed in water or potassium hydroxide solution at different temperatures ranging from 100 to 150 °C in an airtight container. The degree of hydrolysis was determined by measuring the loss of solid material and by measuring the amount of released monomers via HPLC. For the evaluation of anaerobic and aerobic degradation carbon balances were applied to compare different process strategies. For composting, the evolved carbon dioxide was measured gravimetrically in accordance with ISO 14855-2 by absorbing it with soda lime. For anaerobic digestion, methane and carbon dioxide emissions from a miniature biogas plant were measured volumetrically. For future scale up, experiments were performed with composting and fermentation vessels of different volume.

Kinetic models were developed for aerobic and anaerobic degradation as well as neutral hydrolysis. Model parameters and initial states were adapted based on experiments earlier in this study. Based on model behavior process strategies for further experimentation were chosen.

3. Results and discussion

Experiments on aerobic and anaerobic degradation of biodegradable PET-like polyester with different process strategies were performed. The kinetic models have been expanded to reflect the influence of pH and temperature on the degradation process. It has been shown for both the aerobic and anaerobic model, that they can be adapted to reflect the experimental results. For the anaerobic process model-based predictions have been made for different process strategies. The strategy which promised the highest degree of degradation within 31 days was chosen for an additional experiment. As seen in figure 1 the kinetic model could successfully predict an increase of the degree of degradation within 31 days.

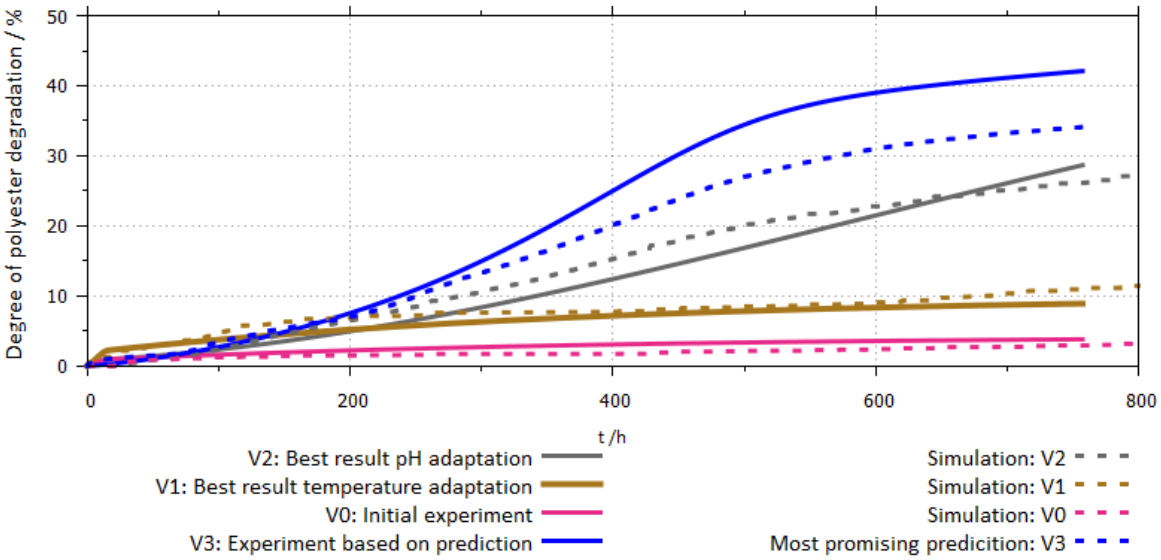

Figure 1. Model based improvement for the anaerobic digestion process of an biodegradable PET-like Polyester. Parameters for the anaerobic digestion model were chosen based on experiments V0, V1 and V2. Different predictions for new process strategies were made via the parametrized model. A new experiment V3 was performed based on the most promising prediction.

For enzymatic and thermal hydrolytic pre-treatment experiments for different pretreatment strategies were performed. The kinetic model for polyester hydrolysis was successfully adapted to reflect the influence of temperature and time on the degree of the resulting hydrolysis.

4. Conclusions

It has been shown, that aerobic and anaerobic degradation of a biodegradable polyester could be accelerated by improved process strategies and enzymatic or thermal hydrolytic pretreatment of the polyester. A kinetic model has been successfully applied to determine an improved strategy for the anaerobic degradation process.

Highlights

- Water-soluble mercaptocarboxylated silver nanoparticles were prepared.
- The silver nanoparticles have antibacterial activity.
- O/W Pickering emulsions using the silver nanoparticles were successfully prepared.

1. Introduction

In recent years, nanomaterials such as metal and semiconductor nanoparticles have been one of the most studied topics in chemistry and physics. Water-soluble nanoparticles have received considerable interest due to the potential environmental and economic benefits of functional "nano" inks and of carrying out catalysis in aqueous systems. Silver is known as an excellent antimicrobial agent and has been well used as disinfectant and microbiocide from old times. Antibacterial activity of silver is enhanced in nano scale and is dependent upon the size of silver particles [1]. Pickering emulsions are emulsions stabilized by solid particles adsorbed at liquid-liquid interface. They are expected as food, pharmaceutical, and cosmetic media because this emulsion system can reduce the use of artificial surfactant. Pickering emulsions stabilized by nanoparticles have been also reported [2]. In this study, preparation of water-soluble silver nanoparticles and their antibacterial properties are investigated. Preparation of Pickering emulsions using the silver nanoparticles is also investigated.

2. Methods

Silver nanoparticles (AgNPs) were prepared by phase transfer method [3]. Using silver nitrate as a model silver salt silver ions were transferred to the organic phase by tetrakis(decyl) ammonium bromide (TDAB) as a phase transfer agent and reduced by sodium borohydride in the presence of 11-mercaptoundecanoic acid (MUA) as a stabilizing agent. The UV-vis spectrum of the prepared AgNPs aqueous solution was measured and the nano-geometry of the AgNPs was characterized by Field Emission (FE)-SEM. Antibacterial activity against *Escherichia coli* (NBRC3301) and *Bacillus subtilis* (NBRC3134) was evaluated. Emulsions were prepared by adding toluene to the AgNPs aqueous phase containing NaCl and stirring them for 2 minutes with a homogenizer.

3. Results and discussion

The prepared AgNPs were well dispersed in aqueous solutions due to the carboxylic group of the stabilizing agent MUA. From UV-vis spectrum measurement the maximum absorption wavelength of the prepared AgNPs was 419 nm (Figure 1). It is known that the maximum absorption wavelength of the UV-vis spectrum of AgNPs exists near 420 nm due to the localized surface plasmon resonance (SPR) of the nanoparticles [4]. FE-SEM measurement showed the diameter of ca. 10 nm of the prepared AgNPs. The AgNPs exhibited excellent antimicrobial activity toward gram-negative *Escherichia coli* and gram-positive *Bacillus subtilis* (Figure 2).

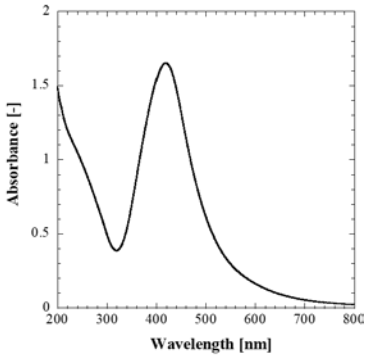

Figure 1. UV spectrum of the mercaptocarboxylated silver nanoparticle aqueous solution.

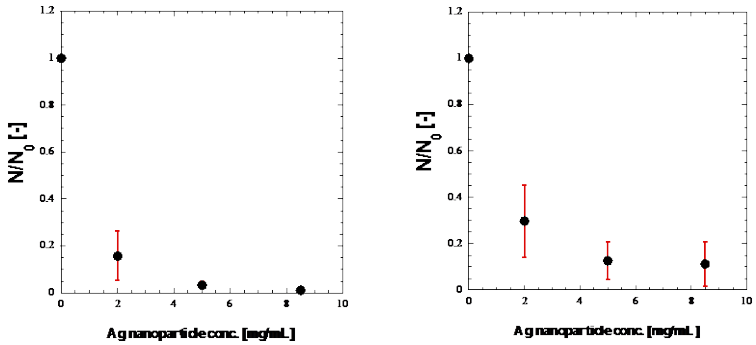

Figure 2. Effect of silver nanoparticle concentration on the growth of target bacteria (a) *E. coli* and (b) *B. subtilis* .

Toluene solution was added to the AgNPs aqueous solution containing NaCl, and mixed by using a homogenizer for 2 min. After mixing the emulsion phase was formed. Emulsions with a diameter of ca. 2 mm were successfully prepared. Fluorescence microscopy of the emulsions with hydrophobic fluorescence dye Nile Red revealed the formation of oil-in-water (O/W) emulsions.

4.Conclusions

Water-soluble AgNPs were prepared by the phase transfer method, and their properties were characterized. The silver nanoparticles have antibacterial activity toward *Escherichia coli* and *Bacillus subtilis.* O/W Pickering emlusions were prepared using the silver nanoparticles.

Cultivation of highly aerobic biomass in an airlift bioreactor with helical flow promoter

Riikka Särkelä[1*], Tero Eerikäinen[1]

1 Aalto University, School of Chemical Engineering, Department of Bioproducts and Biosystems, P.O. Box 16100, 00076 Aalto, Finland

**Corresponding author: riikka.sarkela@aalto.fi*

Highlights

- Airlift reactor with helical flow promoter was studied with aerobic biomass cultivation
- Comparative study was done in similar size stirred tank reactor
- Testing included *e.g.* biomass production rate, final concentration, energy consumption

1. Introduction

Efficient oxygen mass transfer is often a bottleneck factor in aerobic bioprocesses. In addition, poor mixing might cause gradients in the process parameters, such as pH or substrate concentration, which further can cause a stress factor for the cultivated organism. Insufficient oxygen mass transfer and mixing can lead to lower biomass accumulation as well as lower product yield or it can cause the formation of unwanted byproducts. In order to simultaneously improve both, oxygen mass transfer and mixing, with moderate energy consumption, a draft tube sparged airlift bioreactor was occupied with a helical flow promoter in the downcomer zone of the bioreactor (helix-ALR). Besides working as a flow promoter, the helix was used for extra aeration.

2. Methods

The helix-ALR (V=116 L) was tested with aerobic *Pichia pastoris* cultivation to examine its performance with highly aerobic fermentation. Insufficient oxygen supply is unwanted in *P.pastoris* cultivation as it leads to ethanol formation instead of biomass accumulation. The helix in the downcomer zone of the airlift bioreactor was used for the extra aeration in order to improve reactor performance. The aim was to achieve high cell concentration by avoiding high gradients in pH and substrate concentration as well as avoiding oxygen depletion in the bioreactor for the whole cultivation period.

Similar scale conventional stirred tank reactor (V=100 L) was used as a reference for the helix-ALR cultivation. Reactor performances were evaluated in terms of final biomass concentration, biomass yield on carbon source, biomass accumulation rate, glucose consumption rate, total

process time and total energy consumption. Model describing the biomass growth in the helix-ALR was setup.

3. Results and discussion

Previous results with helix-ALR are promising; its energy requirement for volumetric oxygen mass transfer rate of 0.1 s^{-1} was less than 20% of the power requirement of a similar scale conventional stirred tank reactor [1]. In addition, helix-ALR showed good mixing capacity and it was more related to dispersion than to faster liquid circulation, as it is in only draft tube sparged airlift reactor. The mixing at the reactor level was mainly dependent on the sparger aeration rate, but the D-helix aeration had a minor impact on the mixing time as well. Circulation time was mainly dependent on the D-helix aeration rate. Faster circulation time did not mean faster mixing; D-helix aeration extended circulation time, but because of improved dispersion, mixing time was shorter. Based on the results of the previous studies, the reactor performance was enhanced by dividing the aeration with the sparger and the helical flow promoter in the downcomer zone.

4. Conclusions

In an airlift bioreactor with helical flow promoter, mixing and oxygen mass transfer are possible to optimized at the same time, whereas in stirred tank reactors it is difficult [3]. This offered an effective alternative to conventional stirred tank reactor to be used to cultivate highly aerobic organisms, which can reach high cell densities.

Highlights

- The strain *Kluyveromyces marxianus* DSM 5422 was selected among eight yeast strains.
- Cells were immobilised on alumina beads and Raschig rings of plastic, glass and Tygon.
- Cheese whey permeate (130 g/L lactose) was efficiently fermented yielding 60 g/L ethanol.
- Glass Raschig rings and alumina beads allowed a stable performance during 1,000 h.

1. Introduction

Cheese whey is a liquid by-product of milk coagulation during cheese production. It is characterized by a high organic load with elevated BOD and COD values, which makes this waste a potential source of pollution if it is incorrectly disposed of in water bodies [1].

Cheese whey can be used in ethanol fermentation processes, thanks to its lactose content. However, not all yeast strains are efficient to deal with lactose concentrations above 100 g/L. In addition, it is essential to improve and reduce the costs of fermentation processes, a fact that can be partially achieved by cell immobilization.

2. Methods

The raw material used for fermentations was cheese whey permeate obtained after ultrafiltration of the whey resulting from the production of a mixed cheese of sheep and cow milk, and it was provided by Quesería Entrepinares SAU (Valladolid, Spain). Its lactose content was about 130 g/L with a protein content of 34 g/L.

Eight yeast strains [*Kluyveromyces marxianus* DSM 5418, DSM 5422, DSM 7239 and DSM 70799; *Saccharomyces cerevisiae* CECT 13152, CECT 1383, Ethanol Red and Hércules (Lessafre)] were compared for their ethanol production from cheese whey permeate without nutrient addition. In the case of *S. cerevisae* strains, an enzymatic hydrolysis of lactose before fermentation was necessary. Fermentations were performed in flasks plugged with foam stoppers, at 35°C and 150 rpm. The most efficient strain was selected for further experiments.

Four inorganic materials were employed to immobilize the cells of the selected yeast strain: alumina beads and Raschig rings of plastic, glass and Tygon (5–5.5 mm length). Approximately, 10 g of every support were added to 50 mL of cheese whey permeate and 3.7% (v/v) of the selected yeast cells. Every 48-72 h, fresh whey replaced the exhausted medium.

3. Results and discussion

The strain *K. marxianus* DSM 5422 obtained the best performace, with a production of 60.0 g/L ethanol and 100% lactose consumption in 44 h.

Regarding immobilisation experiments, during the first six fermentation batches, the four inorganic supports had a similar behaviour with final ethanol concentrations about 60 g/L. However, the samples containing Tygon and plastic supports suddenly decreased their ethanol production after that moment. On the contrary, the samples with glass Raschig rings and alumina beads kept a good ethanol production until the 14th batch (total time 1,000 h), with average ethanol concentrations of 58-59 g/L, yields of 0.45 g/g and a lactose consumption of 96-98% [1].

4. Conclusions

Cheese whey permeate with high lactose concentration is an attractive feedstock for ethanol production. The selection of an appropriate yeast strain is essential to avoid nutrient supplementation, enzymatic hydrolysis steps and osmotolerance problems. Moreover, it is possible to immobilise the yeasts on simple inorganic supports, which clearly reduces yeast cultivation costs.

Effect of the treatment of gaseous ammonia emissions from pig farms on greenhouse gas emissions

Éric DUMONT

UMR CNRS 6144 GEPEA, IMT Atlantique, Campus de Nantes, La Chantrerie, 4 rue Alfred Kastler, CS 20722, 44307 Nantes Cedex 3, France
eric.dumont@imt-atlantique.fr

Highlights

- NH_3 treatments of gaseous emissions from pig farms can promote N_2O formation.
- The use of bioscrubbers can increase greenhouse gas (GHG) emissions.
- A denitrification step added to a bioscrubber significantly increases GHG emissions.
- The use of chemical scrubbers has no effect on greenhouse gas emissions.

1. Introduction

Gaseous pollution generated by pig farms can originate from animals and the decomposition of piggery waste manure. Pollutants such as ammonia (NH_3), carbon dioxide (CO_2), methane (CH_4) and nitrous oxide (N_2O) are the most abundant gaseous compounds emitted by pig farms. In order to limit NH_3 emissions, various air cleaning solutions are widely applied, i.e. chemical scrubbers, bioscrubbers and biofilters. However, the biological treatment of NH_3 can itself promote the formation of secondary pollutants such as N_2O. Since N_2O has a large greenhouse warming potential (1 g N_2O emitted is equivalent to 298 g CO_2), it seems relevant to investigate the impact of NH_3 treatment on greenhouse gas (GHG) emissions. The objective of this study is therefore to quantify the impact of air cleaning systems on the overall GHG emissions in pig farms from the literature data. The greenhouse gases emitted at the outlet of three different cleaning systems ("chemical scrubber", "bioscrubber" and "bioscrubber + denitrification step") are quantified and compared with the GHG emissions generated by the exhaust air with "no treatment".

2. Methods

Gaseous emissions from pig farms present significant variations from one farm to another and are related to temperature, ventilation rate, animal activity and the physiological stage of pigs. Consequently, mean values have to be used for pollutant concentrations and ventilation rates. The typical mean concentrations used in the calculations are in agreement with the data reported in the literature [1,2] (i.e. ventilation rate: 35 $m^3\ h^{-1}$ $animal^{-1}$; NH_3: 12 ppmv (9.0 mg m^{-3}); CO_2: 2000 ppmv (3880 mg m^{-3}); CH_4: 40 ppmv (28.2 mg m^{-3}); N_2O: 0.5 ppmv (0.97 mg m^{-3}). From the literature data [2,3], mean NH_3 removal efficiency values of 95% and 70% for "chemical scrubber" and "bioscrubber", respectively, are assumed. NH_3 removal efficiency increases to 85% when a denitrification step is added to a bioscrubber [4]. Moreover, N_2O-N production corresponding to 5% and 25% of the NH_3-N amount removed in bioscrubbers are considered for the cases

"bioscrubber" and "bioscrubber + denitrification step", respectively, on the basis of the literature data [4-5]. Lastly, it is considered that "chemical scrubbers" do not promote N_2O formation [6].

3. Results and discussion

The effect of the three treatments on GHG emissions is shown in Figure 1. According to this figure, GHG emissions are only reduced by the use of a "chemical scrubber" in relation to their ability to remove NH_3 satisfactorily and not promote N_2O generation. Both cases involving a bioscrubber show an increase in GHG emissions. The use of a "bioscrubber" can marginally increase greenhouse gas emissions (+1.9%). Such a finding is due to the large CO_2 footprint, which represents 80% of the total GHG emissions. Therefore, the use of bioscrubbers can be considered an acceptable alternative to chemical scrubbers to treat air from pig farms. However, the addition of a denitrification step to treat the discharge water from a bioscrubber has a significant influence. In this case, yearly GHG emissions move from 1583 to 1800 kg $eqCO_2$ $animal^{-1}$ corresponding to a 13.7% increase in comparison with the case "no treatment".

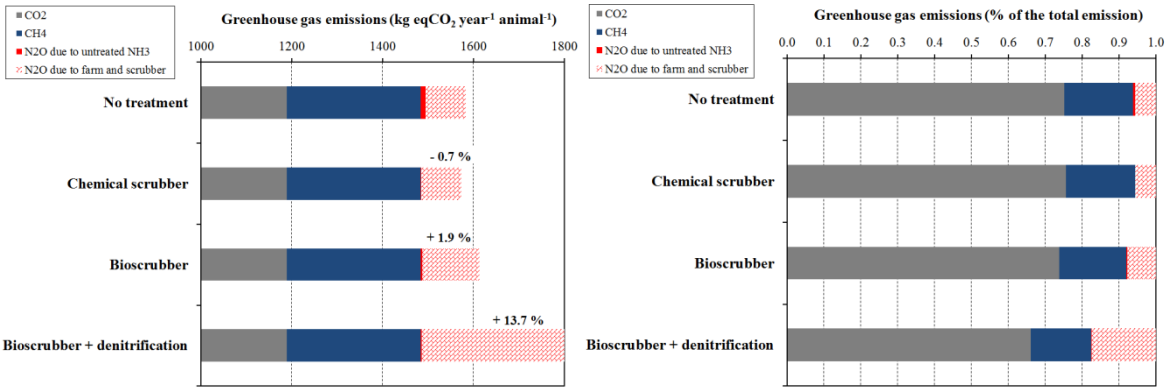

Figure 1. Impact of three NH_3 treatments on GHG emissions.

4. Conclusions

The calculations performed show that a chemical scrubber has no effect whereas biological treatments can increase GHG emissions. The use of bioscrubbers can remain acceptable according to the level of GHG emitted by the pig farm and provided that less than 3 % of the NH_3 entering the apparatus is converted into N_2O. In such a case, a maximum increase of 1.9 % in GHG emissions could be obtained. Conversely, the addition of a denitrification step to the bioscrubber must be avoided. Increases in the overall GHG emissions up to 13.7 % were calculated but more significant increases could occur. With regard to GHG emissions, it is concluded that the use of a chemical scrubber is more suitable than a bioscrubber to treat exhaust air from pig farms.

A new methodology for the process monitoring of enzymatic proteolysis by size-exclusion chromatography

Sophie Beaubier[1,2], Irina Ioannou[1], Xavier Framboisier[1], Olivier Galet[2], Romain Kapel[1]*

1 *Laboratoire Réactions et Génie des Procédés, Université de Lorraine, CNRS, LRGP, F-54000 Nancy, France*

2 *Avril SCA, 11 rue de Monceau, F-75008 Paris, France*

*Corresponding author: * romain.kapel@univ-lorraine.fr*

Highlights

- A method for monitoring enzymatic proteolysis by SE-HPLC is developed
- The method assesses protein conversion rate, peptide size and DH in a single run
- The approach was tested on various proteins and hydrolysis conditions
- The method is as efficiently as TNBS or pH stat methods for DH quantification

1. Introduction

Enzymatic proteolysis is an industrial process used in a wide range of applications [1]. The extent of the enzymatic proteolysis process is usually quantified as the degree of hydrolysis (DH), which represents the percentage of peptide bonds cleaved compared to the initial number of peptide bonds of the protein [2]. An effective follow-up of the enzymatic proteolysis process requires the quantification of 2 others parameters: the protein conversion rate (Xp) and the mean peptide size released (Naa). These three different parameters are classically determined by three distinct analysis. The DH can be either determined by a method based on a spectrophotometric reaction with amino groups released during hydrolysis or based on a titration of protons released during a peptide bond hydrolysis. To determine Xp, the protein concentration must be specifically quantified by Reversed-Phase High-Performance Liquid Chromatography (RP-HPLC) or Kjeldahl method after protein precipitation with TCA. Molecular weight distribution of peptides is classically achieved by Size-Exclusion High-Performance Liquid Chromatography (SE-HPLC) based on the UV signal at 214 nm. This makes the enzymatic proteolysis process laborious to monitor. In this way, the communication describes an original methodology to quantify simultaneously these three criteria by size-exclusion chromatography (SE-HPLC).

2. Methods

The protein conversion rate is simply deduced from the evolution of the protein peak area in the course of the reaction. With the chosen column (Superdex peptide 10/300 GL column), proteins are eluted in the column dead volume due to the column separation domain (< 7 kDa). For the mean peptide size and DH, the methodology consists in converting peptide UV absorbances of chromatograms into concentrations by applying Beer-Lambert law [4]. To do so, a molar extinction coefficient is assessed for each chromatogram point (Eq. 1). The coefficient depends on the hydrolysate aminoacid compositions and the molar weight corresponding to the considered point (deduced from SE column calibration).

$$\varepsilon_x = \varepsilon_{bond} \times \left(\frac{10^{a \times V_x + b}}{\overline{MM}_{aa}} - 1\right) + \bar{\varepsilon}_{aa}\left(\frac{10^{a \times V_x + b}}{\overline{MM}_{aa}}\right) \quad \text{(Eq. 1)}$$

With ε_{bond}, the molar extinction coefficient of peptide bond and $\overline{MM}$aa, the mean amino acid molar mass of the hydrolysate.

The overall concentration signal is integrated and Naa is calculated with the ratio of the molar quantities of amino acids (determined with Eq. 2) to peptides (determined with Eq. 3) in the hydrolysate. DH is deduced from the ratio of Xp and the mean size of peptide.

$$n_p = Qv \int (Cp_x)\, dt \quad \text{(Eq. 2)} \qquad n_{aa} = Qv \int \left(Cp_x\, \overline{N}aa_x\right) dt \quad \text{(Eq. 3)}$$

with Q_v the elution flow rate and dt a fraction of the elution time.

3. Results and discussion

As a first step, the approach was tested on the hydrolysis of bovine serum albumin (BSA) and rapeseed albumin (RA) by Alcalase 2.4L because of their different origin, structure, isoelectric point and composition. Hydrolysis kinetics were monitored by SE-HPLC (Figure 1A) and the 3 parameters were determined in the course of reaction as described above. Values of DH were also determined by TNBS and pH-stat methods. Most of the hydrolysates obtained showed relative differences <20% with the reference methods (Figure 1B). The method was also adapted to fit the TNBS assay.

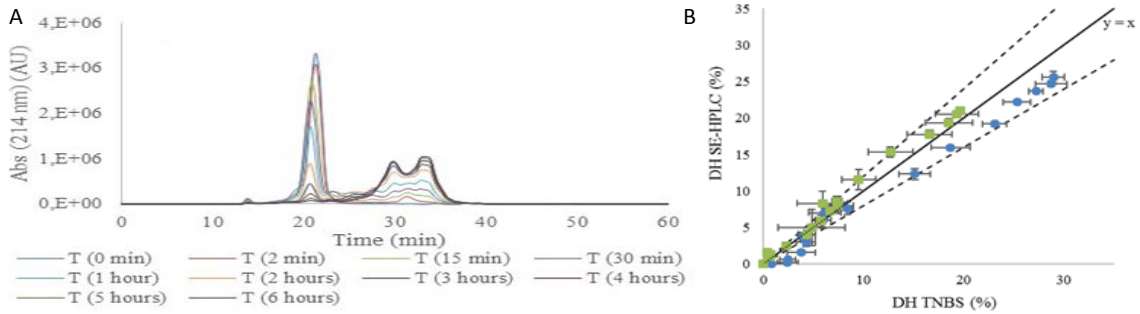

Figure 1. (A) Size exclusion chromatograms obtained for the hydrolysis of 1 % (w/v) RA with Alcalase 2.4 L over 6 h; (B) Comparison of the DH values obtained with the SE-HPLC and TNBS methods for the hydrolysis of 1 % (w/v) BSA (●) and RA (■) with Alcalase 2.4 L. Values are means of triplicate determinations. Error bars show standard deviation.

Then, validation of the methodology was realized through a statistical comparison between the DH values obtained by the method and those obtained with TNBS and pH stat methods for BSA, RA and lysozyme substrates. 39 experimental validation tests were analysed by SE-HPLC, TNBS and pH stat methods. 90% of the validation data show non-significant differences between the DH predicted and the DH measured by TNBS method.

4. Conclusions

The proposed methodology can be efficient for the process monitoring of enzymatic proteolysis while minimizing time and quantity of sample assay required. Moreover, it could be used for functionalities or bioactivities analysis of produced hydrolysates.

Highlights

- Lipase was produced by *Candida tropicalis* URM 7057;
- Enzyme production was conducted using agro-industrial residues: molasses, corn steep liquor and olive mill wastewater (OMW);
- Lipase production was higher when aerated cultivation was conducted.

1. Introduction

Lipases represent around 10% of the global market for enzymes and new processing technologies may boost the interest among researchers to search for new sources of viable lipase stimulating the selection of new strains and the optimization of the production [1].

In this context, this study aimed to evaluate lipase production by *Candida tropicalis* URM 7057 using agro-industrial residues as feedstock in a bench bioreactor. In order to improve enzyme production, some operational strategies were evaluated, such as: effect of aeration and agitation, as well as the effect of feeding pulses of OMW.

2. Methods

The yeast *Candida tropicalis* URM 7057 was isolated from cashew bagasse. The culture was activated in a medium containing 40 g/L of glucose, 10 g/L of peptone in potassium phosphate buffer with PH 7.0 and maintained at 30 °C, 170 rpm for 24 h. To prepare the inoculum, a microbial suspension of cells was transferred to flasks of 500 ml, containing 175 ml of cultivation medium and kept in a rotary sacker at 30 °C and 170 rpm until reaching the concentration of 10^6 UFC/ML.

The cultivation medium contained 5.0 g/L of sugarcane molasses, 6.0 g/L of Corn Steep Liquor (CSL), 0.5% v/v of wastewater from olive plants (OMW), 0.5 g/L of ammonium sulfate and 3.0 g/L of peptone in potassium phosphate buffer, PH 7.0, which was sterilised in autoclave at 110 °c for 15 minutes. The assays were performed in 5L-bench bioreactor (New Brunswick Bioflo Celligen 115, Eppendorf), (HL = 33.00 cm; d = 19.41 cm) with an initial volume of 3.5 L at 30 °C and 300 rpm and pH maintained at 6.5 with NaOH 1, 5m.

The total protein content was determined by the BRADFORD method [2] using bovine serum albumin as the protein standard for the calibration curve. The concentration of reducing sugars was determined by using the DNS reagent [3]. The growth was monitored by counting viable cells in a Neubauer chamber (depth 0.025 mm) performed along the fermentation, using methylene blue

staining technique. *Lipase activity was determined using p-nitrophenyl laurate (pNFL)* as the enzyme substrate [4].

3. Results and discussion

Different agitation speeds and air flows were studied in the production of lipase by *C. tropicalis.* Enzyme production increased with increase in aeration flow rate, figure 1. The production coefficients $Y_{P/S}$ and $Y_{P/x}$ were higher in 0.25 vvm, although the $Y_{P/X}$ for 0.75 vvm was not much different from the value at 0.25 mvv. Table 1 shows the biomass (Y_{XS}) and Product (Y_{PX}, Y_{PS}) yields, as well as lipolity activity and biomass production (titer and productivity).

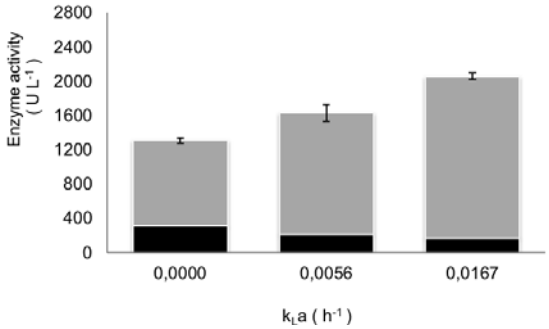

Figure 1. Maximum total enzymatic activity under different aerations: ( ) intracellular activity ( ) Extracellular activity.

Table 1. Kinetic Parameters of batch and batch cultivation fed

Parameter	X_{max} (UFC/ mL)	S_{total} (g/L)	$P_{x,\,max}$ (UFC/mL/L)	$P_{P,max}$ (U/L/h)	Y_{XS} (UFC/gS)	Y_{PX} (U/UFC)	Y_{PS} (U/gS).
Batch	1.9×10^6	4.3	1.8×10^5	24.9	7.6×10^7	0.8×10^{-7}	5.7
Fed-Batch	2.5×10^6	4.7	2.9×10^5	18.1	21.4×10^7	2.3×10^{-7}	50.0

4. Conclusions

In this work, the production of lipase by *C. tropicalis* URM 7057 using agro-industrial residues as feedstock could be optimized in an aerated submerged culture. In addition, batch operation proved to be a good strategy to achieve higher enzyme titer.

**Corresponding author: eric.olmos@univ-lorraine.fr*

Highlights

- Sequential production of organic acids according to the oxygen uptake rate
- The succinate re-consumption depends on the glucose concentration
- Kinetic modelling of succinate production/consumption

1. Introduction

Corynebacterium glutamicum is widely used in industry for the production of amino acids and for a few years, it is known that *C. glutamicum* is also capable of producing organic acids under oxygen-limited and anaerobic conditions [1]. Therefore, this work aimed to understand the physiological behavior of *C. glutamicum* in defined and limiting oxygenation conditions and then to give clues concerning the optimal conditions for succinate production.

2. Methods

Batch cultures of *Corynebacterium glutamicum* 2262 were performed in a minimal medium in glass unbaffled shake flasks [1]. For the estimation of the volumetric gas-liquid mass transfer coefficient (k_La), the following correlation was used [2].

$$k_La = 0.024 * N^{1.16} * V^{-0.83} * d_0^{0.38} * d^{1.92} \qquad \text{(eq.1)}$$

with K_La, the volumetric gas-liquid mass transfer coefficient (h^{-1}), N the shaking frequency (s^{-1}), V the filling volume (mL), d_0 the shaking diameter (cm) and d the maximal shake flask diameter (cm).

It was previously demonstrated that the k_La values calculated from eq.1 or determined experimentally were in very good agreement [1]. In the present work, by modifying the shaking frequency, the filling volume and the maximal shake flask diameter, different k_La conditions (5, 11, 15, 20, 31, 44, 77, 90 and 118h^{-1}) could be imposed.

3. Results and discussion

All the cultures were performed in limiting oxygen condition. This one was noticed 2h after the beginning of the culture with k_La values above 77 h^{-1} and after only a few minutes when the k_La values were below 33 h^{-1} [1]. The maximal organic acid concentrations differed according to the oxygenation conditions. Indeed, the succinate maximal concentration (42 mM) was measured for k_La = 5 h^{-1} with a conversion yield of 0.22 mol succinate/mol glucose. The lactate, which was the major fermentation product in all the culture conditions, reached its maximal concentrations

(170mM) for k_La values between 5 and 31 h^{-1}. The highest acetic acid concentration (88 mM) occurred when k_La values were between 31 and 77 h^{-1}. For k_La ≥90 h^{-1}, the biomass concentration (12 g/l) was maximal. A similar impact of oxygenation conditions on the organic acids was previously observed with *C. glutamicum* ATCC13032 (2) and with a mutant strain of *C. glutamicum* 2262 deleted for *ldhA* (1). Interestingly, succinate production occurred in all the culture conditions with a similar specific production rate in the first hours of the cultures. However, the higher the k_La, the earlier the production ceased and the earlier the succinate was consumed (fig. 1).

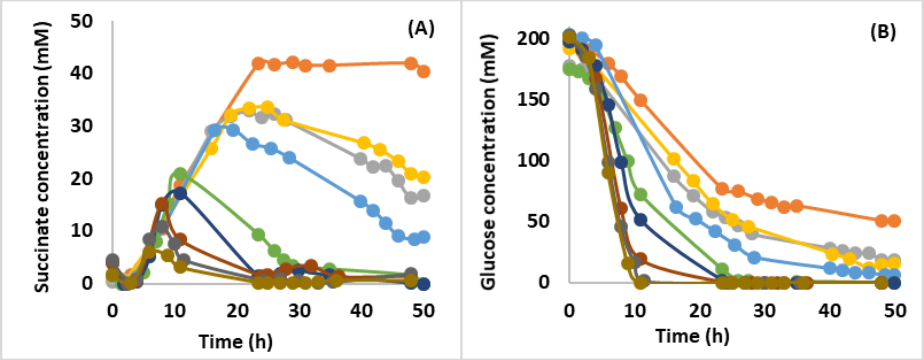

Figure 1. Kinetics of succinate production (A) and glucose consumption (B) by *Corynebacterium glutamicum* 2262 for k_La values of 5 h^{-1} (¬), 11 h^{-1} (¬), 15 h^{-1} (¬), 20 h^{-1} (¬), 31 h^{-1} (¬), 44 h^{-1} (¬), 77 h^{-1} (¬), 90 h^{-1} (¬) and 118 h^{-1} (¬).

The stop in the succinate production was concomitant with a threshold glucose concentration of 50 mM. Glucose and succinate were then both co-consumed until the end of the culture. No growth of *C. glutamicum* was observed with succinate as a unique substrate meaning that the succinate is likely an energy source for this bacterium (complementary data). The specific rates of succinate production were then modeled using Luedeking-Piret equation [3] in which a term modeling the succinate consumption as an energy source was added. The specific rates of succinate production predicted using this model were in accordance with the experimental rates for the different k_La conditions.

4. Conclusions

In oxygen-limited conditions, the specific succinate production by *C. glutamicum* depended on the oxygen uptake rate but its consumption was only observed for concentrations of glucose lower than 50 mM. To identify the metabolic changes responsible for this physiological behavior, the designed kinetic model will be coupled with a FBA simulation using a simplified metabolic model of *C. glutamicum*.

Influence of working parameters on mixing time values in single-use culture bag rocked in WAVE™ 25 bioreactor

Maciej Pilarek[1], Kamil Wierzchowski[1]

[1]*Warsaw University of Technology, Faculty of Chemical and Process Engineering, Waryńskiego 1, 00-645 Warsaw, Poland*

**Corresponding author: maciej.pilarek@pw.edu.pl*

Highlights

- Mixing time ranged from 3s to 500s characterizes mixing efficiency in WAVE™ bioreactor
- Oscillations angle and frequency robustly impacting on mixing time in WAVE™
- Influence of aqueous phase volume in culture bag is irrelevant to mixing time in WAVE™

1. Introduction

Applications of disposable bioreactors for scaling-up of *in vitro* bioprocesses involving fragile animal cells became common in biopharmaceutical industry. In wave-induced agitation systems, mixing is achieved by horizontal oscillation of a single-use culture bag, which is fixed in a rocker unit. An interfacial area between gas and liquid phases filing the culture bag is continuously renewed, what accomplishes gentle and bubble-free surface aeration of a culture medium [1]. Furthermore, the wave-induced agitation notably limits shear stress effects negatively influencing on shear-sensitive animal cells or aggregates of them. A mixing time is a parameter commonly used to quantify mixing efficiency, and its value represents to the time necessary to reach a defined mixing quality [2]. The mixing time values determined for various types of disposable wave-type agitated bioreactors depended on the volume of culture bag, and presets of working parameters of the rocker.

The aim of the study was to determine influence of working parameters defining wave-induced agitation, on values of the mixing time reached in 2-litre culture bag (i.e. Cellbag™ 2L) oscillatingly rocked in *ReadyToProcess* WAVE™ 25 bioreactor (GE Healthcare, USA). Based on our previously published data, i.e. [3], only the impact of aqueous phase volume inside the culture bag (V_L), and angle of oscillations (α), as well as their frequency (ω), were analysed and their influence on the mixing time values have been quantitatively determined. All the experiments were performed and evaluated according to DoE-standards of statistical data processing.

2. Methods

ReadyToProcess WAVE™25 bioreactor (WAVE 25) equipped with disposable, polymer-based culture bag (Cellbag™ 2L; GE Healthcare, USA) with a total volume of 2 dm^3 has been used as an experimental setup. The following values of the operational parameters established for the mixing time determination have been evaluated: V_L equalled to 0.2 dm^3, 0.6 dm^3 and 1.0 dm^3; α equalled to 2°, 7° and 12°; as well as ω equalled to 2 min^{-1}, 21 min^{-1}, 40 min^{-1}.

The decolourisation iodometry method has been applied for determination of the mixing time in the system [4]. Prior to measurement, 2 cm^3/dm^3 iodine potassium iodide (40 g KI + 20 g I_2/dm^3), and then 5 cm^3/dm^3 starch solution (10 g/dm^3), were added to the constantly waving aqueous phase (37°C) inside the culture bag, to obtain the deep blue coloured aqueous phase. Next, 4 cm^3/dm^3 sodium thiosulfate solution (24.6 g/dm^3) has been pipetted under continuous wave-type agitation, with the immediately started time measurement of the aqueous phase decolourization process. The timing was stopped when the colour change of aqueous phase from deep blue to colourless has been completely achieved.

All experiments were planned and evaluated in STATISTICA® Data Miner 13 (StatSoft Polska, PL) software. The DoE-aided analysis comprising in total 135 experiments (i.e. 27 single experiments repeated in 5 series, three levels of varied factors has been applied to statistical data processing.

3. Results and discussion

The range of experimentally measured values of the mixing time reached for the aqueous phase waving in Cellbag™ 2L, which have been performed in the rocker of WAVE 25 system, i.e. from values of less than 5 s to over two orders of magnitude more (Figure 1), was consistent with previously published literature data on the mixing time determined for other single-use bags variously agitated by the other oscillating devices. Moreover, just α and ω have been identified as the working parameters which relevantly and robustly influencing on the value of the mixing time determined in the studied experimental setup of WAVE 25 bioreactor.

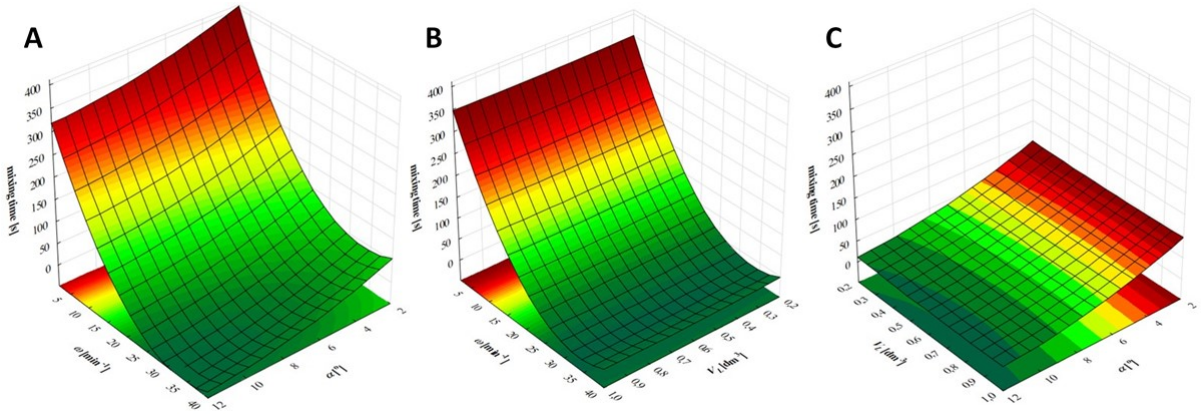

Figure 1. Response surface plots for the mixing time: the influence of α and ω (for V_L = 0.6 dm^3) (**A**), the influence of ω and V_L (for α = 7°) (**B**), and the influence of V_L and α (for ω = 21 min^{-1}) (**C**).

4. Conclusions

The results of the DoE-aided analysis has identified just α and ω as the working parameters which relevantly and robustly influencing on the value of the mixing time determined in the studied experimental setup of WAVE 25 bioreactor. The influence of V_L has been rather minor and may be interpreted as negligible.

Highlights

- Autohydrolysis as suitable process for antioxidants and fibers recovery.
- Antioxidant capacity is more than twice compared to acid hydrolysis.
- Cellulose yield and recovery are 15.88% and 47.01% respectively.

1. Introduction

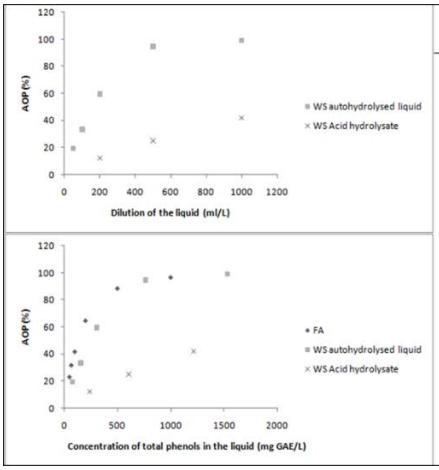
Wheat straw (WS) is an agricultural residue that presents many interesting characteristics that facilitate its biotechnological upgrade in a bio-refinery framework [1]. Based on the data from FAO, world annual WS production is about 577 million tons in 2016 and is supposed to be higher in the next years. Plant cell walls of wheat straw are formed with a polysaccharide network of which cellulose, hemicelluloses and pectin are the most important components [2]. The antioxidant phenolics and cellulosic fiber were conventionally separated using acid/alkaline hydrolysis [3]. However, from the environmental point of view, it is better to avoid the use of toxic chemicals, like sulfuric acid. For these reason, autohydrolysis process is gaining more attention nowadays and was already tested to recover bound phenols from grape stalks [4]. Hence, in the present study an environmental friendly autohydrolytic process was applied for the recovery of both antioxidants and cellulosic fiber in a single process from wheat straw. The cellulose and antioxidant recovery were compared with the traditional process value.

2. Methods

Acid hydrolysis, alkaline hydrolysis and bleaching steps were described in-deep in our previous work [3]. On the other hand, autohydrolysis was carried out as follow. Wheat straw sample (20 g) was taken with 400 ml of distilled water in a Teflon container and placed inside of high pressure reactor that was operated at 190 ºC and 11 bar for 15 min under agitation. Then, the reactor was slowly cooled down at ambient temperature. The following alkaline hydrolysis and bleaching steps were the same as in the traditional process [3]. The solid recovered was weighed to calculate the cellulose residue yield while the liquid, coming from autohydrolysis reaction, was used for the analysis of antioxidant capacity using ABTS analytical method [3]. Finally, the structural carbohydrates including total reducing sugars, acid soluble and insoluble lignins, glucose, xylose and acetic acid were investigated in the cellulose residue obtained from autohydrolysis [5].

3. Results and discussion

The obtained results are reported in Figure 1. The ABTS inhibition capacity of WS autohydrolyzed liquid is very high when compared to acid hydrolysis liquid, because in the acid hydrolyzed liquid achieved only 40% AOP at 1200 mg GAE/L concentration, whereas WS autohydrolyzed liquid has exhibited 94% AOP at 766 mg GAE/L concentration and thereafter the antioxidant activity attained plateau. The autohydrolysis process yielded slightly lower amount of fiber residue (86%) than the acid hydrolysis process (95%). The cellulose content calculated based on glucose concentration was slightly lower in autohydrolysis process when compared to acid hydrolysis method. However, the cellulose yield (15.88%) and recovery (47.01%) of WS fiber obtained from autohydrolysis is closer to that of acid hydrolysis step. Interestingly, the hemicelluloses, acetic acid, acid soluble and acid insoluble lignins content of autohydrolyzed fiber is lower than acid hydrolyzed sample.



Structural carbohydrates	WS autohydrolysis	WS acid hydrolysis
Total sugars (g / L)	6.22 ± 0.05	6.31 ± 0.04
Glucose content of fiber residue (%)	86.43 ± 0.94	95.54 ± 2.05
Cellulose content of fiber residue (%)	76.06 ± 0.83	84.07 ± 1.80
Cellulose yield from raw material (%)	15.88 ± 0.17	15.10 ± 0.32
Cellulose recovery (%)	47.01 ± 0.51	44.70 ± 0.92
Xylose content of fiber residue (%)	1.14 ± 0.02	2.33 ± 0.13
Hemicellulose content of fiber residue (%)	1.03 ± 0.02	2.10 ± 0.12
Acetic acid content of fiber residue (%)	0.19 ± 0.02	0.59 ± 0.01
Acid soluble lignin (%)	0.90 ± 0.04	1.09 ± 0.03
Acid insoluble lignin (%)	5.47 ± 0.50	12.43 ± 0.24

Figure 1. Comparison of AOP and structural carbohydrates of WS autohydrolysis with acid hydrolysis.

4. Conclusions

Autohydrolysis was found to be highly suitable and environmental friendly process compared to conventional acid/alkali hydrolysis process to obtain the antioxidants and fibers from WS. Future investigation on the use of these antioxidants and cellulosic fibers in the development of active and biodegradable food packaging material is necessary for the utilization of agro-food byproducts towards the enhancement of food industry.

Bacterial alginate production under oxygen transfer rate controlled conditions

Belén Ponce, Alvaro Díaz-Barrera*

Escuela de Ingeniería Bioquímica, Pontificia Universidad Católica de Valparaíso, Av. Brasil 2147 Casilla 4059, Valparaíso, Chile.

** Corresponding author: alvaro.diaz@pucv.cl*

Highlights

- Control of the oxygen transfer rate based on the oxygen in the feed gas
- Alginate production and their molecular weight were affected by oxygen transfer rate control
- Under OTR controlled, alginate molecular weight produced during the stationary phase of growth was constant

1. Introduction

Alginates are polysaccharides composed of (1-4)-β-D-mannuronic acid and its C-5-epimer, α-L-guluronic acid. These polymers are used in the food and pharmaceutical industries as stabilizing, thickening, gel- or film-forming agents [1]. Alginates are produced by brown algae, but they can also be produced by the bacterium *Azotobacter vinelandii*. One strategy to produce alginates with defined molecular weight (MW) is through the manipulation of the culture conditions during fermentation. In our group, we have found evidences that the oxygen transfer rate (OTR) affects the molecular weight of alginate [2]. During the stationary phase of growth, both the OTR and the MW alginate decrease. In order to produce alginates with an MW constant during the fermentation time, it is possible to perform cultures at constant OTR. The aim of this work was to implement a control strategy for maintaining value of OTR constant, manipulating the oxygen in the feed gas. Thus, the alginate production was evaluated under OTR constant.

2. Methods

A. vinelandii ATCC 9046 was used. The bacterium was grown under nitrogen fixation conditions, using sucrose as carbon source. Batch cultures were prepared in a 3-L bioreactor (working volume of 1.5-L). The bioreactor was operated at 500 rpm and 30 °C. Mass flow meters/controllers were used to supply gases, keeping a constant value (1.5 L min^{-1}) by the real-time operation computer control system. The OTR was estimated by online measurements of the oxygen in the exit gas using a gas analyzer (Teledyne Instruments, model 7500). The cultures were conducted under controlled OTR or without controlling OTR. The OTR was controlled by gas blending, using a system based on a proportional-integral control, which automatically adapted the proportions of nitrogen and oxygen in the inflowing gas through mass flow controllers (Brooks Instruments, model SLA5800). Samples of cultures (20 ml) were withdrawn from the bioreactor for analytical measurements. All experiments were conducted in triplicate.

3. Results and discussion

Figure 1 shows the cell growth and OTR evolution under controlled OTR and without controlling OTR. In the cultures without controlling OTR, the maximum biomass (6.7 g L^{-1}) was higher as compared to under OTR control (5.0 g L^{-1}). During the cell growth phase, the cultures performed without OTR control shown an OTR constant, which is indicative of oxygen-limited conditions. After 40 h of cultivation (cells stopped the growing), in the cultures conducted under OTR controlled, the OTR was constant, reaching 20 mmol L^{-1} h^{-1}.

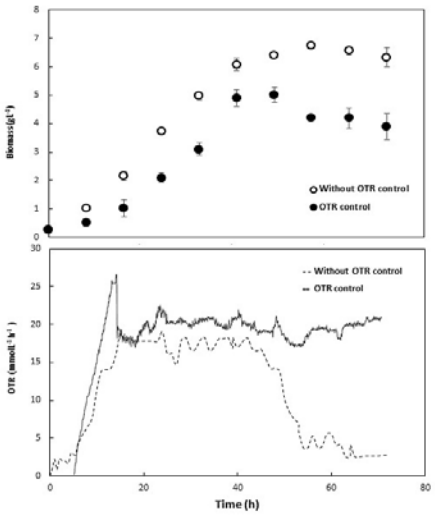

Figure 1. Biomass and OTR evolution in *A. vinelandii* cultures carried out in 3-L bioreactor.

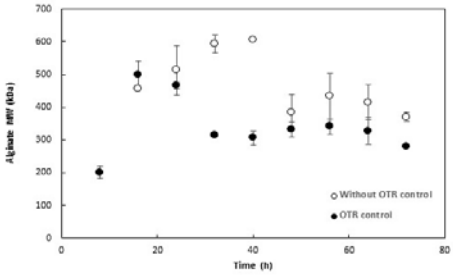

Figure 2. Alginate molecular weight evolution under OTR control and without controlling OTR in 3-L bioreactor.

Table 1. Comparison of specific cell growth rate, biomass yield on sucrose ($Y_{x/s}$), alginate yield on biomass ($Y_{p/x}$), and maximum alginate concentration.

OTR condition	μ (h^{-1})	$Y_{x/s}$ (g g^{-1})	$Y_{Alginate/x}$ (g g^{-1})	Alginate $_{máx}$ (g L^{-1})
Without OTR control	0.12 ±0.01	0.31 ±0.03	0.28 ±0.03	2.88 ±0.10 (56 h)
OTR control	0.17 ±0.02	0.16 ±0.02	1.14 ±0.18	5.34 ±0.13 (64 h)

Figure 2 shows that the OTR control affected the production and the molecular weight of alginate. In the culture with control of the OTR, the alginate MW during the stationary phase of growth was constant (300 kDa). It is possible that changes in genes involved in alginate polymerization and depolymerization could be affected by variation in the OTR during stationary phase. A higher alginate production under OTR controlled was obtained (Table 1).

4. Conclusions

The strategy implemented for controlling the oxygen transfer rate in *A. vinelandii* cultures is useful for maintain constant the molecular weight of alginate during the stationary phase of growth. The OTR control could be used in order to produce alginates with particular characteristics.

Highlights

- *Piper hispidum* endophytic fungi are able to produce tensoactive molecules.
- The fungi were able to use the cooking oil residue as substrate.
- The reduction of superficial tension of the cultivation broths was around 40%.

1. Introduction

Fungi found in plant species, called endophytic fungi, present a great potential for the production of new bioactive substances [1]. Among substances of commercial interest are the biosurfactants, amphipathic compounds that present tensoactive properties and are produced by microorganisms [2]. Biosurfactants comprise a wide variety of industrial applications, which include bioremediation, biodegradation, cleaning of oil containers, and have been employed at the food, pharmaceutical, and cosmetic industries. [3] Recently, the use of residues for the production of biosurfactants has gained attention, since it implies in cost reduction [4]. Therefore, this work has evaluated the biosurfactant production on metabolic broths of endophytic fungi isolated from the Amazon species *Piper hispidum* (Piperaceae) using cooking oil residue as substrate.

2. Methods

The endophytes were isolated previously and maintained on BDA tubes, being activated on this media at 28°C during 5 to 10 days. It was produced a spore suspension (1,0 x 10^8 spores/mL), which was inoculated in 125 mL Erlenmeyer flasks containing the liquid media - $MgSO_4$ (0.5 g/L), Na_2HPO_4 (3.0 g/L), KH_2PO_4 (1.0 g/L) and yeast extract (1.3 g/L) [5]. After autoclaving the media, it was added 0.5 g/L of filtered cooking oil residue in order to induce the biosurfactant production. The fungi were cultivated in triplicate during 7 days in a shaker at 28°C and 170 rpm. After the experiment, the cultivated media was filtered and the supernatant was used to evaluate the biosurfactant production. In order to access the biosurfactant production it was determined the emulsification index (E_{24}) [6]. The lowering of superficial tension (ST) was verified with the of a tensiometer [7] in order to verify the efficiency of the biosurfactant.

3. Results and discussion

The endophytic fungi were able to produce tensoactive molecules using the cooking oil residue, since it was observed a lowering of the superficial tension (ST) of the cultivation broths, and the emulsion formation in the presence of kerosene (Table 1). For the fungi PH I 19F, isolated from the

leaf, the ST went from 67.5 to 35.9 Mn/M (46.8% reduction), within 12 days of cultivation in the presence of the residue. The emulsification index (E_{24}) was 30%. For the fungi PH I 12F, also from the *P. hispidum* leaf), the TS reduced from 67.5 to 32.9 mN/m (51.3% reduction) eitihn 8 days, and the E_{24} was 28%.

Table 1. Emulsification index (E_{24}) and superficial tension (ST) of *Piper hispidum* endophytic fungi cultivation broths containing the cooking oil residue.

PH I 12F			**PH I 19F**		
Cultivation Time (days)	E_{24} (%)	ST (mN/m)	Cultivation Time (days)	E_{24} (%)	ST (mN/m)
0	0	67.5	0	0	67.5
4	23	38.7	4	24	34.3
8	27	36.7	8	28	32.9
12	30	35.9	12	22	35.2

According to same authors, biosurfactants that present low molecular weight have the ability to reduce the superficial tension, and those that have higher molecular weights are more likely to promote stable emulsions, acting as a bioemulsifier [8]. Haba et al [9] affirmed that microorganisms that are considered the best biosurfactant producers are capable to reduce the superficial tension to values below 40 mN/m. Therefore, the *P. hispidum* endophytic fungi may be considered as promising biosurfactant producers.

4. Conclusions

It was possible to access *P. hispidum* endophytic fungi that produce biosurfactants which presented promising physical-chemical properties for being used in different industrial areas. The cooking oil residue showed to be a promising substrate for the production of fungi biosurfactant.

Integrated micro-system for lipase-catalyzed biodiesel production

Martin Gojun*, Anita Šalić, Bruno Zelić

University of Zagreb, Faculty of Chemical Engineering and Technology, Marulićev trg 19, HR-10000 Zagreb, Croatia

**Corresponding author: mgojun@fkit.hr*

Highlights

- Lipase-catalyzed biodiesel synthesis in microreactors was performed
- Different microreactor systems were investigated
- Integrated system composed of lipase-catalyzed biodiesel production and glycerol separation is proposed

1. Introduction

Due to recent widespread issues concerning the over usage of fossil fuels, alternative sources of energy are developed with fast pace. When it comes to transportation, biofuels such as biodiesel, can become a clean and renewable substitute for petroleum diesel. Biodiesel, a mixture of monoalkyl esters of long-chain fatty acids, provides valuable improvement in comparison with petroleum diesel in terms of biodegradability and renewability, better quality of exhaust gas emission and lower environment harmful effect. [1] Between various production processes of biodiesel, transesterification is most commonly used technique, even though the conventional process has some disadvantages. Microreactor technology, as one possible improvement of conventional processes in terms of mixing, mass transfer and reducing the reaction time, has been thoroughly explored in recent decades. [2] However, enzyme-catalyzed process continues to represent area which need to be more briefly investigated. In this work, lipase from *Thermomyces lanuginosus* was used as catalyst in biodiesel production. Oil, both edible and waste, was used as a substrate. To find out the "ideal system" for biodiesel synthesis, different configurations of microreactors have been used. In addition, some other parameters which affect on biodiesel production have been monitored, such as microchannel size, residence time, reaction temperature and source of catalyst. [3]

2. Methods

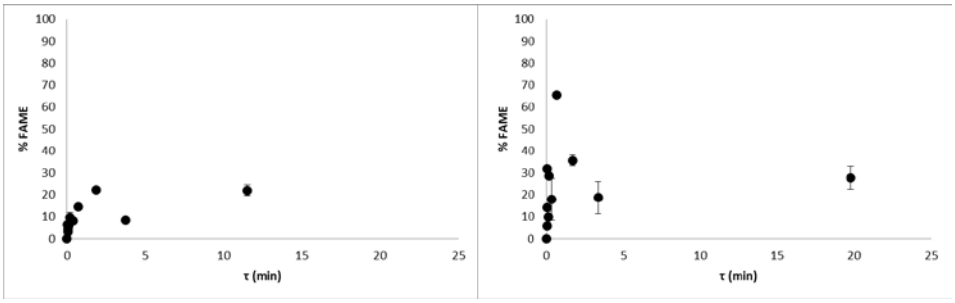
Biodiesel production from both edible sunflower oil and waste cook oil using Lipolase 100L was performed in different configurations of microreactors. According to literature data for feeding ratios, microreactor system was set with a goal to find "ideal system". In addition, each configuration was used for a set of different residence times to examine that impact as well. All experiments were performed at 40°C (optimal temperature for enzyme activity) which was secured with a water bath in which microreactor system was placed. While running the process across few

days for each configuration, lipase activity was determined daily, by measuring the change of absorbance at 410 nm with a spectrometer. Feeding inlets in this experiments were edible/waste oil, methanol, enzyme dissolved in buffer and emulsifier. Due to different configurations of microreactors, emulsifier is sometimes needed to prepare stable water:oil or methanol:oil emulsion.

After investigating all different configurations and selecting optimal system, integrated system is introduced. The idea is to connect two microchips in series, so that the first one is used for biodiesel production and the second one is used for simultaneous glycerol separation. [4] The main goal is that glycerol content in biodiesel is below 0.02%, which is limit according to the American standard ASTM D 6571 and the European standard EN 14214.

3. Results and discussion

Different configurations of microreactors with different feeding inlets were used to investigate biodiesel synthesis. Influence of residence time on F.A.M.E. content is shown in Figure 1. for both investigated microreactor systems: a) 2 inlets and 2 outlets, and b) 3 inlets and 2 outlets. Further investigations of different microreactor system configurations and emulsifiers is planned.



a) b)

Figure 1. Obtained FAME content in a microreactor applzing a) 2/2 microreactor system and b) 3/2 microreactor system.

4. Conclusions

Lipase-catalyzed biodiesel production showed an improvement over conventional transesterification process. Several aspects still need to be investigated. After the biodiesel production, biodiesel purification (removal of glycerol) is required to fulfill American or European standards for biofuels. Thus, integrated system of simultaneous biodiesel production and purification is proposed.

CO_2 and SO_2 removal from cement plant flue gases by *Scenedesmus dimorphus* cultivation - Impact on cell growth and biochemical content

Aldo Mirisola[1], Diane Thomas[1], Anne-Lise Hantson[1]

1 Chemical and Biochemical Process Engineering Unit ; UMONS ; Rue de l'épargne, 56 ; 7000 Mons ; Belgium

**aldo.mirisola@umons.ac.be*

Highlights

- Microalgal cultivation is a promising source of bio-based energy
- Industrial flue gases are a propitious source of carbon and sulfur for the cultures
- Sulphites formed by the flue gas dissolution inhibit growth at high concentration
- *S. dimorphus* composition is slightly impacted by the sulfite content of the medium

1. Introduction

Microalgae are considered as a promising source of bio-based energy thanks to their high photosynthetic rates and their rapid growth compared to terrestrial plants, high lipid content, low surface area demand and year-round cultivation. Nevertheless, life-cycle assessment for production of interesting products like biodiesel from microalgae cultivation have shown that the production of biomass needs to be coupled with some other aspects: the valorisation of microalgal high-value-added by-products (antioxidants, protein and/or polysaccharide contents), the CO_2 mitigation and the use of other industrial waste streams[1].

This is why industrial flue gases are a propitious source of carbon and other nutrients for the microorganisms[2,3]. In such an industrial process, some components of the flue gas (mainly CO_2 and SO_2) are transferred into the culture medium and form dissolved CO_2 and SO_2 as well as (hydrogen)-carbonates and (hydrogen)-sulphites. The latter are then oxidised by oxygen to form sulphates. Sulphates and (hydrogen)-carbonates are nutrients for the culture, but some authors have shown that hydrogen sulphites can inhibit microalgal growth[4,5].

The first objective of this work was to determine the composition of *Scenedesmus dimorphus*'s culture medium (3N-BBM medium) at equilibrium with a synthetic cement plant flue gas. According with the equilibrium compositions, three sulphite stresses were performed on *S. dimorphus* cultures in order to evaluate the impact of the sulphite anions on cell growth and biochemical composition (proteins, polysaccharides and lipids).

2. Methods

Absorption equilibrium between the synthetic flue gas and the 3N-BBM culture medium

The 3N-BBM medium is a fresh autotrophic medium[6]. The synthetic flue gas composition is: 300 ppm SO_2, 33 ppm NO_2, 430 ppm NO, 5% O_2, 20% CO_2, balance N_2. The liquid phase was analysed by ionic liquid chromatography associated with a conductivity detector (SO_3^{2-} and SO_4^{2-} contents) and by a total organic carbon analyser (NDIR) for the determination of the carbon species content.

Scenedesmus dimorphus stock culture and stressed cultures

S. dimorphus (CCAP 276/48) stock culture was performed in a 2L sterile bottle placed on an agitated platform, at 25°C, under a 70 µmol PAR photon.m^{-2}.s^{-1} illumination (12h dark/12h light) provided by fluorescent lamps. The culture medium was the 3N-BBM medium at pH 7 (CO_2 supply regulation). Stressed and control cultures were performed in duplicates in 3L airlift flat panel photobioreactors, at 25°C, under a 100 µmol PAR photon.m^{-2}.s^{-1} illumination (12h dark/12h light) provided by fluorescent lamps. The culture medium was the 3N-BBM medium at pH 7 (CO_2 supply regulation). Biomass density was measured by UV-Vis spectrophotometer at 680 nm. Biomass was harvested by centrifugation and freeze-dried. The lipid content was measured by gravimetric method after solvent extraction (methanol, chloroform, water); (poly)saccharides were quantified by the phenol sulphuric method; finally, total proteins were quantified by the BCA test.

3. Results and discussion

The first part of this study showed that the NO/NO_2 are (practically) insoluble in the 3N-BBM culture medium. The S(IV)-containing anions reached a maximal concentration of 250 $mg_{SO_3^{2-}}.L^{-1}$ (figure not shown). The second part of this study investigated the impact of three sulphite concentrations on the microalgal growth and on the biochemical composition of the biomass. Figure 1 shows a growth inhibition at 200 and 600 $mg_{SO_3^{2-}}.L^{-1}$. No inhibition is observed at 50 $mg_{SO_3^{2-}}.L^{-1}$. Both the 50 and 600 ppm stresses did not induce significant changes in the biomass composition in comparison with controls: 20-27% lipids, 30-35% proteins, 30-37% (poly)saccharides. Regarding the 200 ppm stress, a 10% drop and a 7% rise have been found respectively for the protein and the (poly)saccharide contents. These contradictory behaviours can be explained by the variability of the culture duration.

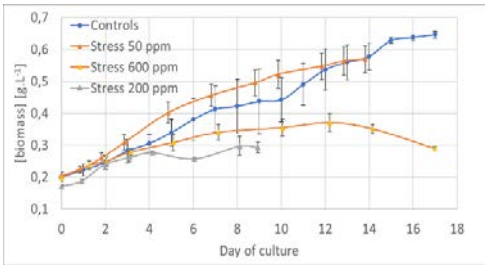

Figure 1. *S. dimorphus* growth under different sulphite stress

4. Conclusions

This study has shown that *S. dimorphus* can grow in a 3N-BBM medium containing 50 ppm of sulphites (related to the solubilization of SO_2) with no significant changes in its biochemical composition. In the future, tests will be done with the *Chlorella vulgaris* and *Cyanidium caldarium* strains. All the cultures will be stopped after 14 days to prevent undesirable differences in the biochemical composition of the biomass due to the culture duration.

Algae4Cycle - Exploiting microalgae biotechnology to treat industrial process waters with extremophilic species

Felix Wollmann*[1], Juliane Steingroewer[1], Thomas Walther[1], Felix Krujatz[1]

[1]*Institute for Natural Materials Technology, TU Dresden, Germany, Bergstr. 120, 01069 Dresden*

**Felix.Wollmann@tu-dresden.de*

Highlights

- Industrial wastewater is treatable with microalgae
- Extremophiles exhibits great potential for process water treatment.
- Nitrogen and carbon load can be reduced significantly
- Process heat can be used economically senseful

1. Introduction

Process waters from food and bioenergy industries commonly exhibit a high load of organic (e.g. sugars) and inorganic (e.g. nitrate, phosphate) residues. The disposal of such process waters is a financial burden for the companies due to high disposal fees or the need to build up an own sewage plant.

In this context, microalgae provide an promising option for wastewater treatments due to their metabolic flexibility, i.e. the ability to metabolize a great variety of organic and inorganic compounds at phototrophic, heterotrophic or mixotrophic growth, coupled with the production of valuable metabolites like fatty acids, proteins or natural pigments. Exemplarily work can be found in literature: The treatment of food waste with *Chlorella pyrenoidosa* and *Schizochytrium mangrovei* showed satisfying growth rates and stable nutrient degradation [1]. *Nannochloropsis* sp. was also used to treat industrial wastewater emitted by an oil refinery, which contains environmental challenging components like cyanide, sulphat and ammonium formate [2]. The wastewater coming from an olive mill was used to produce *Scenedesmus* sp. biomass. [3] There are a lot more published processes using microalgae, for piggery wastewater [4], carpet mill effluents [5] or paper industry wastewaters [6]. A problem for all these approaches is to maintain the axenity of the cultures.

The use of extremophilic strains reduces the probability of contaminations with other microorganisms, caused by their very selective growth conditions. Thus, the project Algae4Cycle aims on the design of a modular on-side plant for treating specifically industrial process waters with high sugar contents using mono- or co-cultures of extremophilic microalgal strains.

2. Methods

First, suitable strains were collected focusing on the utilization of carbon and nitrogen in wastewater-relevant concentrations. Therefore, extremophilic species out of Chlorophyta and Rhodophyta are investigated and their degradation capability and growth capacity is quantified. The growth on different carbon and nitrogen sources is investigated in order to create a database of the metabolic properties of the extremophilic strains.

Galdieria sulphuraria naturally exist in hot thermal springs and is capable of handling harsh

conditions like high concentrations of sulfuric acid or temperatures above 50 °C. *G. sulphuraria* is known for its capability to produce phycocyanin, a blue pigments with high economic value. There are already approaches that show promising results by using *G. sulphuraria* treating urban wastewaters in field scale[7].

Pumiliosphaera acidophila is found in mine-impacted environments with high concentrations of transition metals. It grows optimally at pH 2,5 and 30 °C [8] and is therefore a good candidate for acid-containing wastewaters. Another acidophilic candidate is *Clamydomonas acidophila* which grows optimal at pH 2,5 and offers a high content of lutein [9].

In addition to thermophilic strains there are species which shows a psychrophilic behavior. *Koliella antarctica* was found in the Antarctic sea at temperatures of -1,5 °C. Cultured at 10 to 15 °C *K. antarctica* shows a great accumulation of lutein and astaxanthin [10].

Since not all of the aforementioned microalgal strains were studied regarding the metabolization of organic substrates, growth characteristics using typical organic wastewater constituents were analyzed in this study.

3. Results and discussion

In this study we characterize the spectrum of usable energy sources for growth and assess the capacity for degrading substances arising in common industrial processes. We developed an on-site plant concept, for flexible use with different wastewater compositions and characteristics. Produced process-based waste heat is used for reducing the energy costs of the system and cleaned wastewater is recycled for reuse in producing processes. The aim is, to close the energy and material cycle and gain valuable algae-based by-products.

Techno-economic analysis of xanthan production from liquid wastes of food processing

Bojana Bajić*, Siniša Dodić, Damjan Vučurović, Vladimir Puškaš, Jelena Dodić

University of Novi Sad, Faculty of Technology Novi Sad, Department of Biotechnology and Pharmaceutical Engineering, Bulevar cara Lazara 1, Novi Sad 21000, Serbia

**Corresponding author: baj@uns.ac.rs*

Highlights

- Xanthan production process and cost model was developed using simulation software
- Results represent a basis for preliminary project design of the suggested bioprocess
- Results can be used for further development of xanthan production bioprocess

1. Introduction

Cleaner production through improved material utilization, reduced energy consumption and lower emission levels represents an effective step towards making any production process sustainable. Utilizing waste streams generated from one production process as raw materials for another is just one option for reaching the aforementioned goal. Since large amounts of waste effluents are generated by the food industry, the biotechnological production of xanthan from these effluents could become a solution for re-using wastewater as well as obtaining a valuable product. By modelling the experimental results through a bioprocess simulation software, additional data can be obtained in order to facilitate further research and lead towards the ultimate goal, which is constructing a plant for xanthan production from liquid wastes of food processing [1-3]. Therefore, the aim of this research was to improve the process and cost model of xanthan production on different wastewaters.

2. Methods

Based on the previously published research [3] and in order to improve the xanthan production process, experiments were designed and carried out under optimized conditions for xanthan production on glucose (G) and three different food processing wastewaters (from the production of: biscuits - W1, ethanol from molasses - W2 and sugar - W3) as a basis of the cultivation medium. Experimental data obtained from these experiments has been incorporated into kinetic models, which have been used to simulate a xanthan production bioprocess by the SuperPro Designer simulation software. Figure 1 represents the simplified process flowsheet for xanthan production.

Economic parameters, such as unit production costs, operating costs, total revenues, have been used to compare and evaluate the simulated xanthan production process with the examined wastewaters.

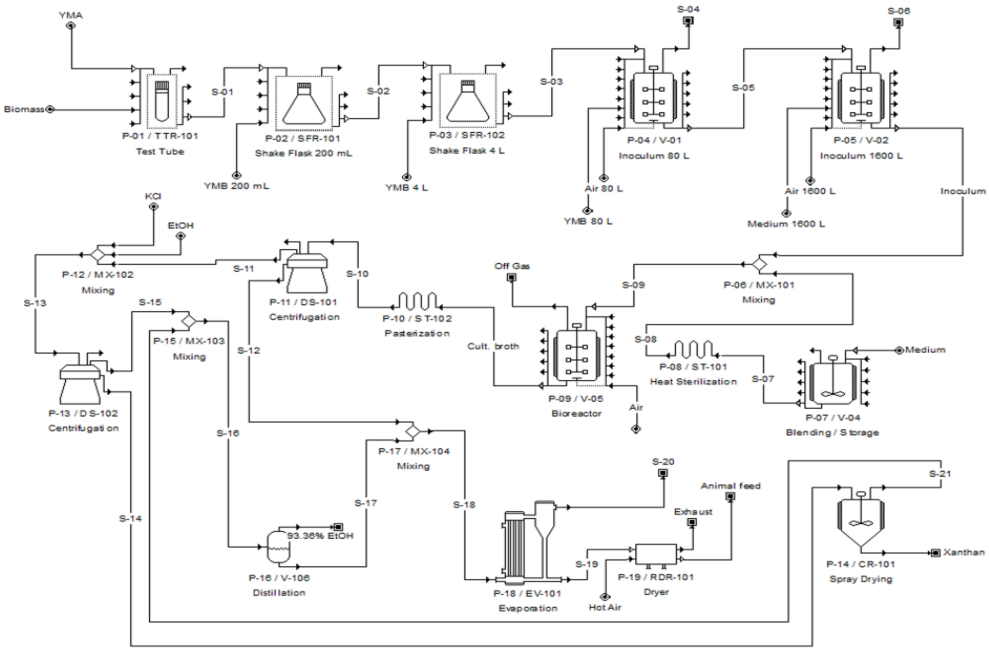

Figure 1. Process flow diagram of xanthan production

3. Results and discussion

As a result of simulated experimental data, table 1 shows the economic analysis of the xanthan production bioprocess model in media based on used wastewaters as well as glucose.

Table 1. Economic analysis of the xanthan production process model

Medium	Working capital [$]	Operating cost [$/year]	Production rate [kg /year]	Unit production cost [$/kg]	Total revenues [$/year]
G	16000	183000	44556.06	4.10	224000
W1	16000	183000	40816.34	4.48	206000
W2	16000	183000	42028.69	4.35	212000
W3	16000	183000	35066.72	5.21	177000

Although xanthan production is the most cost-effective on semi-synthetic glucose based media, the obtained results show that when using different liquid wastes of food processing as a basis of cultivation media, similar values are obtained. Therefore, these wastewaters have great potential to be used as raw materials in this bioprocess.

4. Conclusions

The results obtained through this research showed that the developed process of xanthan production from liquid wastes of food processing is economically and ecologically viable.

**Corresponding author: pfickers@uliege.be*

Highlights

- Three types of erythritol-inducible promoters were compared to *pTEF*.
- *pEYKA3B* and *pHu8EYK* led to 3-fold higher CalB expression than *pTEF*.
- *pEYKA3B* led to 3-fold higher CalB activity than *pTEF*.
- Glycerol 2-L fed-batch enabled consequent *pEYKA3B*-driven CalB production.

1. Introduction

The non-conventional yeast Yarrowia lipolytica is increasingly used as an alternative cell factory for recombinant protein production. Although efficient molecular tools have been developed for this host, there is still a lack of versatile regulated promoters. Such promoters would allow to modulate the detrimental metabolic load inherent to recombinant gene expression [1]. Current regulated promoters respond to hydrophobic inducers, dispersed in the culture medium as an emulsion technically sensitive to maintain, particularly at large scale. Recently, promoters from the erythritol kinase *EYK1* gene [2] and the erythritol dehydrogenase *EYD1* gene [3] have been isolated and shown to be induced by erythritol, a hydrophilic substance. Series of hybrid promoters have been developed from upstream activating sequences (UAS) of *pEYK1*, *pEYD1*, and other promoters, using fluorescent reporter proteins in small-scale cultures [2] [3]. Here we report on the comparison of three types of erythritol-inducible promoters (native, based on *UAS* from *pEYK1*, based on *UAS* from another promoter) and the subsequent selection of the most suitable promoter for proof-of-concept production of the industrial lipase B from Candida antarctica (CalB) in 2-L bioreactor.

2. Methods

CalB expression was driven by promoters *pTEF*, native *pEYD1*, synthetic or *pEYKA3B* (*pEYK1* + 3 *UAS1* of *pEYK1*) and *pHu8EYK* (*pEYK1* + 8 *UAS1* of *pXPR2*). The host strain was optimized for recombinant lipase production, with deletions of alkaline extracellular protease *XPR2*, of extracellular lipases *Lip2*, *Lip7*, *Lip8*, and of *EYK1* gene (to use erythritol as a free inducer, no longer consumed by the cells).

Promoter comparison was based on triplicate 48h cultures in 2Mag mini bioreactors (10 mL working volume). qPCR and lipase activity assays were performed to assess promoter efficiency at gene expression and protein production level, respectively. Proof-of-concept cultures were realized during 72h in duplicate in a 2-L Sartorius bioreactor operated in fed-batch mode, with increasing

glycerol feed values (0.45; 0.9; and 1.35 $g.L^{-1}.h^{-1}$, for 24h each). Lipase activity assays, SDS gel and carbon source HPLC assays were performed on culture supernatants.

The culture medium contained glycerol (10 g/L for 2Mag cultures, 1 g/L initially plus glycerol feed for 2-L cultures) as a main carbon source and erythritol (10 g/L) as an inducer.

3. Results and discussion

Erythritol-inducible promoters *pEYKA3B*, *pHu8EYK*, and *pEYD1* were compared to the strong constitutive promoter *pTEF* for CalB expression and production. At the expression level, *pEYKA3B* and *pHu8EYK* showed a 3-fold higher response than *pTEF*, while *pEYD1* presented the same behavior as *pTEF*. At the production level, *pEYKA3B* delivered a 3-fold higher extracellular CalB activity than *pTEF*, in accordance with qPCR results. *pHu8EYK* and *pEYD1* led to lower CalB activity levels. In consequence, *pEYKA3B* was selected for larger-scale experiments.

In previous studies, the induction levels of *pEYK1*-derived promoters were shown directly correlated with erythritol concentration in the culture medium, and erythritol cellular uptake appeared reduced in the presence of glycerol in the culture medium [2] [4]. Here, reactor cultures were operated in fed-batch mode to allow progressive glycerol feed at 3 increasing concentrations. In these conditions, glycerol accumulation in the culture medium was prevented, while providing sufficient energy for cell growth and CalB synthesis. Hence, during 2-L reactor cultures, CalB was accumulated in the culture medium, reaching a final value of about 900 U/gDCW. SDS gel analysis proved CalB adequate size and integrity in the culture supernatant.

4. Conclusions

Among the three types of erythritol-inducible promoters examined in the present study, the promoter *pEYKA3B* based on 3 UAS_1 from *pEYK1*, stood out with high CalB expression and production levels. Production of lipase CalB in fed-batch bioreactor demonstrated the adequacy of *pEYKA3B* and more generally erythritol-inducible promoters for recombinant protein production.

RECOVERY AND PURIFICATION OF XYLITOL PRODUCED BY THE BIOTECHNOLOGICAL ROUTE USING HEMICELLULOSIC HYDROLYSIS OF CASHEW APPLE BAGASSE AS FEEDSTOCK

José Edvan Marques Junior[1], André Casimiro de Macedo[1], Maria Valderez Ponte Rocha[1*]

[1]*Department of Chemical Engineering, Universidade Federal do Ceará, Brazil*
**Corresponding author: valderez.rcha@ufc.br*

Highlights

- Cashew apple bagasse can be used as substrate for the production of xylitol;
- The anti-solvent and cooling rate influence the crystallization process;
- High crystallization yield and crystals with high purity were obtained.

1. Introduction

The cashew bagasse, an abundant residue, can be used to produce xylitol (Albuquerque et al., 2015) due to its high content of hemicellulose, and after the hydrolysis it is possible to obtain sugars (i.e glucose and xylose) for the production of bioproducts (Albuquerque *et al*., 2015). These carbohydrates can be metabolized by microorganisms capable of transforming them into bioproducts, among them xylitol. Xylitol is a polyalcohol ($C_5H_{12}O$) with wide applicability, ranging from food industry products, as in sweeteners, and to pharmaceutical industry (Albuquerque *et al*., 2015; Misra et al., 2011).

Xylitol is produced in industrial scale by chemical hydrogenation of xylose, but this process presents high operating costs (Misra et al., 2011). Therefore, many studies have sought alternative routes for its production, such as in processes which microorganisms or their enzymes are involved. After the production of xylitol, the recovery and purification of the product exists. In literature, very little information is available about xylitol recovery and mainly reports are related to the obtainment and treatment of the hemicellulosic hydrolysate, its fermentation and metabolic bioconversion (Wei et al., 2010; Kaialy et al., 2014).

In this context, the biotechnological production of xylitol by yeast *Kluyveromyces marxianus* ATCC36907 using the hemicellulosic hydrolysate from cashew apple bagasse was performed with emphasis in the study of the crystallization process. In this crystallization process, different anti-solvents such as: ethanol, isopropanol and protic ionic liquid 2-(hydroxy)ethylammonium acetate (2-HEAA), percentages of anti-solvents and linear cooling rate were studied.

2. Methods

2.1. PREPARATION OF CASHEW APPLE BAGASSE HYDROLYSATE: Cashew apple (*Anacardium occidentale* L.) bagasse (CAB) was kindly provided by Jandaia Industry of Juice (Ceará, Brazil). The CAB was washed, dried at 60 °C for 24 h and milled to pass through 20-80 meshes. Cashew apple bagasse hydrolysate (CABH) was obtained from the treatment of CAB, with diluted acid sulfuric. The treatment was conducted in autoclave at 121 °C for 15 min, using 0.6 mol L^{-1} H_2SO_4 and a solid

percentage of 20% w v^{-1}. Afterwards, the liquid fraction was collected by vacuum filtration, the pH was adjusted to 6.0 ± 0.2 with $Ca(OH)_2$, and it was filtrated to separate the precipitate. The filtrate, here named CABH, was used as culture media for xylitol production.

2.1 PRODUCTION OF XYLITOL: The biotechnological production of xylitol by *Kluyveromyces marxianus* ATCC36907 was carried out in a shaker using the CABH as fermentative medium. This production occurred at 30 °C, 180 rpm for 96 h using 10% v/v of inoculum.

2.2 SOLUBILITY CURVES AND CRYSTALLIZATION OF XILITOL: Initially, the solubility curves of xylitol in different anti-solvent: water, 50% v/v water-ethanol, 50% v/v water-isopropanol, protic ionic liquid (2% hydroxyethanolamine acetate - 2-HEAA) – water 50% w/v at temperature of 5 °C and 70 °C, were constructed. After, crystallization processes were performed, using xylitol PA and the fermentative medium, evaluating different proportion of anti-solvent (50% and 70%) and the linear cooling rate (0.25 °C/min and 0.5 °C/min).

3. Results and discussion

The xylitol was soluble in the four evaluated anti-solvents (water, ethanol, isopropanol and 2-HEAA) at high temperatures, and the solubility decreases with decreasing temperature. The highest solubility of xylitol was observed in water and the lowest solubility was in 2-HEAA. Due to the shape of the curves one can use crystallization by anti-solvent, or physical precipitation, facilitating the formation of crystals of medium size, and may occur primary or secondary nucleation.

In the experiments of crystallization, the influence of the anti-solvent ratio and the cooling rate (C_r) were evaluated. The three anti-solvents showed close yields in process using xylitol PA, except in the process using ethanol 70% v/v and C_r of 0.25 °C/min, which obtained the highest crystallization yield (93%). C_r influenced the crystallization yield, a higher rate favored crystallization using 70% v/v anti-solvent ratios. However, the low cooling rates favors the formation of crystals at a lower temperature. In some conditions, the produced xylitol was not crystallized using the anti-solvent 2-HEAA and the ethanol at C_r of 0.50 °C/min in both proportions (50% and 70%), and using 70% v/v of isopropanol applying both C_r. One possible reason is the presence of xylose in the fermentative medium. Higher crystal purity 85% and higher crystallization yield 69% were obtained using 50% v/v isopropanol. Similar results were obtained by Wei *et al*. (2010).

4. Conclusions

These results show that the studied microorganism can be applied in promising experiments based on xylitol production from CAB hemicellulosic hydrolysate as carbon sources. Moreover, it was possible to recover xylitol from the fermentation medium through the crystallization process.

Highlights

- Three samples of Colombian crude glycerol were characterized.
- The effect of crude glycerol components on volumetric productivity of lactic acid fermentation was evaluated.

1. Introduction

In recent years, biofuels has been widely used and their production has grown exponentially. Crude glycerol – CG- is the main by-product obtained from the production of biodiesel from vegetable oils, in quantities of 10-40% by weight. In 2017 the production of biodiesel in Colombia was 459,807 tons and it is estimated that by 2020 its production will be six times higher than the market demand. As a consequence, CG has a great potential to be used as a raw material in other processes due to its low commercial price. However, one of the main challenges is the variability of its composition, since it depends on biodiesel production parameters. Despite the importance of CG chemical composition, few references have been found on its characterization [1,2].

On the other hand, our previous work showed that crude glycerol used as a substrate in lactic acid fermentation allows higher productivities than glycerol USP. Therefore, it is vital to understand the effect of CG components on reactions catalyzed by microorganisms [3].

In this sense, this research explains the effect of CG components on the volumetric productivity of lactic acid. To fulfill this scope, the following stages are being developed: a) chemical characterization and identification of CG compounds of three samples, b) design of experiment of mixtures to evaluate the productivity of Lactobacillus sp. in a fermentation medium.

2. Methods

In general, three methods were used for the chemical characterization of CG: the periodic iodometric acid method, liquid chromatography (HPLC), and gas chromatography [1]. The density of CG was determined by measuring volume and weight at room temperature. To determine the pH, CG was measured by a digital pH meter at room temperature. The viscosity of the CG was obtained using a viscometer, and the ash content was determined by a high temperature furnace. The soap and alkalinity content in CG were determined following the methodology recommended in AOCS Cc 17-95. The water content was determined by volumetric Karl Fischer titration. All measurements were made in triplicates [2].

Also, aerobic fermentations were performed with *Lactobacillus* strains (ATCC 7469 and 393) in a medium with CG as a carbon source, which contained nutrients and and trace elements that favored lactic acid production [4].

Fermentations were carried out with each sample of CG, with glycerol USP, and synthetic CG composed of the main CG components. In this way, the influence of the compounds identified as potential substrates in the fermentative production process of lactic acid was evaluated. Considering the CG characterization, different media were formulated. A synthetic glycerol medium was constructed in which three minority components found in the samples were involved, and the fermentation process was developed as described. The simplex network design, Simplex-Centroid Design - DCS, was chosen because it was desired to consider the points inside the region, because in the case of glycerol it is possible to obtain mixtures containing all the components. Finally, the metabolites were identified and quantified by HPLC, each test was done triplicated.

3. Results and discussion

All CG samples showed low FFA contents, it indicates they are derived from the acidification of the soap that existed in it. Also, the soap contents were relatively high. The composition of the samples varied significantly. The strain *Lactobacillus rhamnosus* ATCC 7469 in an axenic culture, achieved a satisfactory assimilation of CG. Reaching conversions up to 90%, after a stage of adaptation. For the evaluated conditions, it was possible to identify that the optimal volumetric productivity is around 10 hours of fermentation.

4. Conclusions

Despite the variation in the proportion of their components, all CG samples were shown to contain glycerol, soap, methanol, FAMEs, water, glycerides, FFAs, and ash. It is necessary to characterize the composition of CG before considering any value-added conversion.

The CG components influence the response variables of the fermentations, which improves or inhibits the growth and the conversion capacity of the microorganism. These effects depend directly on the biodiesel production process and its conditions, the raw materials used and the purification processes.

Highlights

- Optimization and characterization of an aerosol-based photobioreactor
- Long-time cultivation and characterization of phototrophic biofilms
- New downstream process for extraction of EPS and pigments

1. Introduction

Cyanobacteria offer a great potential for the production of biotechnological products. They can be divided into two groups: terrestrial and aquatic cyanobacteria. Terrestrial cyanobacteria are living embedded in self-produced extracellular polymeric substances (EPS) and show a pronounced surface-associated or air-exposed growth. They have so far been neglected as potential production organisms due to the lack of cultivation systems (Strieth 2018). And that regardless of the fact, that biofilms can render biotechnological processes simpler and more efficient. Thus, no (harmful to humans) chemicals for an artificial immobilization are necessary because phototrophic biofilms naturally adhere to surfaces. Product purification of secreted substances is facilitated by immobilized cells and higher productivities can be achieved in continuous processes (Strieth 2017) as the growth rate can be decoupled from the dilution rate (Muffler 2014). At the chair of bioprocess engineering an emerse photobioreactor (ePBR) was developed where the medium is given as an aerosol (Kuhne 2014, Strieth 2017). The system imitates natural habitats of terrestrial cyanobacteria in the desert and the rain forest. During the last decade, a few biofilm photobioreactors were developed imitating different natural habitats of terrestrial cyanobacteria. The latest developments are summarized, illustrated and compared in the reviews of Podola 2017 and Strieth 2018. Hitherto, the majority of biofilm photobioreactors are used in lab scale resulting in small amounts of biomass that can be utilized for further analysis. To facilitate the characterization of small amounts of biomass, a combined extraction of EPS and the pigments (i) chlorophyll-a, (ii) carotenoids and (iii) phycobiliproteins has been developed. This is important for a comprehensive characterization of the cells in order to be able to draw conclusions about the state of the cells. For example, EPS are produced as protection against suboptimal culture conditions. Carotenoids are produced, among other things, for cell wall stabilization. Essentially, the pigment composition depends on the available light spectrum, temperature and availability of nutrients.

2. Methods

The most important parameter of the optimized ePBR were characterized like residence time resolution of the aerosol (experimental by using high-speed camera and simulated using OpenFOAM), droplet size, the light and temperature distribution (experimental by using a quantum

sensor and a laser thermometer and simulated using MatLab) and the surface texture (roughness using AFM and hydrophobicity). The terrestrial cyanobacterium *Trichocoleus sociatus* was cultivated on three different substrates (PMMA, borosilicate glass, silicone) in the ePBR at 24 °C and 24 hours of aerosol supply. In addition, the influence of different temperatures (24, 30, 37 °C), amount of aerosol per day (4, 8, 12, 24 h) and the influence of higher amounts of CO_2 (0,03, 2, 5, 10 %) and flue gas were investigated. To characterize the biofilm a new downstream process was developed where the EPS was extracted in a first step using an optimized method and the pigments (phycobilisomes, chlorophyll and c-phycocyanin) in a second step. Optical coherence tomography was used to determine the biofilm thickness over the cultivation time and two-dimensional growth was measured over chlorophyll-a fluorescence using a PAM fluorometer.

3. Results and discussion

Different surfaces showed no influence on the biomass production and the pigment composition, whereas on hydrophilic surfaces more vertical growth and on the hydrophobic surface rather horizontal growth could be observed, which was attributed to the hydrophobicity of *T. sociatus*. In addition, increased EPS production was demonstrated on the hydrophilic surfaces due to the horizontal spread of the biofilm in combination with the hydrophilic properties of the EPS. The layer thickness stagnates in the ePBR at 600 µm, which is presumably caused by the low light availability. Thus, higher layer thicknesses of up to two mm were achieved at higher light intensities. The biofilm thus actively adapts to the availability of light, as shown by the degradation of the pigments but also in the production of EPS. The growth of *T. sociatus* at 24 °C was antiproportional to the amount of aerosol per day and higher EPS yields were achieved at longer dry times. An increase in temperature led to a desiccated biofilm were no growth could be achieved at 37 °C and 8 h aerosol supply. The interaction between aerosol delivery and temperature could be modeled via the black-box system and verified with a further experiment. A developed semi-continuous process led to increased EPS yields with targeted growth and dry phases. In addition, an increased production of an antibacterial substance under extreme conditions was demonstrated. The structure of the substance is currently being investigated. The developed process could be used in industry for the production of EPS or secreted substances. Cultivations with elevated CO_2 concentrations unexpectedly led to growth inhibition. Interestingly, almost identical biomass productivities were achieved using atmospheric CO_2 (380 ppm) and flue gas (10 % CO_2). Thus, CO_2 does not appear to be the reason for growth inhibition at elevated CO_2 concentrations.

4. Conclusions

The cultivation of *T. sociatus* in the optimized ePBR was successful and the influence of temperature and aerosol per day could be modeled. The biomass and EPS productivities in the ePBR are higher than in submerse reactors and can be targeted influenced using different times of dry phases.

Highlights

- Cyphos 108 is able to permeabilize the cells.
- Lipids are extracted from intact cells.
- Proteins and carbohydrates are recovered after cell disruption
- Hydrophobic and hydrophilic compounds can be efficiently separated.

1. Introduction

Microalgae are promising feedstocks for biofuel production. These photosynthetic microorganism have high lipid productivity and do not compete for arable land when compared to terrestrial oleaginous crops. Microalgae have a very tough cell wall and thus require energy intensive unit operations to break open the cell and release the intracellular content. Apart from lipids, microalgae are also good sources for proteins, carbohydrates and pigments. Utilization of these value added co-products for food, cosmetics, health and chemicals would help in making the process economically feasible.

The primary objective of this article is to fractionate the algal biomass into a hydrophobic fraction (lipids) using mild pre-treatment at low temperature with an aqueous solution of ionic liquid and keep the microalgae intact followed by cell disruption to obtain the hydrophilic fraction (proteins, carbohydrates) in their functional state. [Calibri 11].

2. Methods

N. oleoabundans cells ~10 mg of cells (freeze dried and/or fresh cells) were treated with 1.5 ml of aqueous solution of IL at 45°C for 30 minutes. Fresh and freeze dried cells used in the study were from different batches. The studies were conducted with 2 different ILs BMIM DBP and TBP SO4 (see Table 1). The influence of IL concentrations (40, 80) % w/w on extraction efficiency of lipids was investigated. The amount of lipids extracted in the IL phase was determined by measuring the residual amount of lipids remaining in the cells. [Calibri 11].

Sr. No.	Ionic Liquid Names	Abbreviations
1	Tributylmethylphosphonium methyl sulfate (Cyphos 108) > 95 %	TBP SO4
2	1-Butyl-3-methylimidazolium dibutylphosphate 97 %	BMIM DBP

3. Results and discussion

Two classes of ILs (see Table 1) were studied. Pre-treatment with imidazolium (BMIM DBP) based ionic liquid showed better lipid extraction efficiency and phosphonium (TBP SO4) based ionic liquids showed low extraction efficiency but could have impact on the cell wall and hence selected for further studies. Lipid extraction efficiency of aqueous IL solutions at different concentrations (40, 80) % w/w were studied at temperature of 45°C (see figure 1). In this study, lipids represent the fatty acid methyl ester content that could be converted to biodiesel. As the concentration of IL increases from 40% w/w to 80% w/w at 45°C, the amount of lipid extracted increases from 2.61% to 9.89% per mg of biomass for BMIM DBP and from 1.28% to 3.27% per mg of biomass for TBP SO_4. This increase in extraction capacity could be attributed to the increase in hydrophobicity of the IL solution. IL solutions under mild conditions were able to extract lipids from intact microalgae cells. Based on the results in figure 3, BMIM DBP could permeabilise the cells and extract lipids better than TBP SO4 indicating that the cation and anion influences the extraction efficiency, but to a different degree. Although, TBP SO4 shows low lipid extraction efficiency, it might still have an influence on the cell wall. The hypothesis is that the hydrogen bonding network of the cell wall is disrupted leading to the formation of pores through which lipids can leak-out. ILs are known to solubilize natural polymers such as cellulose and pectin by direct IL interaction. [Calibri 11].

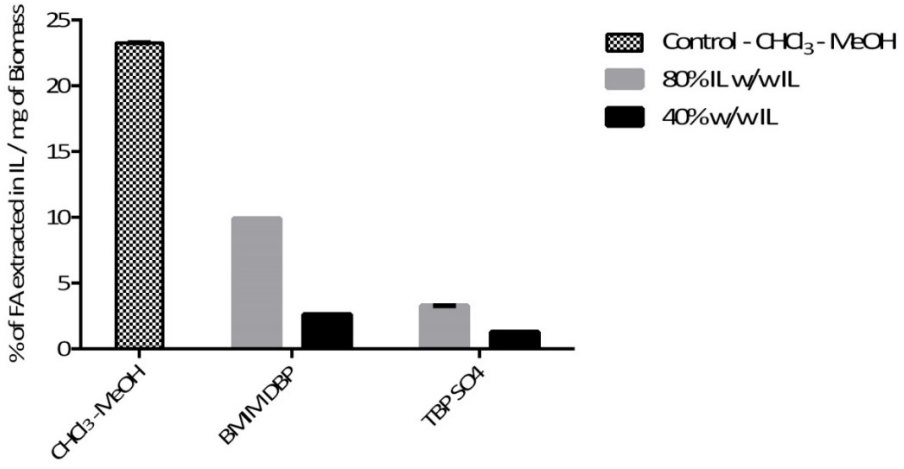

Figure 1. Effect of IL concentration on extraction of lipids at 45°C Caption. [Calibri 9].

4. Conclusions

In this article, pre-treatment of *N. oleoabundans* using ILs and subsequent fractionation into hydrophilic and hydrophobic components was studied for both fresh and freeze dried biomass. Additionally, the lipid extraction efficiency of aqueous IL solution under different concentration conditions were studied. We have demonstrated that aqueous solution of imidazolium and phosphonium based ILs was able to extract lipids from intact microalgae, albeit to a different degree. We have also shown that pre-treatment of microalgae with BMIM DBP and TBP SO4 at low concentration (40% w/w) results in permeabilisation of cells. The biomass can then be fractionated into hydrophilic and hydrophobic components whereby the proteins were recovered without losing their nativity. The recovery of total fatty acids was ~68% and that of proteins and carbohydrates was ~ 80% and 77% respectively of the total amount present in the cells, after pre- treatment of fresh biomass with TBP SO4. [Calibri 11].

Highlights

- Methanol feeding rate PID-control
- *P. pastoris* DCW of 100 g/L
- HBcAg yield 3.5 mg (protein)/g (cell wet weight)

1. Introduction

Hepatitis B virus core-antigen (HBcAg)-made capsids are being intensively investigated for various biomedical applications [1]. Industrially-applied recombinant protein expression host of methanotroph *P. pastoris* GS115 is well suitable for obtaining HBcAg. Characteristic methanotroph *P. pastoris* host property is utilization of methanol as a carbon and energy source, while methanol presence in the medium ensures induction of recombinant protein synthesis. Although methanol concentration (MC) influence on recombinant protein synthesis level is well known, this factor is not studied on HBcAg obtainment with *P. pastoris*. If on-line MC measurements are available, PID-control algorithm can be applied for pre-set MC control by manipulating methanol feeding rate to the bioreactor. Screening results of various MC levels of "methanol-limited (≈0 g/L)", 1, 3 and 5 g/L for improved HBcAg obtainment, will be analyzed within the Postdoctoral research project (Project Agreement No. 1.1.1.2/16/I/001, Research Application No. 1.1.1.2/VIAA/1/16/186).

2. Methods

Methanol PID-control algorithm, adapted from Cos O. et al. [2], was programmed in Matlab. Laboratory bioreactor (5 L) communication architecture of DCU-SCADA-(OPC)-Matlab is well described in the previous research [3]. Detailed information on recombinant host and HBcAg downstream processing is available [4]. Cultivation conditions selected regarding Invitrogen co. protocol (Pichia Fermentation Process Guidelines) for Mut+ strains. On-line methanol was measured with BCP-EtOH off-gas analyzer (Bluesens).

3. Results and discussion

Results of methanol 1 g/L set-point control process are shown in Figure 1. Characteristic methanol peak appears at the beginning of methanol feed start phase (peak height around 3 g/L). During culture adaptation to methanol (30-42 h), methanol limited conditions are obtained. Afterwards, automatic methanol feeding for set-point control of 1 g/L was activated. Around 2-hours-long

methanol peak of 2 height g/L appears at the beginning of the automatic methanol control phase. Further methanol control resulted in close process MC to the set-point value, where at the process end phase, due to process disturbance from operator's side and achievement of culture maximum capacity, methanol deviation from set-point occurs. Finally, culture dry weight biomass of 100 g/L was obtained. HBcAg accumulation dynamics was analyzed from "methanol-limited" process: HBcAg yielded in 2.8 mg (protein)/g (wet cell weight) at 48 process h, and 3.5 mg (protein)/g (wet cell weight) at process 75 h. The following identified PID control parameters: Kp=0.05 L*L/g*h (proportional gain) and t_pid=10 min (integral time constant) were used.

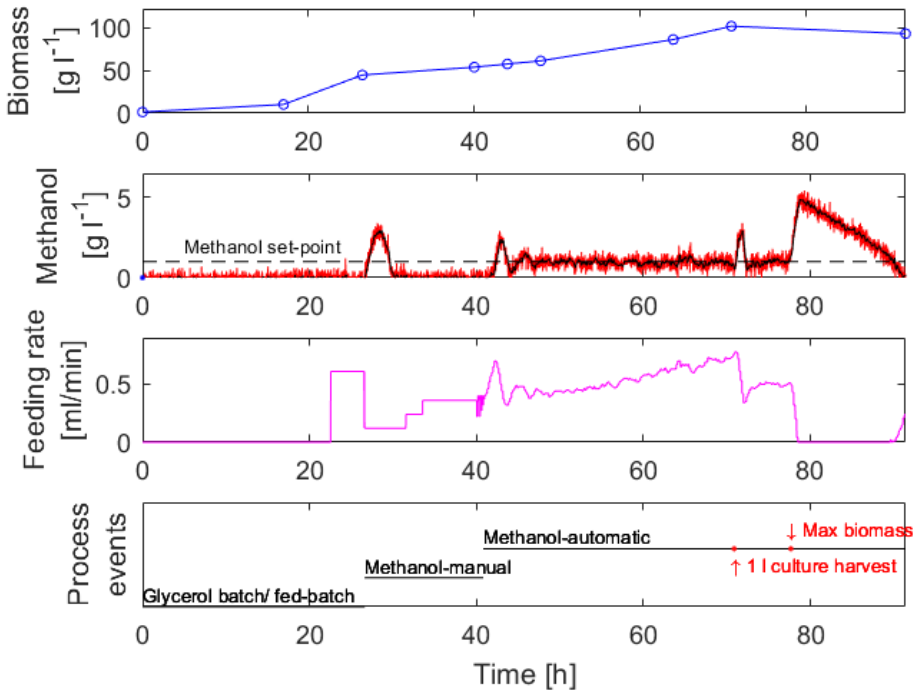

Figure 1. Biomass: off-line dry weight measurements (circles); Methanol: on-line signal (red line), filtered signal (black line), set-point (dashed line); Feeding rate: bioreactor variable; Process events: control, events and observations.

4. Conclusions

Implemented MC PID-control is capable for on-line MC close control to set-point of 1 g/L. Further process optimization with set MC of 3 and 5 g/L should be performed. HBcAg accumulation dynamics in these processes should be analyzed.

**Corresponding author: elen.aquino@unifesp.br*

Highlights

- Selection of four methanotrophic consortia highly resistant to methane.
- Methane consumption confirmed through pMMO activity analyzed by PCR.
- PHB production of 15% (w/w) under 70% methane atmosphere

1. Introduction

Methane gas is abundantly present in the environment due to its both natural and anthropogenic production. However, methane is a harmful gas since it is one of the causes for the greenhouse effect. Its production has been increasing 10 ppb per year [1] and since methane has a greenhouse warming potential (GWP) 28 times higher than carbon dioxide [2], it is necessary to search for alternatives to mitigate it from the atmosphere. The use of methane as substrate for biodegradable plastics production would be an alternative to solve another issue of public awareness: the damage caused by the increasing production of non-biodegradable plastics. Methanotrophic bacteria are ubiquitous in the environment and have the ability of producing polyhydroxybutyrate (PHB) from methane under specific conditions [3]. PHB is a biodegradable plastic that still presents high production costs [4] and using methane as feedstock for biopolymer production could make the price competitive for the commercial market.

2. Methods

Mangrove sediment samples were collected and enriched with methane concentrations in the atmosphere increasing from 20% to 70% (v/v) during 40 days. The enrichment was performed using closed flasks coupled with needles and hoses to perform atmosphere change every seven days. From these samples, four different consortia were selected and analyzed by molecular biology through PCR reaction to confirm the methane monooxygenase (pMMO) activity and methane consumption. These consortia were tested for PHB production with N-free NMS during 30 days

under 28 °C and 180 rpm. By the end of the experiment, PHB was extracted from inside bacterial cells as described in [5], collected and characterized by magnetic nuclear resonance (NMR).

3. Results and discussion

From mangrove samples, four consortia were selected and named MC, MG1 SED, MG2 and MG2 SUB. PCR analysis of the pmoA gene were performed and resulted positively for all the consortia. The gene pmoA is responsible for pMMO enzyme which oxidizes methane to methanol in the first step of methanotrophic metabolic pathway, confirming the methane consumption. PHB production was tested in closed flasks under 70% methane atmosphere in air (v/v). Atmosphere was changed every seven days to ensure the availability of high methane concentration inside the flasks. Results of PHB production reached nearly 15% of PHB (w/w) for all the consortia (Figure 1). Extracted PHB was collected and characterized by RMN to confirm the chemical characterization.

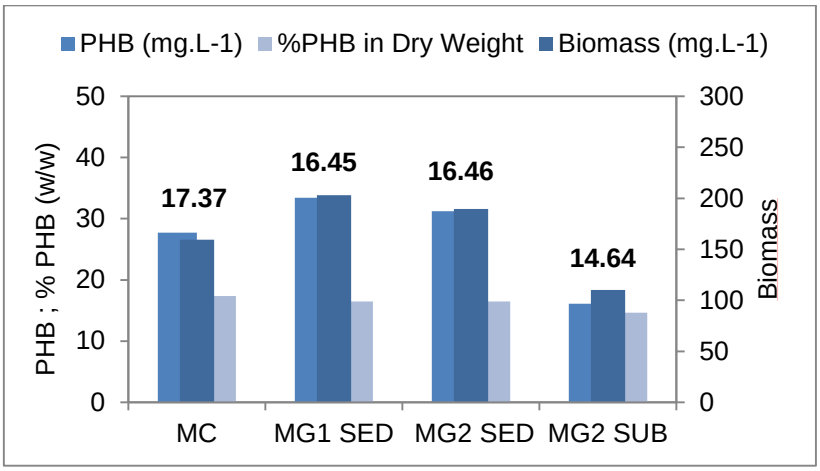

Figure 1. Biomass, PHB production and %PHB (w/w) of the consortia under 70% methane atmosphere after 30 days.

4. Conclusions

Four methanotrophic consortia highly resistant to methane were selected from environmental samples. All of them presented the pmoA gene, ability to consume methane and to produce PHB. PHB production reached 15% (w/w), which is a promising result when considering it has been made using a one-carbon molecule as feedstock.

Photohydrogen production from cheese whey by recombinant strains of *Rhodobacter capsulatus*

Patricia Castillo-Moreno[1], Carlos Arturo Martínez[1], Juan Carlos Serrato[1], John Willison[2] and Jean Pierre Magnin[3]

[1]Laboratorio de Ingeniería Química, Universidad Nacional de Colombia, Bogotá, Colombia; [2]Laboratoire de Chimie et Biologie des Métaux, CEA-Grenoble, 38054 Grenoble, France; [3]LEPMI, Grenoble INP- Université de Savoie - Université Grenoble Alpes BP75. 38402 Saint Martin d'Hères Cedex, France

**Corresponding author: pcastillomo@unal.edu.co*

Highlights

- H_2 production from cheese whey was modeled and optimized.
- Recombinant *R. capsulatus* IR3 strain containing the E. coli lacZ gene was used.
- Hydrogen production was obtained with cheese whey concentration of 90%.

1. Introduction

Hydrogen is considered as a clean energetic source [1]. Biological methods are a strong option to produce it because less energy than conventional methods is required, and waste materials or byproducts of the industry can be use as substrate. However, the efficiency of biological methods is low so many researches focus on increase it by optimized conditions and media [2]. Among the industrial effluents that can be use as substrate, cheese whey (CW) was selected due to it's composition [3]. The photofermentation process stands out among the biological methodologies for its rates of substrate conversion. Photosynthetic non-sulfur bacteria catalyze the hydrogen production by the action of the nitrogenase [4,5]. In this study, a photofermentative process was used to produce hydrogen from CW with a recombinant strain of *Rhodobacter capsulatus*. The recombination allows the degradation of the lactose by the action of a plasmid containing β galactosidase gene under dependence of nifH promoter [6].

2. Methods

2.1 Bacterial strain and cheese whey

The bacteria used in this study was *Rhodobacter capsulatus* strain IR3::LacZ originated from a H_2 superproducer strain IR3 [7]. Bacterial pre-culture medium was RCV, under anaerobic conditions. The cheese whey powder used was bought to CIMPA s.a.s a Colombian company. The CWP was solubilized in deionized water (1 kg CWP / 9 L water) and heat-pretreated.

2.2 Batch experiments

Reactors used for the batch experiments were 0.125 L glass square bottles, sealed hermetically with a rubber stopper and with a magnetic stirrer for mixing. The cultures were carried out in an

illuminated incubator (lab-made) with temperature regulation at 30°C. Illumination was provided by a high-pressure Na lamp. Biogas produced volume was measured by water displacement.

2.3 Experimental Design

A Central composite face centered design of experiments was applied using the statistics software Design Expert 8.0 to evaluate the effects of 3 variables: **A.** Cheese whey concentration (%), **B.** Molybdenum concentration (µM), **C.** Light intensity (lx). The response studied was the H_2 specific volumetric production (ml L^{-1}).

3. Results and discussion

A quadratic model was the best fit for the relation between the three continuous parameters and the response (equation 1). The 3 variables studied were significant.

$$\mathbf{Y\ (ml\ L^{-1})} = 5668 + 3118\ A + 1265\ B - 867*C + 1227\ B*C - 2036\ A^2 \quad \text{(Eq1)}$$

The model was statistically validated, and the 3D surface response and the cubic plot were used to describe the behavior of the study's area. Maximum values of H_2 production were observed at superior levels of CW concentration. This is a desirable result because the higher concentration of CW, the lower work volume and that increases the productivity of the process. The equation and plots indicate that the variable that influences the most the H_2 production is the CW concentration. The interaction of Mo concentration and light intensity is also significant to the process.

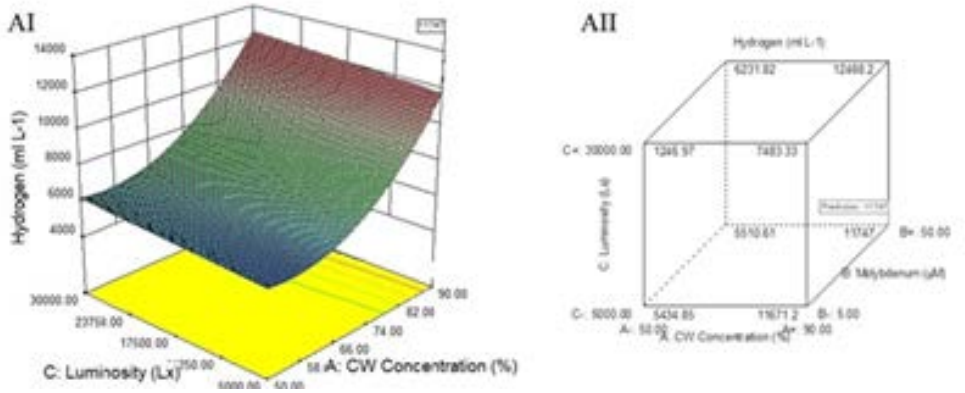

Figure 1 3D and cubic representations of H_2 specific volumetric production

4. Conclusions

The influence of the variables CW and molybdenum concentration and light intensity over the H_2 production by *Rhodobacter capsulatus* IR3::LacZ was successfully determined and optimized with DOE methodology. The study led to improvements in the efficiency and productivity of the process. This methodology proves to be useful both for producing hydrogen and as a treatment for cheese whey. The consumption on lactose, after the bacterial action, can reach 98% reducing the environmental impact of this waste stream.

Effect of enzymatic pretreatments on sewage sludge anaerobic digestion.

Montserrat Perez[1], Cristina Agabo[1], Juan Parrado[2], Rosario Solera[1]

1. Dept. Environmental Technologies. IVAGRO. University of Cadiz
2. Dept. Biochemistry and Molecular Biology. University of Seville

*montserrat.perez@uca.es

Highlights

- Anaerobic digestion process.
- Enzymatic hydrolysis of sludge.
- Biomethane potential.

1. Introduction

Stabilization of sludge by anaerobic digestion is a crucial step to remove pathogens, solids and bad odours, to increase the ammonia content and to enhance the partial mineralization of organic matter. This operation has an extra value due to the biomethane potential production and hence energy saving. For this purpose, different technologies have been developed in order to increase the biomethane potential in anaerobic digestion processes. These studies are mainly focused on increasing the biodegradability of sludge by physico-chemical and/or biochemical methods, improving hydrolysis step in overall anaerobic digestion process (Yu et al., 2013). In this sense, the application of purified enzymes is recognised as an effective hydrolysis pretreatment in order to increase biodegradability of residues (Zhen et al., 2017).

2. Methods

The inoculum was obtained from 5L single-phase dry-mesophilic AD operating at HRT = 20 d. The sludge as substrate was obtained from the aerobic digester in Experimental WWTP in Center for Water New Technologies (CENTA) in Carrión de los Céspedes (Seville, Spain). The substrates were previously pre-treated by different enzymatic pretreatments Glucanase (G), Cellulase (C) and Protease (P), at concentration 0.3% w/w.

250 ml BMP serum bottles were used in order to determine the methane potential of different pretreated samples. The digesters were initially loaded with a mixture of 40% v/v inoculum and pretreated sludge. Control reactors were also incubated. All the anaerobic digestion experiments were carried out until all the available carbonic content was converted to biogas (23 days). All reactors were run in duplicates. At the beginning and at the end of each experiment the samples were characterized in order to evaluate the biodegradability of the samples. During the experiment volume and composition of biogas produced were registered.

3. Results and discussion.

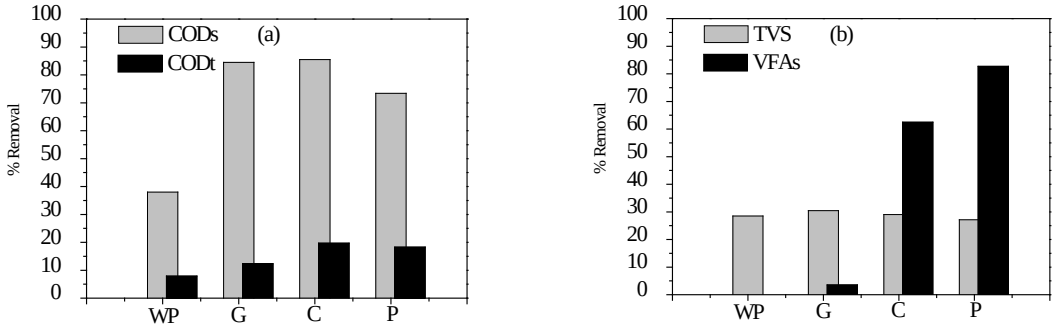

Figure 1. Biodegradability parameters removal. (a) CODs and CODt ; (b) TVS and VFAs.

In general, CODt and TVS removal efficiency is in the range 10-20% and 30% respectively. However, CODs removal percentages are very similar and higher (73.4-85.5%) than control (WP) (38%). In the case of experiments C and P the elimination of VFAs was optimal and in the range of 63-83% typical from sewage anaerobic digestion process. In the case of G pretreatment, the removal of VFA was reduced (about 3.5%) due to the substrate was worse conditioned by using glucanase.

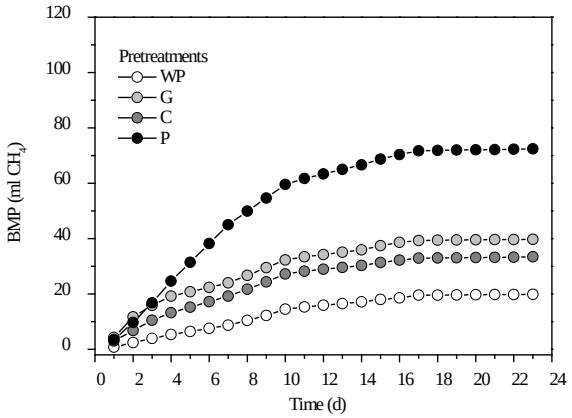

Figure 2. Accumulated biomethane production through the time for different pretreated substrates.

Maximum values of biomethane production (72 mL CH_4) were obtained using substrates pretreated by P treatments. On the other hand, C experiment only produce 33.2 mL CH_4 biogas, probably due to lower values of VFAs removal. Glucanase also increase biomethane production generating values between 30 mLCH_4 in 20 days. Regarding that, control sample (WP) produced only 20 mLCH_4.

4. Conclusions

Any of the tested pretreatments enhance biomethane generation. Pretreatment of protease is the best pretreatment enhancing biodegradability of substrates as well as biomethane production.

Highlights

- Plant-based protective agent for wood-based materials
- Biotechnological process with *Salvia* cell suspension cultures
- Combination of sucrose fed-batch and elicitor increase the volumetric triterpene yield

1. Introduction

Wood is one of the most important renewable raw materials. The use of wood preservatives contributes to the protection and increases the resistance of the material against harmful organisms such as mold fungi. Most currently available protective agents for the treatment of wood-based materials are almost completely chemicals that contain substances that are harmful to the environment and hazardous to health. In order to minimize these harmful effects on the environment and humans, manufacturers are searching new bio-active substances as alternative to conventional fungicides for products made of renewable raw materials.

Plant secondary metabolites occur in a wide variety and high structural diversity in all higher plants. They are involved in the defense mechanisms of plants and accumulate in cells when abiotic or biotic stress occurs. Therefore, many secondary metabolites have an antimicrobial, hydrophobic and antifungal effect. *Salvia* species contain a large number of bioactive pharmaceutical ingredients, like flavonoids, terpenes or phenols that exhibit antibacterial, antiviral and antifungal activities. Two of these compounds are oleanolic acid (OA) and ursolic acid (UA). Both are constitutional isomers and belong to the group of pentacyclic triterpenic acids.

Extracts or ingredients of plants are traditional produced from agricultural material. Depending on several influencing factors such as the location and period of production, the obtained extractives differ in quality and quantity. For a continuous, sustainable production of plant ingredients, the use of biotechnological processes based on plant *in vitro* cultures is required. The cultivation of plant cells in a closed bioreactor system ensures the sustainable production of plant secondary metabolites with consistent quality and quantity [1]. To reach reasonable productivities with plant cell suspension cultures, elicitation is a widely used strategy. The systematic use of so-called elicitors in plant cell cultures stimulates the plant defense mechanisms, which can be used to increase the yield of the active substances [2].

The aim of the presented work is to develop a sustainably produced bio-based wood protective agent with plant *in vitro* cultures in a closed bioreactor system. To increase the productivity of the process, an elicitation strategy combining treatment with fungal medium filtrate and sucrose feeding will be applied.

2. Methods

The development process of the production for a protective agent for plant-based wood materials is illustrated in Figure 1.

Figure 1. Planned process flow for the production of a bio based protective agent for wood-based materials.

For the fungal medium filtrates, the mold fungi *Aspergillus niger* (DSM 1957) and *Trichoderma virens* (DSM 1963) were each cultivated in 1 l shaking flasks with 500 ml of 1.5 % malt extract medium for 14 days. The mycelium pellets were separated from medium by a three-step filtration [3]. For the plant cell culture, *Salvia fruticosa* was cultivated in Linsmaier and Skoog medium with 30 g l^{-1} sucrose and 0.2 mg l^{-1} 2.4-dichlorophenoxyacetic acid at 26 °C, 110 rpm in darkness and sub-cultivated every 10 days with 20 % inoculum volume. The fed-batch cultivation and the elicitation procedure were performed as described in [3]. The extraction of intracellular triterpenes was carried out with a mortar and ethanol as extraction agent. The analysis of the extracts for OS and US was performed by HPLC [4].

3. Results and discussion

To further increase triterpene productivity of *S. fruticosa* cell suspension, preliminary experiments of nutrient feeding with the application of 30 g l^{-1} sucrose at the end of the cell growth on day 10 successfully led to additional growth and higher levels of triterpene contents, volumetric yield and productivity. With the combination of sucrose fed-batch and elicitation with fungal medium filtrate, this value was further exceeded. Expressed in analytical values, a content of 16.3 mg l^{-1} OA was determined for the pure *S. fruticosa* cell suspension. The yield was increased to 32.6 mg l^{-1} by the addition of *T. virens* fungal medium filtrate. Through the combination of elicitor and sucrose fed-batch the yield could be increased to 112.9 mg l^{-1}, which represents an increase of 500 % in the volumetric triterpene yield. The results with the fungal filtrate of *A. niger* as elicitor showed similar results. For the elicitation, a concentration of 3 % *(v/v)* of each fungal medium filtrate was selected because higher concentrations of 12 % *(v/v)* demonstrated strong growth inhibition of the plant cells. The detailed results of the effects of fungal medium filtrates of *A. niger* and *T. virens* as well as of the sucrose fed-batches on growth and productivity are described in [3].

4. Conclusions

A biotechnological process for the production of triterpenic acids with *S. fruticosa* cell suspension cultures has been developed on a laboratory scale. By an elicitation strategy combining treatment of the cell cultures with fungal medium filtrate and sucrose feeding, the yields of the secondary metabolites could be significantly increased. It was demonstrated that the eliciting effect of the fungal extracts depends on the concentration, the time of addition and the age of the culture. In further studies, the eliciting substances in the plant extracts have to be determined. In addition, the protecting effects of the extracted triterpenic acids for wood-based materials have to be intensively evaluated. Subsequently, the process has to be scaled up into the industrial scale. This work has been financially supported by the Central Innovation Program for SMEs of the Federal Ministry of Economics and Technology (BMWi, grant number KF2049810SA2), German Research Foundation (DFG, Project ID BL345/10-2) and Federal Ministry of Education and Research (BMBF), the project ID is: 031B0691.

Highlights

- Corning dissolvable carriers provided a scalable solution for large-scale harvest of functional hMSC by enabling simplified detachment.
- Complete dissolution of microcarriers was observed during the harvest phase resulting in an efficient hMSC recovery.

1. Introduction

Mesenchymal stem cells extracted from the Wharton's jelly of human umbilical cords (hWJ-MSC) are of increasing interest for cell therapies due to their reduced immunogenicity, high expansion capabilities, fast growth kinetics and various growth factors synthesis capabilities. Development of bioprocesses capable of producing large numbers of hMSC in a robust and safe manner is critical for therapeutic applications. Scalable expansion of hWJ-MSC on Cytodex-1 or other types of microcarriers usually found in cell culture, involved specific cell detachment using trypsin. Trypsin or other cell detachment enzymes could have harmful effects on cells and their viability. Besides, a filtration step is required because carriers remained in the cell culture medium. In this study, the efficiency of novel xeno-free dissolvable microcarriers for the culture and detachment of hWJ-MSC was demonstrated.

2. Methods

hWJ-MSC were cultivated on Corning Synthemax II-coated dissolvable microcarriers (DM) in HPL-supplemented medium, with an initial concentration of 7000 cells/cm^2. Previous studies (Loubière et al. 2018) showed that the best choice of microcarrier for hWJ-MSC adherence and expansion, in dynamic conditions, was Cytodex-1 [1], but cell detachment remained difficult. A culture in 200 mL spinner flasks with DM microcarriers was performed and compared with a culture on Cytodex-1. Glucose, glutamine, ammonium, lactate and lactate dehydrogenase concentrations were monitored every day. Moreover, cells were counted from the post-processing of DAPI-stained cells pictures [1]. At the end of the culture, cells were harvested following the protocol given by Corning. A solution of harvest was prepared using a mix of different enzymes and chemicals: a protease and a pectinase, and a chelating agent (EDTA). This harvest solution was directly used in the culture system and its action was about 20 minutes. After this, cells were directly centrifuged.

3. Results and discussion

The first results showed that the choice of Cytodex-1 or dissolvable carriers from Corning did not influence cell adherence. Cell viability was equivalent and maintained over time in both cultures (Figure 1). Once the attachment and kinetics of cell culture (growth, death, glucose and glutamine consumption, lactate and ammonia production) evaluated, cell detachment was studied. After the treatment with the harvest solution, cells were counted and microcarriers observed under microscope. Results indicated that Corning microcarriers were well digested, and two million of viable cells were collected after centrifugation (95% of viability), against, only 800 000 cells collected from Cytodex-1 using the classical proteolytic harvest treatment (89% of viability). By image analyses, it was shown that with DMC, complete cell detachment and microcarrier dissolution were obtained while cells remained attached on Cytodex-1 microcarriers.

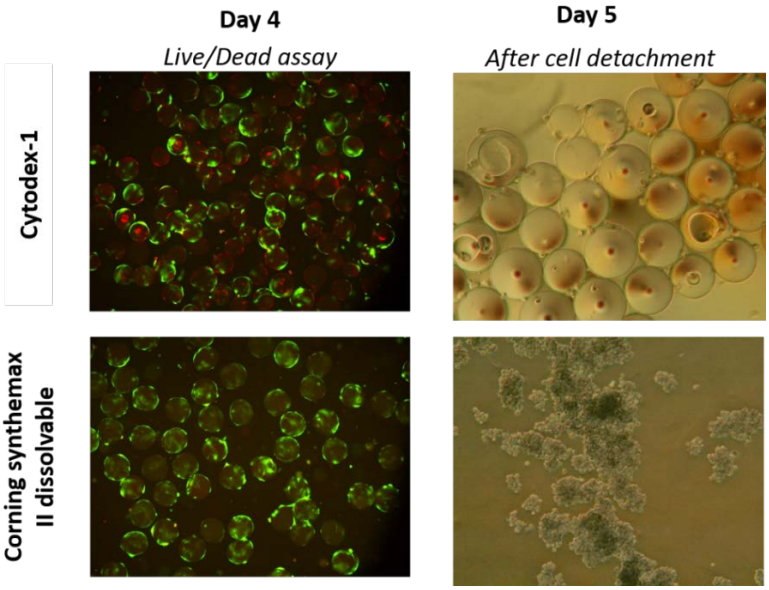

Figure 1. Comparison of cell culture and detachment on dissolvable carriers and Cytodex-1.

4. Conclusions

Recently, Nienow and colleagues developed a method of harvesting cells, which combines more intense agitation speeds, proteolytic enzymes and temperature inside the bioreactor, in order to improve cell detachment and viability. After the cell detachment, most of the applications, especially therapeutics, will require separation of cells from microcarriers, but by using dissolvable carriers this step would be avoided. To conclude, the use of dissolvable microcarriers would be an effective way to do scalable expansion and harvest of hWJ-MSC.

Highlights

- Anaerobic digestion process.
- Biological pretreatment of sludge.
- Biomethane potential.

1. Introduction

The sludge line from conventional wastewater treatment plant (WWTP) generates high amount of sludge after decanting the solids coming from primary (sedimentation) and secondary (biological) treatments. In this sense AEBIOM estimated a potential of 6 billion Nm^3 of biomethane coming from sewage sludge in 2018 (Scarlat et al., 2018). Different biological pretreatments such as temperature phased digestion (TPAD) or fungi treatment are being widely studied to increase the biomethane potential in anaerobic digestion processes. These types of pretreatments are designed in order to improve the hydrolysis step in an eco-friendly way and with no special equipments (Zhen et al., 2017). In this regard, in this work a pretreatment based on fermentation using *B licheniformis* has been carried out with the aim to prepare the sludge for following anaerobic digestion step.

2. Methods

The inoculum was obtained from 5L single-phase dry-mesophilic AD operating at HRT = 20 d. The sludge as substrate was obtained from the aerobic digester from CENTA, in Carrión de los Céspedes (Seville, Spain). The crude and diluted (1:2 and 1:10) sludge was autoclaved (30 min 121 ºc) before fermentation with *B. licheniformis* ATCC 21415. Growing bacteria conditions were: Medium:LB, T =37 ºC, agitation rate =150 rpm, Time = 288 h.

250 ml BMP serum bottles were used in order to determine the methane potential of different pretreated samples. The digesters were initially loaded with a mixture of 40% v/v inoculum and pretreated sludge. Control reactors were also incubated. All the anaerobic digestion experiments were carried out until all the available carbonic content was converted to biogas (23 days). All reactors were run in duplicates. At the beginning and at the end of each experiment the samples were characterized in order to evaluate the biodegradability of the samples. During the experiment volume and composition of biogas produced were registered.

3. Results and discussion

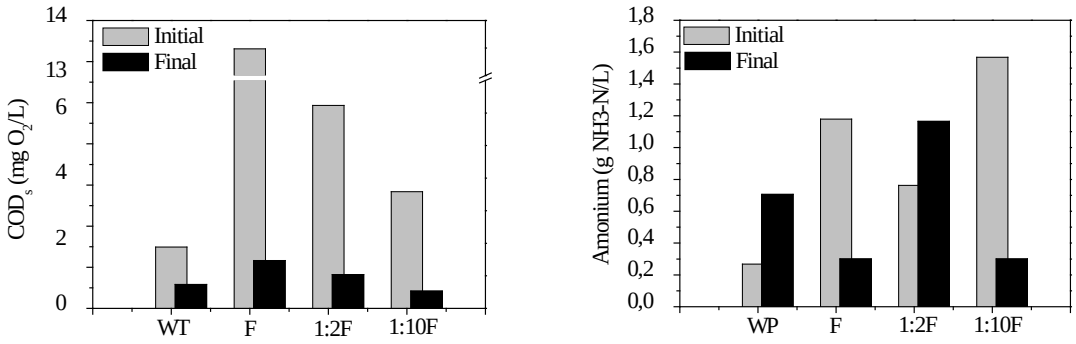

Figure 1. Initial and final CODs and Amonium in BMP experiments.

CODs the removal percentages are very similar and more than twice higher (73.4-82.7%) than control WP (38%). Fermentation pretreatment of crude and diluted substrates obtained high values of ammoniacal nitrogen with values of 0.762, 1.57 and 1.17 g NH3-N/L respectively for pretreatments 1:2F, 1:10F and F. This fact can be explained because protein degradation efficiency during fermentation pretreatments.

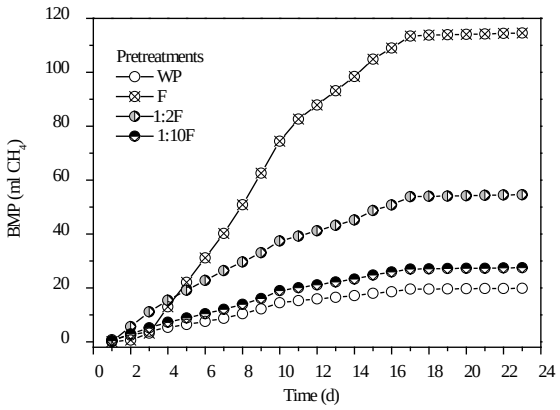

Figure 2. Accumulated biomethane production through the time for different pretreated substrates.

As it can be observed in the Figure 2, F sample need 3 days in order to adapt the inoculum to high ammonium values. In the pretreatment 1:10F there was inhibition by ammonia content because excess of that. This effect could also have happened in the 1:2F pretreated sample but, here, the organic load content was higher, increasing the C/N ratio (and thus the biogas yield).

4. Conclusions

Biochemical treatments tested for sewage sludge result in higher depuration efficiency in terms of CODs. Fermentation increase the biogas volume in 5.77 times respectively compared with control. The selection of optimal pre-treatment must take into account the final C/N ratio.

Highlights

- Extreme natural and industrial environments are a source of microorganisms with unique potential.
- An acidophile consortium was isolated from effluents of a mining operation.
- The consortium is capable of oxidizing high arsenic concentrations.
- A metabolic reconstruction of the consortium was developed to study its metabolic capabilities.

1. Introduction

A permanent challenge for the mining industry is the development and application of metal recovery technologies that are efficient, low cost and ecologically friendly, since during the process many contaminating elements are released [1]. Most of the minerals present in the rock represent a rich source of elements of high economic value, but some may contain toxic metals or metalloids, such as arsenic.

Northern Chile has a variety of poly extreme natural and industrial ecosystems, with high rates of solar radiation, low relative humidity, extreme temperature variations and the presence of high concentrations of metals. Microbial life develops under these challenging environmental conditions, which makes it an ideal place to search for extremophile microorganisms with specific physiological and metabolic adaptations.

Our aim is to describe and understand the metabolic capabilities of the microorganisms that are able to resist, reduce or oxidize different metals and metalloids commonly associated with the mining industry, in particular arsenic. In this context, we present a unique opportunity for the discovery and development of technologies that will carry out the transformation of arsenic.

2. Methodology

Microorganisms were isolated from geothermal sites in northern Chile and also from samples of industrial effluents from an arsenic treatment plant. The isolates were identified by Illumina sequencing techniques.

The determination of the diversity of microorganisms present in the samples, allowed the generation of strategies to enhance their growth and oxidative activity, through two approaches:

• Experimentally, optimizing the growth conditions according to the reported nutritional requirements of the microorganisms present.
• Through *in silico* optimization. The consortium's metabolism was reconstructed and modeled, according to the genomic information obtained from the sequencing.

3. Results and discussion

The industrial consortium showed the best oxidation results (about 80% of As(III) oxidized) in solutions with high arsenic and acid content (around 1-3 gpl of As (III) and 20-40 gpl of H_2SO_4). The most likely species in the consortium according to the experimental and metabolic analysis are *Acidithiobacillus, Rhodanobacter, Leptospirillum, Thiobacillus, Terracoccus* and *Acidianus.*

The metabolic model was simplified by depuration and *gap-filling,* and is composed of about 176 reactions representing the consortium. Main pathways of the model are reverse TCA cycle for carbon fixation, energy uptake by iron metabolism and arsenic resistance by detoxifying mechanisms and dissimilatory oxidation of As (III).

We are presently using both the metabolic model and the experimental results necessary for the oxidation of arsenic in order to design a process that takes advantage of the microbial oxidation of arsenic.

4. Conclusions

A consortium was isolated from industrial effluents, which showed high tolerance to mining operation conditions and elevated capacity to oxidize arsenic (III) from acid effluents.

The development of a metabolic model of an industrially isolated consortium was useful to describe and represent the capabilities of these microorganisms to oxidise arsenic in solutions with high acidity and high ion concentrations. This model is being used to simulate growth under different conditions and, in this way, perform mathematical analyzes for optimization.

Removal of pharmaceuticals from artificial and real wastewater matrices using *Trametes versicolor* in fed-batch and trickle-bed bioreactors

Highlights

- The performance of two bioreactor configurations was studied.
- Pharmaceuticals were treated in bioreactors containing *Trametes versicolor*.
- Removals over 95% were achieved for 11 drugs in a fed-batch bioreactor over 14 days.

1. Introduction

The presence of pharmaceuticals in the environment has been a raising concern over the past years. There is lack of information about their effect on ecosystems, making their impact on the environment and public health difficult to predict [1]. Current wastewater treatment plants (WWTP) are not designed to remove these pollutants; consequently, many of them reach surface waters unaltered [2]. In the search for alternatives to minimize their chronicle impact, the use of white-rot fungi as a biological treatment for the removal or transformation of pharmaceuticals has been studied and has been proven to be an environmentally friendly and effective alternative [3]. Specifically, studies using bioaugmentation with *Trametes versicolor* have obtained better pharmaceutical removal values compared to conventional activated sludge (CAS) treatment [4][5]. This work aims to explore the fungal treatment of real wastewater matrices and synthetic wastewater spiked with different pharmaceuticals including psychiatric drugs, anti-inflammatory drugs and antibiotics, in two different bioreactor configurations, a fed-batch stirred tank bioreactor and a trickle bed bioreactor. The fed-batch bioreactor uses molasses, obtained as a secondary product in the production of sugar, as a nutrient source for the employed microorganism. While the trickle-bed bioreactor was designed to be an easy and economically competitive alternative to be used as tertiary treatment in WWTP.

2. Methods

Artificial wastewater was prepared with 16 commercial drugs (1 mg/L each), while real wastewater was obtained from a secondary treatment plant. Two bioreactors containing polluted water, inoculated with *T. versicolor* pellets, were operated in fed-batch mode with intermittent additions of molasses solution as carbon and nitrogen source. Results were verified by triplicate assays in Erlenmeyers, operated under the same conditions. Moreover, three trickle-bed bioreactors were built using a lignin-rich substrate mixed with an artificial substrate for support,

inoculated with *T. versicolor*. In both bioreactor configurations, heat-killed and abiotic control assays were performed in order to determine abiotic losses and sorption to the fungal biomass, as well as ecotoxicological assays with *Daphnia magna* and *Lactuca sativa*. Removal of pharmaceuticals was quantified by LC-MS/MS analysis.

3. Results and discussion

Removals over 95% were achieved for 11 pharmaceuticals during the treatment of synthetic wastewater in the stirred tank bioreactor; in general, individual removal values were above 50% for this system (see Figure 1). The highest removals were found for ceftiofur, lincomycin, acetaminophen and ketoprofen, while the lowest corresponded to azithromycin. Acetaminophen showed the highest removal rate.

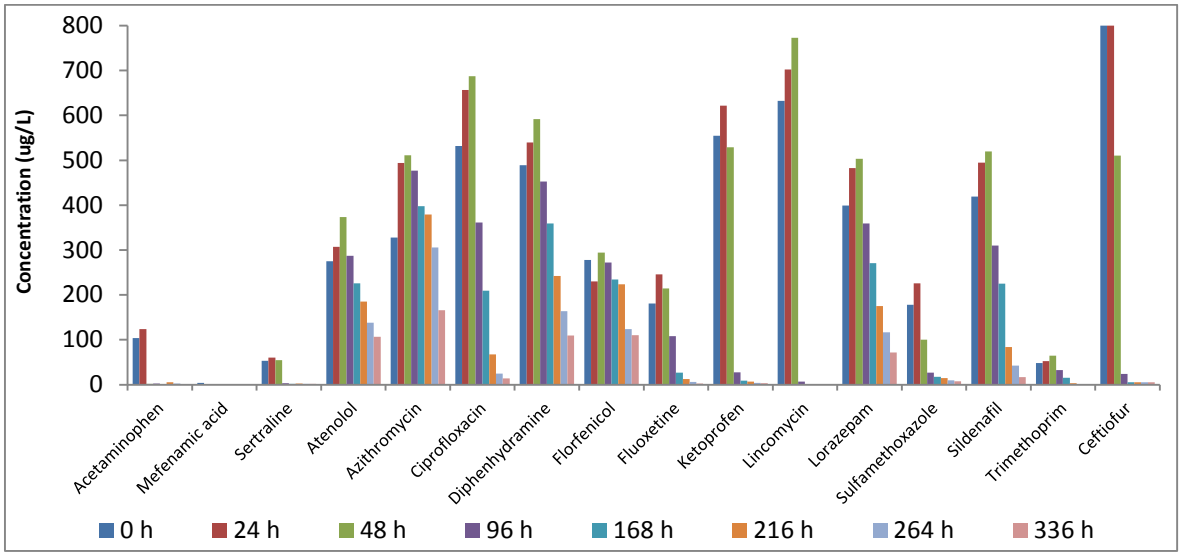

Figure 1. Removal of pharmaceuticals from artificial wastewater in a fed-batch bioreactor with *Trametes versicolor*.

We will further discuss the results obtained for the trickle-bed reactors. Results will include pharmaceutical removal in synthetic and real wastewater matrices, as well as EC_{50} values.

4. Conclusions

The fungal bioreactors studied with *Trametes versicolor* can be used as methods to overcome the lack of specialized treatment given in WWTP. Given the results, a fed-batch stirred tank bioreactor could be used as a removal system for punctual discharge of pharmaceuticals. While on the other hand, the trickle bed bioreactor could be used as a tertiary treatment in farms to treat animal residues, hospital or municipal wastewater, among others.

Effect of extracellular pH on lactate metabolism in Chinese Hamster Ovary (CHO) cell cultures

Victoria Gkoutzioupa[1], Edward Close[2], Alexandros Kiparissides[1,*]

1 Advanced Centre for Biochemical Engineering, Department of Biochemical Engineering, University College London, London, UK; 2 Process Systems Enterprise Limited, London, UK

**Corresponding author: alex.kiparissides@ucl.ac.uk*

Highlights

- Understanding of the effect of extracellular pH on lactate metabolism, cell viability and product titer
- Improved prediction of lactate concentration including the shift from lactate production to consumption

1. Introduction

In spite of the outstanding research developments in biotechnology, there are still several aspects of cellular metabolism whose impact on bioprocess efficiency and product quality we do not fully comprehend. A notable and industrially relevant example is the interplay between glucose, lactate and amino-acid metabolism and in particular the metabolic switch that occurs in high-density cultures of fast growing mammalian cells from lactate production to lactate consumption (Zhou et al., 1997; deZengotita et al., 2000). Recent studies have shown that supplementing CHO cell cultures with lactic acid or artificially altering extracellular pH can promote the effect resulting in the preferential uptake of lactate even in the presence of excessive amounts of glucose (Li et al., 2012). Surprisingly this transition, from lactate production to consumption, results in higher product yields. The aim of the current study is to develop an in depth, quantitative understanding of lactate metabolism in CHO cells and how it responds to variations in extracellular pH. The experimental data will be subsequently used for the development of a predictive unstructured model.

2. Methods

GS-CHO cells (kindly provided by Lonza Biologics, Slough, UK) were cultured in 500 mL shake flasks (Presens, Germany) with 110 mL working volume. The flasks had integrated pH and oxygen sensors. The cells were incubated at 5% CO_2, 37°C and 180 rpm (d_s=19 mm). Viable cell density, total cell density and average cell diameter were measured with the Vi-CELL XR (Beckman Coulter, USA). Metabolites (glucose, glutamate, glutamine, lactate, ammonia) were quantified with the BioProfile FLEX Analyzer (Nova Biomedical, USA). Monoclonal antibody concentration was determined with the use of High Pressure Liquid Chromatography (HPLC) techniques (Agilent Technologies, USA). pH was maintained in predefined levels with the manual addition of 1M HCl and 1M $NaHCO_3$. pH and oxygen were monitored by using a Presens platform (Presens, Germany).
The gPROMS FormulatedProducts© modelling platform was employed for model development and analysis. The parameters of the model were estimated through minimization of the maximum likelihood objective function, where the experimental data were given as inputs.

3. Results and discussion

ODEs were constructed for the description of the system's dynamic response. Monod-type kinetics were mainly used for the development of the model. So far, equations for viable and total cells, glucose, glutamate, lactate and mAbs have been developed and are given by the following expressions:

$$\frac{d(V\cdot X_V)}{dt} = \mu \cdot X_V \cdot V - \mu_d \cdot X_V \cdot V - F_{out} \cdot X_V \quad (1)$$

$$\frac{d(V\cdot X_T)}{dt} = \mu \cdot X_V \cdot V - F_{out} \cdot X_T \quad (2)$$

$$\mu = \mu_{max} \cdot \frac{[GLC]}{[GLC]+K_{glc}} \cdot \frac{[GLU]}{[GLU]+K_{glu}} \quad (3)$$

$$\mu_d = \mu_{d,max} \cdot \frac{K_{d,glc}}{K_{d,glc}+[GLC]} \cdot \frac{K_{d,glu}}{K_{d,glu}+[GLU]} \cdot \frac{[AMM]^3}{K_{d,amm}{}^3+[AMM]^3} \quad (4)$$

$$\frac{d(V\cdot[GLC])}{dt} = F_{in} \cdot [GLC]_{in} - F_{out} \cdot [GLC] - V \cdot \left(\frac{\mu}{Y_{x,glc}} + m_{glc}\right) \cdot X_V \text{ (Jang \& Barford (2000))} \quad (5)$$

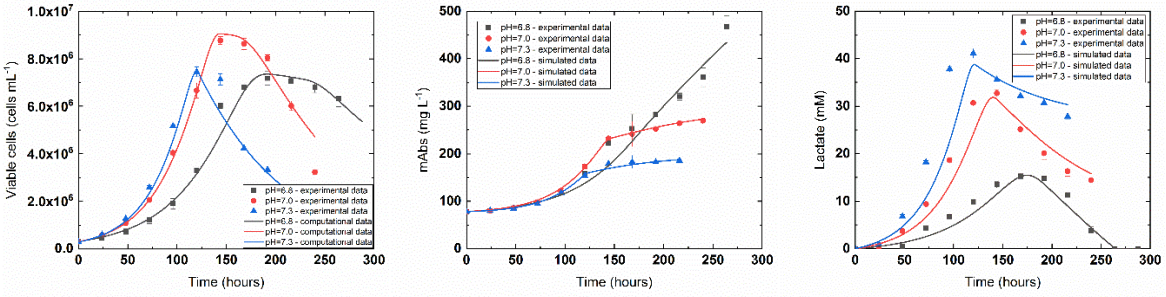
$$\frac{d(V\cdot[GLU])}{dt} = F_{in} \cdot [GLU]_{in} - F_{out} \cdot [GLU] - V \cdot q_{glu,max} \cdot \frac{[GLU]}{[GLU]+K_{glu,2}} \cdot \frac{K_{i,glc}}{K_{i,glc}+[GLC]} \cdot X_V \quad (6)$$

$$\frac{d(V\cdot[LAC])}{dt} = Y_{lac,glc} \cdot V \cdot \left(\frac{\mu}{Y_{x,glc}} + m_{glc}\right) \cdot X_V - V \cdot q_{lac,max} \cdot X_V - F_{out} \cdot [LAC] \quad (7)$$

$$\frac{d(V\cdot[mAbs])}{dt} = V \cdot \left(\frac{\mu}{Y_{x,mab}} + m_{mab}\right) \cdot \frac{[GLC]}{[GLC]+K} \cdot X_V - F_{out} \cdot [mAbs] \quad (8)$$

The values of the parameters differ according to the pH of the media. For pH equal to 7, the parameters that were derived from parameter estimation (PE) are μ_{max} = 0.031 h^{-1}, K_{glc} = 4.098 mM, K_{glu} = 0.045 mM, $\mu_{d,max}$ = 0.016 h^{-1}, $K_{d,amm}$ = 255.711 mM, $K_{d,glc}$ = 21.8 mM, $K_{d,glu}$ = 18.284 mM, $Y_{x,glc}$ = $4.34\cdot10^{8}$ cells·mmol^{-1}, m_{glc} = $2.39\cdot10^{-11}$ mmol·cells^{-1}·h^{-1}, $q_{glu,max}$ = $3.43\cdot10^{-9}$ mmol·cells^{-1}·h^{-1}, $K_{glu,2}$ = 19.11 mM, $K_{i,glc}$ = 0.24 mM, $Y_{x,mab}$ = $3.2\cdot10^{8}$ cells·mg^{-1}, m_{mab} = $2.81\cdot10^{-10}$ mg·cells^{-1}·h^{-1}, K = 0.0375 mM, $Y_{lac,glc}$ = 2.0 mmol·$mmol^{-1}$, $q_{lac,max}$ = $7.0\cdot10^{-11}$ mmol·cells^{-1}·h^{-1}.

The results of the simulation are graphically represented in Figure 1.



(a) (b) (c)

Figure 1. Simulated and experimental profiles of (a) viable cell, (b) mAb and (c) lactate concentrations for different pH levels in batch cultures.

4. Conclusions

From Figure 1, it is evident that extracellular pH levels affect cell viability and productivity. Specifically, it is observed that lower pH values, in the culture media, result in higher integral viable cell concentration (IVCC) and higher titer. Additionally, extracellular pH levels can control the lactate switch. In higher pHs, more lactate is accumulated in the system (Figure 1c). Regarding the model, the simulated results are in good agreement with the experimental data. We come to the conclusion that Monod and Hill kinetics can adequately describe the dynamics of the system. However, the equations have to be refined with amino acids data.

A combined mathematical and experimental investigation of multiphase flow and shear sensitivity in the performance of mammalian cell cultures

Artemis Danae Charalambidou[1*], Martina Micheletti[1], Alexandros Kiparissides[1]

1 University College London, Department of Biochemical Engineering, Torrington Place, London, WC1E 7JE, UK
**Corresponding author: a.charalambidou@ucl.ac.uk*

Highlights

- Conduction of detailed single phase computational fluid dynamics (CFD) simulations in a 250 mL bioreactor.
- Study of the impact of critical simulation parameters on model output and accuracy.
- Experimental validation of CFD simulation output via particle image velocimetry (PIV) measurements.

1. Introduction

The biopharmaceutical industry is in the forefront for the production of innovative drugs from mammalian cell cultures. Baffled or unbaffled stirred tank reactors (STRs) equipped with one or multiple impellers are most commonly used for the production of monoclonal antibodies (MAbs) and recombinant proteins. Their flexibility arises from the ease to control several operating parameters such as impeller speed and aeration techniques, which can improve homogeneity and thus the transport processes in the interior of the vessel (Rodriguez et al., 2013). Nevertheless, the large number of operating parameters makes the selection of an optimal configuration a laborious task and its complexity arises from the lack of detailed understanding of the underlying physics within a stirred vessel (Joshi et al., 2011). Experimental and computational fluid dynamics are widely recognised tools that contribute in the prediction of flow mechanics in STRs and estimation of turbulence associated quantities such as, microeddy formation, energy dissipation rate (EDR) and turbulence kinetic energy (TKE) which might eventually affect cell morphology, viability and productivity (Farzan, Mistry, & Ierapetritou, 2017; Morchain, Gabelle, & Cockx, 2014). However, although many attempts have been made to investigate the flow dynamics in STRs, a well-established and experimentally validated model for the meticulous description of critical hydrodynamic parameters in STRs does not exist. In this study we follow a systematic approach to establish a robust and experimentally validated CFD model based on a 250 mL STR configuration with one Rushton turbine, to assess various turbulent models and mesh structures as well as the effect of each on the estimation of key hydrodynamic parameters which influence mammalian cell cultures.

2. Methods

Commercial CFD software package ANSYS Fluent 19.0 is used to solve the liquid phase hydrodynamics in 3D. The liquid used is water (ρ=998.2 kg m^{-3}, μ=10^{-3} Pa s) and the impeller rotational speed is initially set to 250 rpm, resulting in a Reynolds number of 5,000. Simulations are conducted in both steady state and transient mode via moving reference frame (MRF) and sliding mesh (SM) technique respectively for the simulation of impeller rotation. Convergence criteria were

10^{-5} and 10^{-6} for the continuity and turbulence closure equations respectively. The grid of the rotational zone was formed to be finer than the grid in the outer zone to achieve better accuracy. For mesh independence studies grid densities evaluated varied from 280,638 to 1,728,348 tetrahedral cells.

3. Results and discussion

Figure 1 presents preliminary results of the mesh independence study conducted over a wide range of grid densities. Reynolds Averaged Navier-Stokes equations (RANS) approach coupled with k-epsilon Realizable turbulence model is initially used due to its success to satisfactorily model rotational flows. Global maximum for radial velocity and EDR was located at the impeller plane. Minor differentiations were exhibited among the grid densities for radial velocity profiles (Fig. 1(a)). The consistency of the results was tested via calculating average velocities in dispersed control volumes in the interior of the bioreactor (results not shown). Lower grid density resulted in lower global maximum for EDR (Fig. 1(b)) leading to the conclusion that the corresponding solution is not optimum.

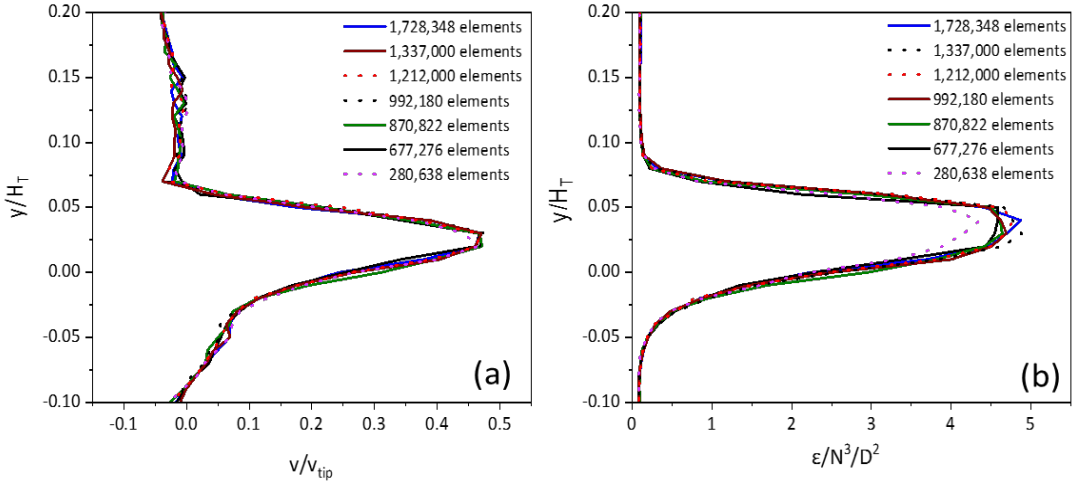

Figure 1. Local effect of grid density in the prediction of selected variables. Axial profiles close to the blade tip (r=T/4) of (a) radial velocity, (b) EDR.

4. Conclusions

A variety of different grid densities gave acceptable approximations for the critical parameters evaluated when RANS approach was used. For both EDR and TKE the results obtained were similar and 11% increase was observed from the coarser to the finer grid density. At the next stage, simulations will be run with structured mesh and different turbulence models to assess results quality and accuracy while experimental validation will mainly contribute in the clarification of the location and intensity of critical hydrodynamic parameters to ultimately quantify potentially destructive effects on mammalian cells.

Highlights

- Continuous extraction of foam is an excellent recovery and concentration method for surfactin.
- This technique can be used to reduce costs of extraction and purification of surfactin.
- The proposed method avoids operation problems found in batch bioreactors.

1. Introduction

Surfactin is a very powerful surfactant produced by the bacteria *Bacillus subtilis*, which is able to reduce the interfacial tension of water from 72 to 27 $mN.m^{-1}$. Although it has excellent properties and therefore a large number of potential industrial applications ranging from petrochemistry to pharmacy, the costs involved in its production and purification processes are still restricting its commercialization. A common strategy to reduce these costs is to focus on the optimization and innovation on the purification stages. During the production of surfactin in a stirred tank bioreactor, the continuous change of the physicochemical properties of the culture and the high stirring and aeration requirements are responsible for the formation of a significant amount of foam. Thus, an operation strategy must be used.

In the present study, fractioning with foam was directly applied during the culture of *B. subtillis* in a batch stirred tank bioreactor to concentrate surfactin.

2. Methods

The experiments were performed in a 3 L Applikon® bioreactor provided with a Rushton agitator with 6 paddles, always operating discontinuously and with a working volume of 1.7 L. The diameter of the Rushton turbine is 4.5 cm., while the internal diameter of the bioreactor is 12.9 cm. The exhaustion air outlet was redesigned to continuously collect the formed foam and store it in sterile vessels. Then, the foam was stored at -18 °C to facilitate its collapse. The agitation, air flow, temperature and pH were set and controlled at 200 r.p.m, 1 v.v.m, 30 °C and 7, respectively. Two different chemically defined culture media with slight differences in their elemental traces were used, which had a significant influence on the production of surfactin. During the reaction, the dissolved oxygen concentration was continuously measured. Also, the concentrations of biomass, residual sugar, and surfactin were determined in the bioreactor. Finally, the volume, surfactin and biomass content were analyzed in the obtained foams.

3. Results and discussion

In order to evaluate the efficiency and convenience of the foam separation process coupled to the bioreactor, the variation of foam and remaining culture as a function of time and the surfactin recovery index were analyzed. These results are shown on Figures 1 and 2. The surfactin percentual recovery (SR%) was obtained by means of the following expression:

$$SR\% = \frac{Surfactin\ mass\ in\ the\ foam}{Total\ surfactin\ mass}\ x\ 100$$

This quantity represents the percentage of extracted surfactin in the foam and it is an indicator of the efficiency in the continuous extraction of foam as a fractioning and concentration method for surfactin.

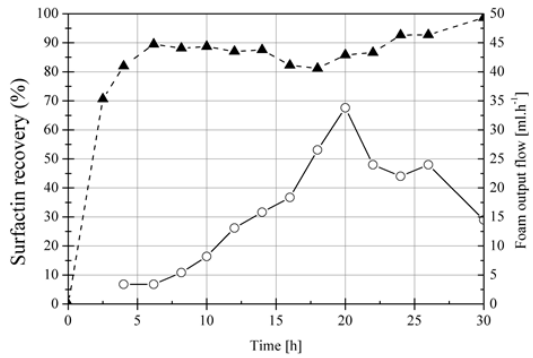

Figure 1. Surfactin recovery % (▲) and foam output flow (○)

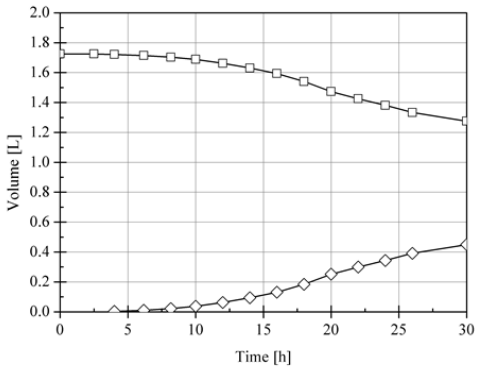

Figure 2. Culture volume in the bioreactor (□) and foam volume (◇)

As shown in Fig. 1, the recovery of surfactin in the foam reaches values over 98% of the total produced surfactin. What is more, by using an agitation of 200 r.p.m. only 26.1 % of the initial liquid volume in the bioreactor is dragged with the foam after 30 hours of operation, as presented in Fig. 2. These results indicate that the production of foam was not significant and didn't complicate the operation of the bioreactor in any way. These results are not in agreement with the ones of Davis et al. [1] where agitation velocities of 204 and 269 r.p.m. generated excessive levels of foam formation and losses of 50% of the culture volume after 36 hours of operation, which consequently led to very low levels of surfactin production. However, the obtained results in the present study agree with Cooper et al. [2].

4. Conclusions

Based on the obtained experimental results, one can conclude that the continuous extraction of foam is an excellent recovery and concentration method for surfactin from a culture medium, with the additional advantage of reducing the extraction and purification costs of the overall process.

Nano-scale enzyme membrane reactors for compartmentalized multienzyme syntheses

Michael Mertz[1], Sarah Poschenrieder[2], Ludwig Klermund[2], Kathrin Castiglione[1*]

1 Institute of Bioprocess Engineering, Friedrich-Alexander-Universität Erlangen-Nürnberg, Paul-Gordan-Straße 3, 91052 Erlangen, Germany; 2 Institute of Biochemical Engineering, Technische Universität München, Boltzmannstraße 15, 85746 Garching, Germany

**Corresponding author: kathrin.castiglione@fau.de*

Highlights

- Vesicles made from amphiphilic block-copolymers were used as reaction compartments.
- Inserting porins into the polymer membrane created nano-scale enzyme membrane reactors.
- Enzymes in the vesicle lumen were spatially separated from inhibitors in the bulk phase.
- New strategies to augment the catalyst loading of the vesicles are under investigation.

1. Introduction

When looking for examples of complex biocatalytic systems, one has not to look far. Already the estimated 3.72*10^13 cells of a human [1] depict a perfect example in which nature designed an astonishing biocatalyst network. In natural cells, a vast array of chemical reactions takes place simultaneously. Two fundamental principles allow these reactions to proceed efficiently: compartmentalization and selective mass transport. By spatial separation of enzymes and control over the reacting compounds, highly productive reaction cascades can be established.

To make use of these principles in bioprocess engineering, nano-compartments made from self-assembling, amphiphilic block-copolymers can be used to mimic these principles of cells and to improve biocatalytic reactions. By entrapping enzymes in vesicles with a selectively permeable membrane, nano-scale enzyme membrane reactors (nano-EMRs) can be created (Figure 1). The spatial separation of incompatible reactions can lead to more efficient one-pot multi-enzyme syntheses by avoiding cross-inhibitions and undesired side-reactions.

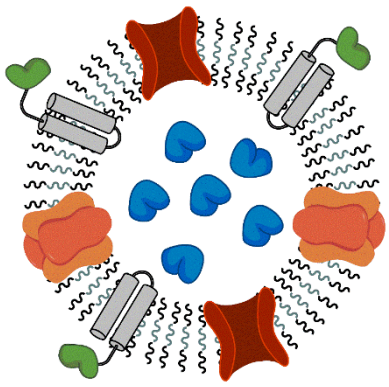

FIGURE 1: Nano-scale enzyme membrane reactor

2. Methods

The triblock-copolymer poly(2-methyloxazoline)$_{15}$-*b*-poly(dimethylsiloxane)$_{68}$-*b*-poly(2-methyl-oxazoline)$_{15}$ (PMOXA-PDMS-PMOXA) is ideally suited for the formation of selectively permeable nano-EMRs because natural (or engineered) channel proteins can be embedded in functional form into this polymer membrane. The polymer vesicles are formed by injecting a 20 % (w/v) polymer solution in ethanol into a stirred tank reactor containing an aqueous phase [2]. Upon vigorous stirring for 1- 3 hours (depending on the composition of the aqueous phase), vesicles with a narrow size distribution (polydispersity index < 0.25) are obtained.

To turn the vesicles into nano-EMRs, enzymes are encapsulated during vesicle formation. Additional enzymes can be immobilized on the surface of pre-formed vesicles by using genetically modified enzymes [3]. By equipping them with membrane anchoring domains, the enzymes of interest can associate with the polymer membrane. In the process of nano-EMR assembly, this is achieved by simply combining the different components. Enzymes with membrane anchoring domains and channel proteins spontaneously integrate into the nano-EMR membrane as the integration minimizes hydrophobic-hydrophilic interactions with the surrounding aqueous phase.

3. Results and discussion

Using the three-step enzymatic synthesis of CMP-*N*-acetylneuraminic acid as an example, it was demonstrated that the nano-EMR technology can be applied to avoid cross-inhibitions mediated by low molecular mass compounds in cascade reactions. This synthesis suffers from a strong inhibition of the first enzyme in the cascade, the *N*-acylglucosamine 2-epimerase (AGE), by CTP, which is a substrate of the third enzyme, the CMP-sialic acid synthetase (CSS). The implementation of a highly specific mass transport over the compartment boundaries was demonstrated by using the engineered channel protein OmpF G119D. This porin was the key element for the spatial separation of two incompatible reactions since it allows for the free diffusion of the substrates of the AGE, but fully excludes the larger substrates of the CSS thereby abolishing their inhibitory effects. It was shown that the compartmentalization of the enzymes enables synthesis of CMP-*N*-acetylneuraminic acid, whereas no product was formed with the free enzymes [4].

One of the major limitations of the nano-EMR technology is the low biocatalyst loading of the vesicles due to the statistical encapsulation of the enzymes during the nano-EMR formation. Thus, several strategies to augment the biocatalyst loading are currently under investigation.

4. Conclusions

The nano-EMRs are new tools to tackle the incompatibility challenge in enzymatic cascade reactions. Further developments of this exciting technology are needed to improve their operational performance, e.g. by increasing the enzyme concentration in the vesicle lumen.

Synthesis of valuable carotenoids in a heterotrophic microalgae fed-batch process – aspects of process modelling and scale-up

Felix Krujatz*[1], Christiane Grasse[2], Felix Wollmann[1], Thomas Walther[1], Juliane Steingroewer[1]

[1]*Institute for Natural Materials Technology, TU Dresden, Germany, Bergstr. 120, 01069 Dresden*

[2]*Li-iL GmbH Arzneimittel und Arzneibäder, Leipziger Straße 300, 01139 Dresden*

**Felix.Krujatz@tu-dresden.de*

- Heterotrophic microalgae bioprocess was scaled-up from shake flask to 50 L stirred tank reactor
- *In-silico* approach allows the design of process strategies
- Heterotrophic fed-batch process yielded dry weight concentrations > 30 g L^{-1}
- Astaxanthin, Canthaxanin and Lutein/Zeaxanthin are the predominant carotenoids.

1. Introduction

Algal biotechnology has gained an increased industrial interest over the last decade. For several years, microalgae served as source for natural-derived antioxidants and coloring carotenoids like ß-carotene or astaxanthin [1]. The photoautotrophic production of algal biomass and products is still state of the art. However, the supply of photosynthetic active radiation (PAR) as sole source of energy in photobioreactors systems remains one of the major challenges for photo-biotechnological processes resulting in low biomass concentrations of 0.5 – 5.0 g L^{-1} dry weight in large scale bioprocesses [2]. Additionally, photoautotrophic production impedes a world-wide production of algae biomass due to the process boundary conditions (e.g. temperature, light). Consequently, a trend is towards the production of high-quality microalgae products (e.g. the production of poly-unsaturated fatty acids by DSM/Evonik) by heterotrophic bioprocesses based on organic carbon and energy sources. This strategy allows the use of established technologies in biotechnology and the avoidance of some bottlenecks using photoproduction. The aim of this study is the development of a heterotrophic bioprocess to produce natural-derived carotenoids (with special focus on Astaxanthin) from microalgae [3].

2. Methods

First, a suitable production strain was identified by screening several *Chlorella* ssp. strains originated from European strain databases (SAG, CCAP, CCALA). The strains were screened on their heterotrophic growth rates µmax [h^{-1}] and yield coefficients $Y_{X/S}$ [g_{dw} g_{Glc}^{-1}] to identify a potential production strain. The chosen strain was characterized regarding the growth kinetics using glucose as sole carbon source (100 mL shake flask scale, modified BM medium) to setup a process model for an in silico process development and scale up (to 3 L and 50 L stirred tank bioreactors).

All modeling approaches were conducted in the free accessible software Berkley Madonna®. Finally, batch and fed-batch processes were performed in 3 L (Labors 5, Infors HT) and 50 L (Applikon Biotechnology) stirred tank bioreactors to validate the scale-up. Process monitoring was performed by glucose and nitrogen analytics, flow cytometry analysis (population dynamics), microscopy, carotenoid extraction and HPLC analysis.

3. Results and discussion

By screening several Chlorella ssp. strains we could identify a suitable natural producer which attained a high yield coefficient $Y_{X/S}$ using glucose as sole carbon source. The kinetic growth parameters µmax, K_S, K_I and $Y_{X/S}$ were determined in shake flask cultivations and implemented into a MONOD based process model. Using the in silico approach a fed-batch feeding strategy was established which was validated in 3 L and 50 L scale-up processes. The heterotrophic bioprocess yielded high dry weight concentrations > 30 g L^{-1}. Astaxanthin, Canthaxanthin and Lutein/Zeaxanthin were identified as the major carotenoid fraction in the cells.

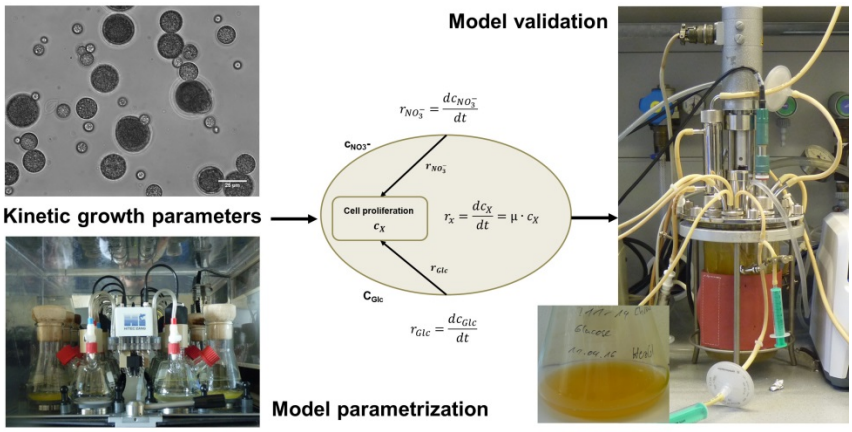

Figure 1. Process development of a heterotrophic *Chlorella* ssp- based bioprocess to produce natural-derived carotenoids.

This process allows the production of high-quality natural carotenoids from microalgae at high cell densities and thus offers an alternative to the complex photoautotrophic production by *Haematococcus pluvialis* which is independent on the production site and their climatic conditions (e.g. temperature, light).

4. Conclusions

Heterotrophic microalgal bioprocesses allow high cell density cultivation and facilitate scaled-up compared to photoautotrophic cultivation. Model validation performed in shake flask experiments and lab-scale bioreactor fermentations indicated robustness of the process model at different scales. Thus, the results provide a foundation for advanced model-based bioprocess development for heterotrophic microalgal processes.

Rapid estimation of fractal dimension of microalgal aggregates

Patricio Lopez-Exposito, Carlos Negro, Angeles Blanco

Universidad Complutense de Madrid
Department of Chemical Engineering and Materials, Avda. Complutense s/n
28040 Madrid
Corresponding author: cengro@ucm.es

Highlights

- A method to estimate the fractal dimension of microalgal aggregates is proposed
- A machine learning model processes laser reflectance data to estimate fractal dimension
- The method is effective to resolve the 3D geometry of microalgal flocs
- The model can be used to control flocculation and produce optimally shaped flocs

1. Introduction

In order to deploy the full potential of microalgae as a source of variety of valuable products, the cultivation and harvesting costs associated to the production of microalgal biomass. The most cost-effective strategy to attain the harvesting of microalgal biomass is considered to consist in the combination of a flocculation stage followed by a concentration step based on settling, filtration or centrifugation. The effectiveness of the concentration step is affected by the size and shape of flocs produced in the flocculation stage. At present, however, no control over these two parameters is carried out at industrial level. The present communication describes a novel approach to estimate the average fractal dimension (D_f) of microalgal flocs suspensions by interpreting chord length distribution spectra acquired through a laser beam reflectance probe. This monitoring method could be applied on-line to control the stirring in flocculation processes so that the average geometry of aggregates is optimal for the subsequent concentration step.

2. Methods

The development of the estimation method involves *in-silico* and experimental steps. First, several families of virtual flocs, each having a consigned fractal dimension were created by means of applying a random growth algorithm. These virtual aggregated were virtually scanned through a computer emulator of the FBRM probe. The data generated were employed to train a machine learning random forest regression model (RFR) to learn the relationship between chord length distribution data and average fractal dimension. The estimation model was validated with real data of microalgal flocs suspensions of known fractal dimension.

3. Results and discussion

- Several families of virtual flocs resembling real ones were generated though a growth algorithm (Fig. 1).
- The virtual flocs were scanned through an FBRM emulator to produce the training data for a random forest regression model (fig. 2a).
- The model was successfully verified with real CLD data of real suspensions of known D_f. (fig. 2a).

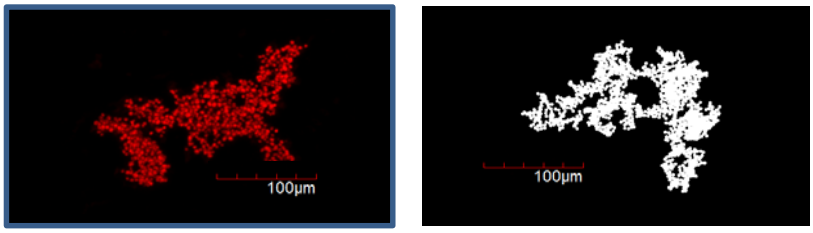

Figure 1. Real (left) and virtual (right) flocs of similar size.

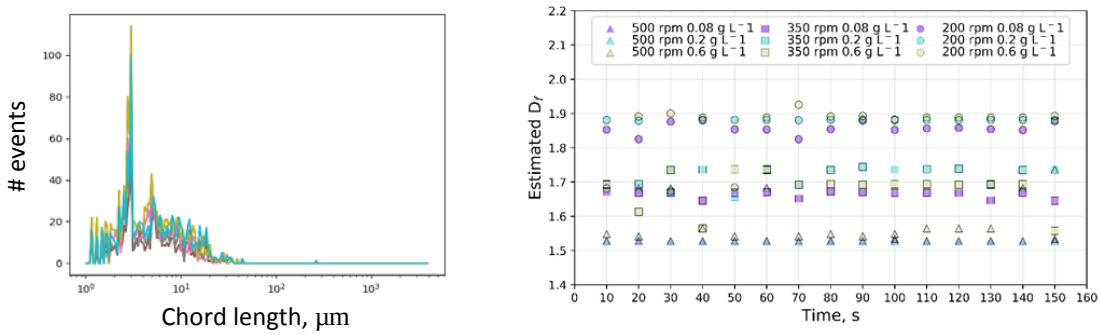

Figure 2. a) CLD of virtual floc and b) estimation of D_f on real data. [Calibri 9].

4. Conclusions

A model to directly estimate the fractal dimension form CLD data was successfully developed and verified with real data. The model can be applied as a means to monitor the flocculation of biomass to tune the stirring conditions so as to produce optimally shaped flocs for the subsequent separation phase. The present method could be adapted to other flocculating systems of organic or inorganic nature involving particles detectable through FBRM.

Effect of the addition of oak wood biochar and hydrochar in anaerobic digestion

Jessica Quintana-Najera[1,*], John Blacker[2], Louise Fletcher[3], Aaron Brown[1], Andrew Ross[1]

1 School of Chemical and Process Engineering, University of Leeds, LS2 9JT Leeds, UK; 2 Institute of Process Research and Development, School of Chemistry, University of Leeds, LS2 9JT Leeds, UK; 3 School of Civil Engineering, University of Leeds, LS2 9JT Leeds, UK

Highlights

- Anaerobic Digestion
- Hydrothermal Carbonisation
- Pyrolysis

1. Introduction

Anaerobic digestion (AD) is a technology highly used for the sustainable management of a wide variety of waste while producing energy. The main product of AD is biogas, an alternative gaseous biofuel, composed principally of CH_4 [1]. Nevertheless, AD presents a major problem regarding inhibitory compounds from the organic feedstocks or produced during their hydrolysis, which detriment the CH_4 final yields [2]. Among the reported approaches for improving the CH_4 yields is the addition of adsorbent materials. It has been suggested that the addition of carbon materials for their role in the mitigation of the NH_4^+ inhibition, increasing CH_4 metabolism, reducing lag time, and facilitating the syntrophic metabolism between the different microorganisms involved [3].

Therefore, the integration of carbon materials, such as char products from the thermochemical treatment of biomass with AD has a growing interest. The thermochemical products of interest are biochar (BC) and hydrochar (HC). The former is produced by pyrolysis in non-oxidative conditions, whereas the latter is produced by hydrothermal carbonisation (HTC) in water at sub-critical conditions [4]. For the purposes of this work, the term 'char' is used to refer to both BC and HC. Particularly, the interest on the chars is due to certain characteristics, such as inertness, porosity, high surface area, and high surface functionality [5]. Even though there are indications of their positive effect on the stability of the AD process and higher quality of the digestate, their full potential as adsorbent materials in AD has not been properly assessed [2].

2. Methods

Oak wood was employed for the production of the chars. Firstly, the BC450 and BC650 was obtained by pyrolysis in a mono retort reactor at 450 and 650 °C for 1 hour, respectively. Secondly, the HC250 was produced by HTC in a non-stirred 2 L stainless steel batch Parr reactor at 250 °C, for 1 hour at 40 bar. Subsequently, the two biochars (BC450 and BC650) and the hydrochar (HC250) were used for AD. The anaerobic sludge inoculum was collected at Esholt Wastewater Treatment Plant, West Yorkshire, UK. The AD was performed in 500 mL reactors coupled to a Bioprocess™ Automatic Methane Potential Test System (AMPTIIS) system with daily online Biochemical Methane Potential

(BMP) measurement. The reactors were supplemented with inoculum 5 g VS/L, cellulose 5 g/L, and 15 g of the corresponding char, whereas the control contained only the inoculum and the cellulose. At the end of the AD the volatile fatty acids (VFA) content were measured by gas chromatography with an Agilent 7890A GC System, a DB-FFAP column, and a flame ionisation detector (FID).

3. Results and discussion

The effect on the CH_4 production largely differed between the systems with HC and BC (**Fig 1**). Firstly, the addition of HC250 lead to a BMP significantly lower than the control. This inhibitory effect could be related to the VFA accumulation (**Fig 2**) and the acidic nature of hydrochar, since the optimal pH for AD is around neutrality. Secondly, the addition of BC450 lead to a BMP 22% higher than the control. Thirdly, in comparison to the control, the BC650 system presented a similar BMP but a shorter lag phase. The variations on the effect of the chars could also be related to the differences between BC and HC, since their surface functionality and structure are dependent of the pyrolysis and HTC process conditions and the nature of the feedstock employed. For instance, in contrast to the HC, the BC presents a higher porosity and surface area that could promote the immobilisation of cells, and an alkaline nature that could provide a buffering effect. Although while comparing both BCs is worth considering the different temperatures employed for their production, since higher temperatures lead to lower O/H ratios and surface functionality. Thus, the different effect of the chars in AD could be related to their functional and physicochemical properties.

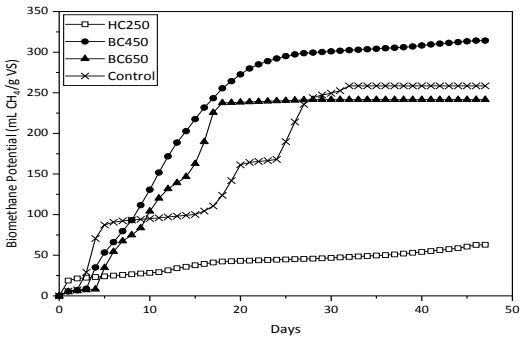

Figure 1. Production of biomethane during AD.

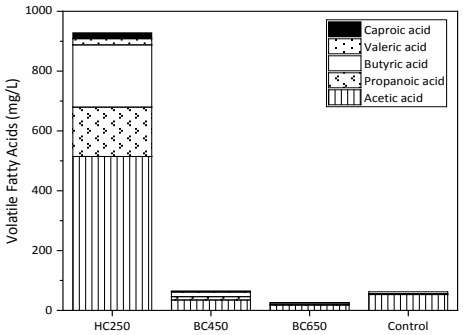

Figure 2. Production of volatile fatty acids during AD.

4. Conclusions

The addition of oak wood BC and HC had a different effect on AD. The HC250 presented an inhibitory effect on the production of CH_4 and a higher accumulation of VFAs. On the other hand, the BCs presented no inhibition on the anaerobic digestion. In consequence, the addition of BC450 improved the BMP and reduced the lag phase, whereas the addition of BC650 presented no significant effect. Therefore, given the BMP values obtained, it could be stated that the oak wood BC could have a beneficial effect on AD, whereas the oak wood HC presented a detrimental effect.

Highlights

Fed-batch experiments increase viable cell density, lactic acid and exopolysaccharides

Lactic acid maybe a valuable side product of the production of probiotic biomasses

Purified exopolysaccharides play a role in inhibiting the growth of pathogen microorganisms

Purification and characterization of exopolysaccharide of potential biomedical interest

1. Introduction

Functional food and nutraceuticals are frequently based on the use of viable probiotic strains. Viable cells at a certain titer are known to be responsible of the beneficial effect on health. However, more recently the specific action of secreted metabolites seems to play a more important role, especially in respect to immonomodlation. Exopolysaccharies in this respect are proposed for use in the food, pharmaceutical and biomedical fields, thanks to their unique properties. We performed a fermentation and downstream process, using *Lactobacillus Brevis*, in order to produce antimicrobial compounds such as lactic acid and exopolysaccharides, that inhibit the growth of pathogens [1]. As a member of the genus Lactobacillus and due to its long-term use in various traditionally fermented food products, *L.brevis* has the GRAS status. Exopolysaccharides and other substances originated *L. Brevis* fermentation such as organic acids (lactic acid), contributed to their antimicrobial properties [2]. EPSs have been used in the production of several fermented foods, thickeners, stabilizers, emulsifiers and gelling or water-binding agents [3]. The possibility to evaluate the potential use of LAB EPS as food supplement or medical device can be explored if they are extensively purified before characterization. The production, partial purification and characterization of exopolysaccharides (EPSs) produced by *Lactobacillus brevis*

was among the target of this paper.In this work, after the centrifugation, membrane processes have been used for the concentration and recovery of products released in the fermentation broth, in order to decrease the number of volume of organic solvent to be used for the precipitation of exopolysaccharides, reducing process costs and above all environmental impact.

2. Methods

The bioreactor used for the batch and fed-batch processes was Biostat CT plus (Sartorius Stedim, Italy) with a total and working volume of 3.2L and 2.4L, respectively. *Lactobacillus brevis* was grown at T= 32°C, pH 6, 100 rpm, 0.75 vvm. Batch experiments were conducted in order to optimize the process parameters, such as gas inlet, pH, stirring, carbon and nitrogen source. Fed-batch experiments start after 12-14h with a predeterminated profile and they were performed in order to increase the viable cell density (CFU/mL), biomass yield and beside, the lactic acid and exopolysaccharide production respect to the batch processes. The antimicrobial activity was evaluated on pathological strains.

3. Results and discussion

In fed-batch processes we obtained a total average CFU/mL of about $9.5x10^9$ CFU/mL, with a final OD600 of 23.4. The lactic acid produced was 63.7 g/L. Comparing the results of fermentation processes it can be seen as the fed-batch processes has increased in terms of cell number and lactic acid production of 2.1 and 2.9, respectively, respect to the batch processes.

4. Conclusions

Using fed-batch processes we doubled the number of live cells compared to the batch process and increased the production of exopolysaccharides and organic acids that were inhibitory for the growth of pathogen microorganisms.

Membrane processes were implemented to recover a High MW fraction in supernatants, with specific interest in the characterization of exopolysaccharides that were determined with specific biochemical and analytical characterization exploiting SEC-TDA chromatographer and light scattering.

Highlights

- Hempseed protein hydrolysates possess antioxidative activity.
- Hempseed protein hydrolysates showed antiproliferative effects in HeLa cells.
- Protective effects of hydrolysates were observed during H_2O_2 induced oxidative stress.
- Enzyme hydrolysis of hempseed proteins resulted in high value-added products.

1. Introduction

In recent years, many research groups had focused on the production of peptides/hydrolysates with potential application in food and nutraceutical industry. Protein hydrolysates or bioactive peptides derived from food proteins have been reported to exhibit a wide range of bioactivity including immunomodulatory, anticancer, antihypertensive, antioxidant, osteoprotective and antimicrobial effects [1]. Industrial hemp (*Cannabis sativa* L) seed is by-product obtained after utilization of plant fibers and is used as oil and protein source. It contains 20-25% of proteins and its amino acid profile showed similar or even higher level of essential amino acids (except for lysine) in comparison to soy proteins [2]. Recent studies have reported antioxidative properties of hempseed protein hydrolysates obtained by enzyme *Alcalase® 2.4L* on induced oxidative stress in PC12 cells [3]. However, more studies are needed to investigate effects on hempseed protein hydrolysates obtained by other enzymes on different cells. The aim of this study was to prepare hempseed protein hydrolysate (HPH) from hempseed protein isolate (HPI) by three commercial enzymes: *Alcalase® 2.4L, Neutrase and Protamex*. In addition, biological potential of prepared HPHs was measured by ORAC assay as well as their effects on viability and cellular changes of normal and tumor cells.

2. Methods

HPHs were prepared using the commercial enzymes *Alcalase® 2.4L, Neutrase and Protamex* as described by [3]. Antioxidant activity of obtained HPHs was assayed by ORAC method. Effects of HPHs on proliferation of normal (HaCaT) and tumor (HeLa) cells were determined by colorimetric MTS assay while cellular changes were assayed by spectrofluorimeter and MUSE cell analyzer.

3. Results and discussion

Prepared HPHs showed strong antioxidant activity (ORAC values in range 576.52±36.5 - 695.2±6.75 µM TE/g protein) in comparison to 32.6±2.35 µM for HPI, indicating releasing of antioxidant

peptides during hydrolysis process. Tested hydrolysates showed cytotoxic activities toward tumor HeLa cells with no effects on normal HaCaT cells (Figures 1-2). Similar results of concentration-dependent antiproliferative effects of germinated soybean protein hydrolysates on breast and cervical cancer cell lines with minimal effects on normal cells was reported by [4]. Observed antiproliferative effects of HPHs in tumor cells suggested relationship between cytotoxicity and antioxidant activity also indicating their potential as functional food ingredient in anticancer therapy.

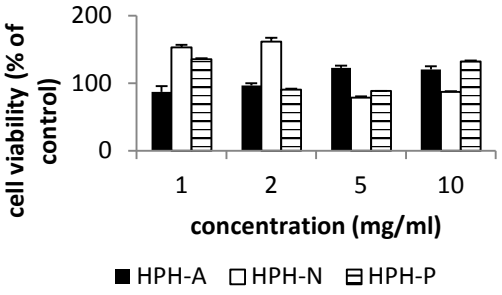

Figure 1. Effects of HPHs on HaCaT cells by MTS assay

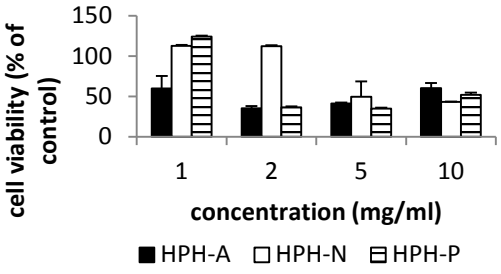

Figure 2. Effects of HPHs on HeLa cells by MTS assay

The ability of HPH-N to protect HaCaT and HeLa cells against oxidative stress induced by H_2O_2 is shown in Figure 3. Pretreatment of cells with HPH-N significantly reduced ROS (+) cells on concentration-dependent manner (29.13-40.5% for HPH-N *vs.* 44.2% for H_2O_2 in HaCaT cells and 27.03 -32.87% for HPH-N *vs.* 54.8% for H_2O_2 in HeLa cells) indicating its protective role against ROS formation.

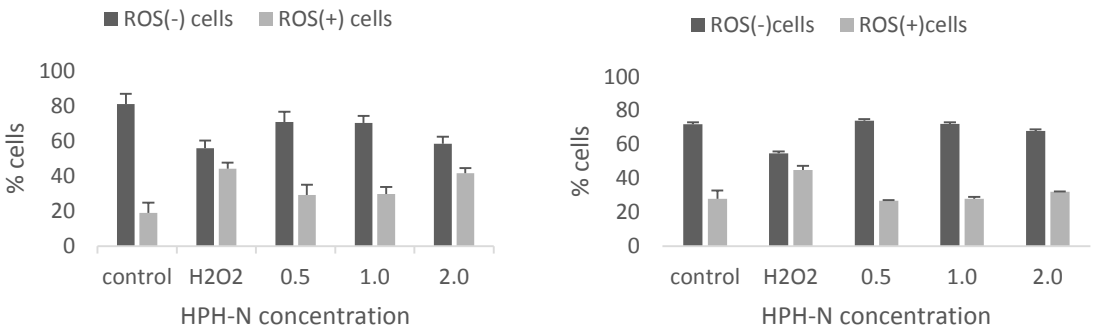

Figure 3. Protective effects of HPH-N on induced oxidative stress in HaCaT (left) and HeLa (right) cells.

4. Conclusions

The results indicate that hempseed protein hydrolisys results in releasing peptides with antioxidative and anticancer activities and might be considered as functional food ingredient.

Highlights

- Optical accessible high-throughput fed-batch cultivation in microtiter plates
- High-throughput protein purification in microtiter plates

1. Introduction

For the development of biotechnological processes, a large number of microbial strains or enzyme variants are generated and have to be analyzed by high-throughput technologies. In these small-scale processes, the cultivation conditions are crucial for a successful strain development as well as for high protein productivities. To imitate production conditions already during early process development, the polymer-based Feed Plate® technology enables fed-batch conditions in microtiter plates [1]. Based on this technique, this study develops an upgrade to enable fed-batch feeding, protein purification and optical accessibility in one microtiter plate. This is realized by a 3D shaping of the polymer matrix (so-called feed rings) which are introduced into each well of a microtiter plate. Additionally, the surface of these feed rings is functionalized with Ni-NTA groups, which allows selective binding and thus purification of His-tagged proteins.

2. Methods

Feed Rings were produced by injection molding of a polysiloxane based polymer matrix containing defined amounts of glucose crystals. Surface modification of feed rings was achieved by addition of carboxylated monomers to the polymer matrix and subsequent esterification with suitable Ni-NTA groups.

3. Results and discussion

First prototypes were constructed, realizing the high-throughput fed-batch cultivaton in 96 well plates through the 3D shaped polymer matrix. The matrix is additionally surface modified to allow for targeted protein binding through Ni-NTA groups (figure 1).

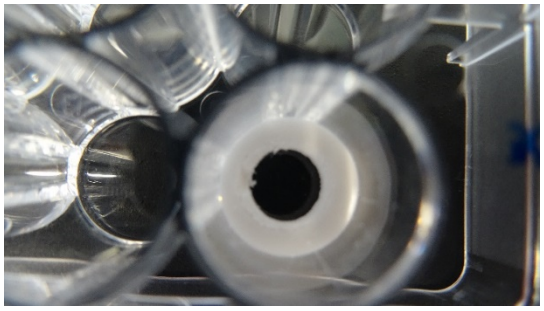

Figure 1. Feed ring in a 96 well plate.

4. Conclusions

Until now, cell culture, digestion, purification and analysis are performed in different microtiter plates. In doing so, almost every step consumes a new plate. Additionally, sterile pipette tips are required for transferring the solutions by means of pipetting. Thus, significant savings in consumables and thus costs can be achieved by the Feed Plate® technology. Another advantage for the scientific work is the reduction of sources of error that occur in particular through frequent pipetting.

Highlights

- Oscillatory Flow Bioreactor (OFB) readjusted from batch to continuous mode
- Continuous processing of cellulose slurry with 15% solid loading possible
- 4 continuous hydrolysis procedures for optimized mixing and overcoming product inhibition
- Enhanced conversion rates at low enzyme input

1. Introduction

The extraction of valuable and pure resources from biogenic material such as lignin, hemicellulose and cellulose is of great importance for the economic realization of biorefineries. Lignocellulosic waste (food waste, forest residues, agricultural waste, etc.) is abundant and therefore a source of special interest, when looking at the production of biobased chemicals and commodities. [1]

Within this study a special focus was put on process intensification steps in terms of an innovative reactor design (Oscillatory Flow Bioreactor, OFB) for overcoming some of the main challenges and hurdles occurring in lignocellulosic conversion processes. The OFB was designed addressing the inefficient (mass and heat transfer inefficiencies) and energy consuming mixing of viscous bioslurries which conventionally are handled at low solid loadings in stirred tank reactors and suffer poor process performance due to a rather slow reaction and product inhibition.

2. Methods

A modular setup of the Oscillatory Flow Bioreactor – enabling batch mode as a first step was designed as follows: Reactor length is adjustable by applying 1 to 2 reactors, baffles of various thickness (2 mm and 3 mm) and different shape (helical) can be inserted. Sinusoidal waveform oscillations in ranges of 0-10 Hz frequencies and 0-11 mm amplitudes are imposed. The overall OFB design is based on Oscillatory Baffled Reactor OBR studies in literature [2] such as on experimental studies at the University of Newcastle.

The conversions were conducted with pure α-cellulose in 50 mM sodium citrate buffer (citric acid monohydrate and tri-sodium citrate dehydrate, Merck Millipore) at pH 4.8, at 50 °C. A DMA 35 device (Anton Paar) was used to measure Glucose formation by density assessment with. Conventional Dinitrosalicylic (DNS) assay were used for detailed evaluation. Batch OFB tests were conducted at different angles, frequencies, amplitudes, viscosities, with different media (ligno-cellulosic material), solid loading (mg/ml) and enzyme loadings (FPU).

3. Results and discussion

The specifically designed Oscillating Flow Bioreactor OFB has been successfully developed for high solid loading (SL) biogenic slurries to ultimately switch from batch to continuous enzymatic hydrolysis processes. Enzymatic conversion experiments of 24 h duration showed, that the batch OFB system generated 3,69 % (70,54 mg/ml) more sugar at similar theoretical mixing power density (12% SL, 2,05 Hz) compared to the reference STR system. The treatment of very high SL (15%) revealed sugar formations of up to 6,7 % higher than its reference system. As shown in Table 1 the 3 mm baffle showed a better conversion performance (+5%) than the thinner 2mm type. Notably also, the OFB system demonstrates similar conversion as the STR while using 20% less FPU of enzyme blend at only 4,8 % power density. Summing up the OFB system exhibited high potential for enzymatic conversions.

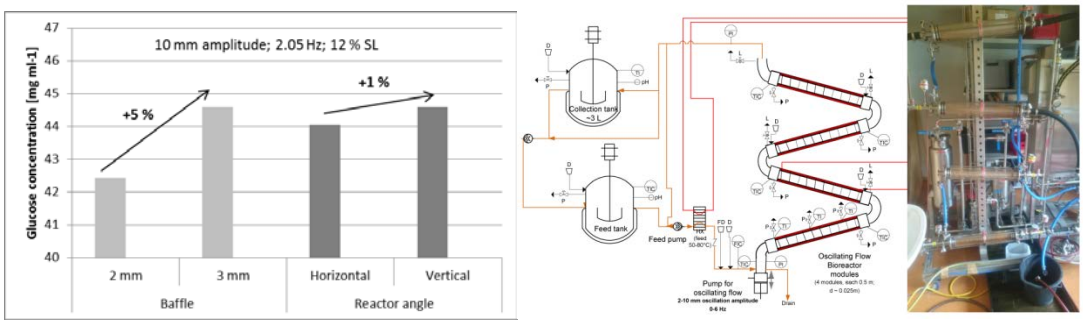

Figure 1. : Steps towards design optimization (left), schematic of OFB plant (right)

The final plant concept is shown in Figure 1 (right side). Conti OFB set-ups consisted of the following configurations ranging from 1-4 OFB reactors in series, Oscillation parameters of 10 mm amplitude, 1-3 Hz and net-flow velocities of up to around 150ml/min.

4. Conclusions

Different steps resulted in best configuration and operating conditions in OFB - Batch mode, these were transferred into OFB - Conti mode. OFB - Batch results gave very satisfying results in terms of glucose production, enzyme input and theoretical energy input, compared to reference STR system. High solid loading of 15% ±-cellulose were reproducibly tested. Various configurations of OFB - Conti tests are tested at the moment. Results will be presented at the conference

**Corresponding author: alvaro.diaz@pucv.cl*

Highlights

- Specific growth rate is improved by high k_La
- PHB productivity was affected by the volumetric oxygen transfer coefficient
- Variation of k_La allowed to define maximal PHB productivity

1. Introduction

The poly-hydroxybutyrate (PHB) is a polyethylene-like bioplastic naturally synthetized by several classes of microorganisms, as a source of energy and carbon unit [1]. This material, which is a promising candidate for the replacement of fossil-based plastic, is already present at an industrial scale. However, the maximization of its production process is the goal to achieve in order to reduce production costs. *Azotobacter vinelandii* is strictly aerobic gram-negative soil bacteria, able to produce PHB in a carbon substrate-rich environment and under oxygen-limitation conditions [2]. The production of this polymer is particularly interesting in this species, because it can accumulate up to 85% of its dried biomass as PHB [3]. It is known that agitation rate affects the PHB production by *A. vinelandii* [2]. In this work, the PHB productivity under fed-batch cultivation was evaluated to different volumetric oxygen transfer coefficient (k_La). Thus, it was possible to determine an adequate k_La range for scale-up the production of PHB.

2. Methods

Batch cultures of *Azotobacter vinelandii* OP were performed in a 3 L bioreactor (30 g L^{-1} sucrose as carbon source) at 600 rpm during 30 h. After of this time, the cultures were fed by a single medium feeding pulse of the carbon source and the agitation speed was varied between 400 and 1000 rpm. The biomass evolution and the PHB production were evaluated. The k_La was estimated at different agitation rate using dynamic method.

3. Results and discussion

The maximal accumulation of biomass was 13.3 g L^{-1}, obtained at an agitation speed of 800 rpm (Table 1). A highest agitation speed increased the specific growth rate, reaching a value of 0.069 h^{-1} to 1000 rpm. During fed-batch cultivation, a change in the agitation speed affected the PHB accumulation, obtaining the highest value (79.1 % w w^{-1}) to 600 rpm.

Agitation speed (rpm)	k_La (h^{-1})	μ (h^{-1})	X_{max} (g L^{-1})	PHB (% w w^{-1})
400	30.3	0.011 ± 0.001	9.45 ± 0.14	66.0 ± 2.6
600	65.6	0.021 ± 0.001	11.50 ± 0.24	79.1 ± 1.5
800	103.6	0.062 ± 0.002	13.25 ± 0.49	54.7 ± 3.5
1000	188.0	0.069 ± 0.001	11.80 ± 0.05	46.3 ± 3.0

Table 1: Parameters obtained in the fed-batch cultures of *A. vinelandii*

Figure 1 shows the influence of k_La on the PHB volumetric productivity. A maximal PHB productivity of 0.28 g L^{-1} h^{-1} was obtained at a k_La of 104 h^{-1}. Overcoming the k_La of 104 h^{-1} the PHB productivity decreased until 0.18 g L^{-1} h^{-1}. Under the conditions evaluated, the PHB productivity obtained to 100 h^{-1} was similar to previous studies [2,3].

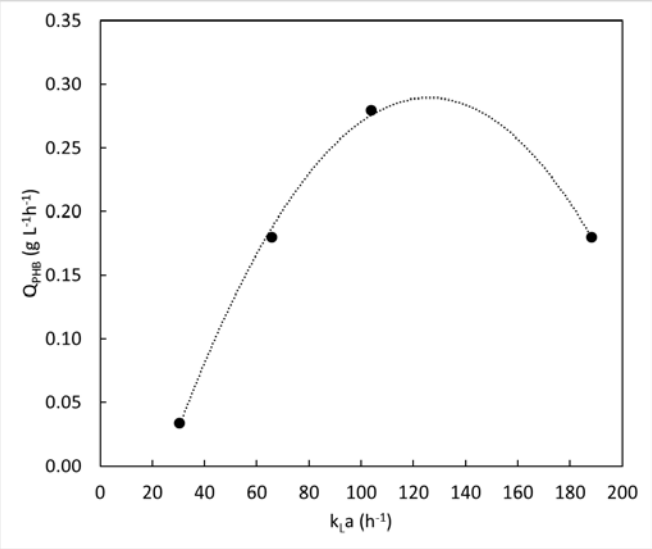

Figure 1. Relationship between the PHB volumetric productivity and k_La values in *Azotobacter vinelandii* OP. The k_La values evaluated correspond to the agitation speed of 400, 600, 800 and 1000 rpm.

4. Conclusions

In fed-batch cultures of *Azotobacter vinelandii*, the PHB productivity was affected by the volumetric oxygen transfer coefficient. The highest PHB productivity was obtained in the cultures performed to 104 h^{-1} (800 rpm). In order to develop a bioprocess to produce PHB, it was possible to identify the optimal oxygen transfer conditions for further bioprocess scale-up.

Development of an external pH monitoring system for a 10 L bioreactor

Nathalia Peruch[1], Fábio Cavalcante[1], Arnaldo Prata[1*]

[1] *Departament of Biotechnology – Engineering School of Lorena – University of São Paulo*
Estrada Municipal do Campinho, sn - CEP 12602-810, Lorena, São Paulo – Brasil

**Corresponding author: amrprata@usp.br*

Highlights

- External pH monitoring system avoids electrode insertion in the bioreactor cover.
- A nylon cilyndrical device and a peristaltic pump are needed in addition to pHmeter.
- Broth pH can be continuously and accuratelly monitored in simple biorreactors.

1. Introduction

A new bioreactor was designed specifically for culturing shear stress sensitive cells and avoid problems caused by adherent filamentous fungi growth (Domingos et al., 2017). This bioreactor can also be used for other bioprocesses using yeasts and bacteria. It was named *Low Shear Aerated and Agitated Bioreactor* (LSAAB). Once the bioreactor was developed without internal prominent parts to avoid micelial adherence, no electrode or sensor holes were provided in its cover. However, in many cases pH must be monitored and controlled in order to ensure cell growth and product formation during a bioprocess. Domingos et al. (2017) verified that pH increases and it must be controlled during the basidiomycete *Ceriporiopsis subvermispora* culturing in LSAAB for optimizing biomass production. During 2,3-butanediol production by *Klebsiella oxytoca* the pH decreases due to organic acids synthesis and excretion (Tsvetanova, Petrova, Petrov, 2014) and it must be controlled for better enzyme activity. Therefore, in the present work it was proposed a strategy of external broth circulation through a device containing the pH electrode inserted, providing broth pH monitoring in LSAAB. The system was tested with water and during the yeast *Saccharomyces cereviseae* growth.

2. Methods

Electrode holder: The device was first drawn, in order to enable its machining. Nylon was used, an appropriate material for both machining and further sterilizations. A cylindrical configuration was addopted, with a diameter 8 mm larger than that of the pH electrode, for a free broth flow. This device was attached to the bioreactor and the peristaltic pump using silicone hoses.

pH mesuring and liquid circulation: pH was mesured with a Sppencer Scientific SP3611 model pHmeter, with an armored electrode inserted in the holder. Liquids were pumped with a VELP Scientifica SP311 model peristaltic pump.

Tests with water: The system was first tested with water in order to verify pH reading stability as a function of pump flow rate (4.5, 19.0, 39.0, 58.0, 78.0, 92.0 e 112.0 mL/min). Samples were collected and had their pH measured separatelly with the same pHmeter. Following, it was

investigated the time for pH change detection by the electrode after acid (5 mol/L HCl) addition, for each pump flow rate above and under agitation speeds of 140 and 200 rpm. For 200 rpm it was also performed tests with aeration (0.8 vvm). Acid was added at the liquid surface in the bioreactor.

pH monitoring during fermentation: *Saccharomyces cereviseae* was used to carry out the culturing in LSAAB for the external pH monitoring system avaliation. Culturing medium (10 L) consisted of (in g/L): glucose (20.0), $(NH_4)_2SO_4$ (5.0), KH_2PO_4 (3.0), $MgSO_4$ (1.5) and yeast extract (6.0). Initial pH was adjusted to 4.5. Temperature and aeration were 25 ^oC and 0.8 vvm, respectivelly. Substrate and cell concentrations were measured by DNS and optical density methods, respectivelly.

3. Results and discussion

The cylindrical device was attached to the bioreactor and showed to be proper for liquids (water and culturing medium) circulation using flow rates from 4.5 to 112.0 mL/min. Using water, on line pH readings remained constant after 1 minute from the adjusting for flow rates from 19.0 to 112.0 mL/min, indicating an adequate fluid dynamics accross the system. Collected samples and on line pH readings showed a difference from 0.01 to 0.04 pH units, considering all flow rates tested. Considering the simmulation of microrganism actuation, pH readings remained constant after 2.0 minutes from acid addition, for flow rates from 58.0 to 112 mL/min, at 140 rpm agitation. At 200 rpm the time was 1.0 min for flow rates 92.0 and 112.0 mL/min, showing the effect of agitation on the whole broth pH change. Aeration did not affect the time for obtaning on line constant pH readings. This facts indicate that a flow rate about 90 mL/min and an agitation of 200 rpm are sufficient for monitoring and controlling broth pH in LSAAB using the proposed system. It can be considered that a delay of 1.0 minute from acid or alkali addition to pH correction in the whole broth do not compromise the bioprocess.

However, regarding the yeast cultivation, the differences between samples pH and on line pH readings varied from 0.1 to 0.15 pH units. Although higher than those obtained for water, such values represent a maximum of 3.75% of the desired pH value. It should be mentioned that broth samples were cooled and had their pH mesured from 3 to 15 hours after collected. Due to the intense metabolism of the yeast some changes in the broth could have occurred, even during cooling. Therefore, it can be considered that the proposed external pH monitoring system does not interfere in the actual broth pH inside the LSAAB. Further investigations include carrying out fermentations requiring pH adjustment.

4. Conclusions

The external pH monitoring system proposed for LSAAB is adequate for obtaining the actual broth pH value during fermentation processes and its control in simple bench bioreactors, without insertion of an electrode in the bioreactor cover. Best results are obtained with an agitation of 200 rpm and a minimum of 90 mL/min of broth circulation flow rate, considering the geometric characteristics of LSAAB, like liquid height, vessel internal diameter and “L” shaped stirrer.

Highlights

- Efficiency solubilization of phosphate present in iron ore.
- Iron ores wastes may be used as source of phosphorus when properly treated.
- Biolixiviation using fungus proved to be efficient for reduction of phosphorus in iron ore tailings reducing its environmental pollution.

1. Introduction

In iron and steel production chain, phosphorus element is present in almost all stages, tending to concentrate during the extractive process, due to its ability to pass from the oxidized form to elemental form, being present in metallic iron after reduction mineral (Delvasto et al., 2009). Steel produced at high phosphorus levels will be brittle and can easily break, hence the need for dephosphorization (Chime et al., 2011). As a result, different iron dephosphorization techniques have been developed. These methodologies tend to have high production costs with low productivity (Mendes et al., 2013, Xiao et al., 2015). In view of this problem, it is necessary to develop sustainable and cost-effective processes for the exploitation of minerals containing different levels of phosphorus (Liu et al., 2015). One of the most promising solutions is the use of microorganisms in a process called microbial bioleaching, when compared to other physical-chemical processes (Chime et al., 2011). Its advantage is the use of mild conditions, usually without addition of toxic chemicals. The objective of this work was to test a filamentous fungus isolated from the iron ore tail itself in the solubilization of the phosphorus present in this ore.

2. Methods

Fungus was isolated by enrichment cultivation in NBRIP medium (Nautiyal, 1999), whose phosphate was withdrawn and added 5g of iron ore tailings for the fungus isolation and also as N_2 source. Erlenmeyers containing 50mL of medium were incubated under agitation (130 rpm) at a temperature of 30 ± 2 °C. Every 7 days 1.0 ml aliquot was withdrawn and inoculated into fresh culture medium and incubated for another 7 days. This process was repeated two more times. After last repeat, aliquots were taken, diluted conveniently and inoculated into Petri dishes containing NBRIP medium plus $Ca_5(OH)(PO_4)_3$ as source of phosphorus. Plates were incubated in a BOD oven at 30 ± 2 °C for a period of 7 days. Colonies that had a characteristic halo of phosphorus solubilization were isolated. Following parameters were determined: growth curve, pH evolution, acid phosphatase activity, phosphorus solubilization. Parameters were performed for 168 hours with collection of 24/24 hours. For growth curve, samples were taken at described time, filtered in previously weighed Millipore® type filter (0.22µm). The material was dried in a desiccator with silica gel in an oven at 30 °C for 24 hrs until constant weight and the fungus mass was

deteminated. pH was determined in aliquot of the aliquots after centrifugation using a pHmeter. Phosphatase acid activity was performed using the Labtest® Trade Kit according to the manufacturer's guidelines. Phosphorus solubilization was performed by dosage of the solubilised phosphate using the Spectro Kit of the Alfakit® brand, according to the manufacturer's guidelines.

3. Results and discussion

Results obtained for determination of fungic mass, pH, acid phosphatase activity and phosphate solubilization can be observed in Figure 1.

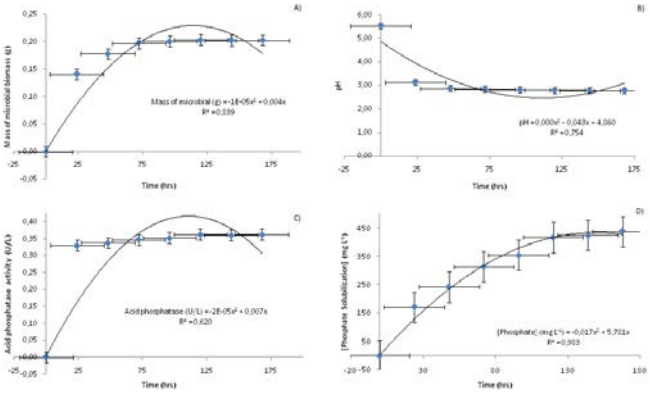

Figure 1. Results obtained for determination of fungal mass (A), pH (B), acid phosphatase activity (C) and phosphate solubilization (D).

According to analyzed parameters, it was observed that, between 144 and 168 hours, its stabilization occurred (Fig. 1). Xiao et al. (2015) testing dephosphorization of iron ore with high concentration of phosphorus by different strains of *Aspergillus niger*, observed similar results of pH reduction, phosphorus solubilization and fungal growth. Phosphate biosolubilization has been shown to be a very efficient process for conversion of insoluble phosphate into phosphorus, corresponding to a solubilization of 43% in 7 days of incubation, ie, equivalent to a mass of 0.1539 g of phosphate in the counterpart of 0.3576 g of iron ore.

4. Conclusions

Using of filamentus fungus for phosphorus solubilization, present in iron ore tailings, proved to be efficient in this study. Researches are underway to make this process feasible on a large scale

Highlights

- Synthesis and hierarchical structuring of superparamagnetic iron oxide nanoparticles
- Functionalization with ligand that interacts specifically with recombinant model proteins
- Highly efficient purification and regeneration over multiple cycles
- Modification of nanoparticle structures in terms of magnetization and morphology

1. Introduction

Magnetic nano- and microparticles have become highly promising for diverse areas of biomedicine, including *in vitro* applications in diagnostics and downstream processing due to their highly selective manipulation possible by applying external magnetic fields.[1] For these applications, homogeneous particle properties, e.g. the magnetization, are of crucial importance, allowing a uniform response and defined chemical and physical characteristics. In addition, the surface chemistry must be tailored for the intended application to ensure stability of the particles against agglomeration in the desired medium as well as the targeted interaction with the biological system.

2. Methods

A multi-step synthesis process for biofunctionalized superparamagnetic iron oxide nanoparticles has been established and their application for the purification of recombinant model proteins has been investigated in detail. As-synthesized nanoparticles were structured to hierarchical micron-sized aggregates in a spray drying process to improve the magnetic separation efficiency. The aggregate surface was then modified with a previously established ligand system capable of forming metal complexes with histidine tags that allows for the use in multiple separation cycles.[2] *In situ* purification experiments were performed, separating recombinant proteins with His_6-tags produced by genetically engineered *Bacillus megaterium* in a lab-scale stirred tank bioreactor with an external separation loop using handheld magnets.[3] Additionally, the

modification of the aggregates was studied by varying the magnetization after the partial substitution of the magnetic iron oxide nanoparticles with silica nanoparticles.

3. Results and discussion

Structuring of iron oxide nanoparticles via spray drying of aqueous suspensions leads to micrometer-sized aggregates with a specific magnetization comparable to that of the individual nanoparticles. Modification of the aggregates via addition of silica nanoparticles to the suspension allows for control of the resulting magnetization by adjusting the iron oxide content. Moreover, the morphology of the produced aggregates is gradually shifted from irregular inflated-like shapes in case of pure iron oxide aggregates to spherical structures when bringing the silica-content to only 20 % (see Figure 1).

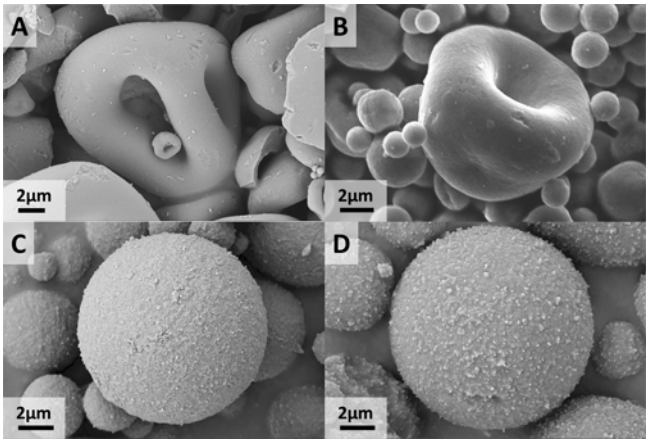

Figure 1. Scanning electron micrographs of spray-dried aggregates with an iron oxide content of (A) 100 %, (B) 90 %, (C) 80 %, and (D) 40 %, respectively.

High efficiency magnetic separation of aggregates with different magnetization is shown. Functionalization of pure iron oxide aggregates with a previously coupled ligand holding an NTA moiety and subsequent loading with Ni^{2+}-ions leads to the ability to bind His_6-tagged target proteins via a chelation complex. The functional recyclability of the particles and the successful application of protein purification in an automated set-up over multiple cycles with a protein purity above 97.5 % will be presented.

4. Conclusions

The successful synthesis of superparamagnetic iron oxide nanoparticles and their structuring in a spray-drying process with subsequent functionalizaton for bioseparation processes will be shown. The highly efficient selective purification of recombinant proteins over mutliple cycles will be demonstrated.

**giselladeq@gmail.com*

Highlights

- The continuous process allowed double the total GOS yield, compared to batch process.
- The continuous process favors a balance between the transgalactosylation reaction and the hydrolysis reaction.
- The maximum concentration of GOS in the continuous process was 256.72 g mL^{-1} of solution, against 129.90 g mL^{-1} of solution in the batch process.

1. Introduction

Galacto-oligosaccharides (GOS) are nondigestible carboydrates mostly produced from lactose transgalactosylation with β-galactosidases [1]. GOS are synthesized from lactose in a kinetically controlled reaction catalyzed by β-galactosidase (β-D-galactosidase galactohydrolase E.C.3.2.1.23), where the transgalactosylation and hydrolysis reactions occur simultaneously [2]. The high substrate concentration required is one of the main technological challenges in GOS synthesis; because of the relatively low solubility of lactose. Continuous stirred tank reactor has not been so much reported in the literature for the GOS synthesis, being the purpose of this work to evaluate the potentials of this strategy and to compare it with conventional batch synthesis. The present work has been conducted using β-galactosidase immobilized on macro porous silica, implementing a strategy for lactose feeding to the reactor and withdrawal of products; in order to avoid the effects of low lactose solubility, and thus achieve an increase in GOS yield at the end of reaction.

2. Methods

The chemical modification of the controlled porous silica was based on the study of Bernal et al [3]. Silanization was made using GPTMS (3-glycidyloxypropyltrimethoxysilane) solution. The immobilization of β-gal on glyoxyl-silica was done by the covalent method. After the immobilization, the enzyme was cross-linked with glutaraldehyde.

A duplicate experiment of GOS synthesis with *K. lactis* β-galactosidase was conducted in continuous process in order to evaluate its advantages over the batch operation mode. Operational sequence considered three stages at the following conditions: (i) An in initial batch synthesis stage lasting 45 min. (ii) A second stage in which a 40% w/w lactose solution was feed for 16 h at a feed of rate of 0.05 g of solution.$h^{-1}$and withdrawal of products with the same rate. (iii) A final batch stage during the next 48 h. The main product profiles were compared to the ones obtained by batch process. Lactose and products synthesis were done using HPLC system refractive index detector (SHIMADZU, UV-1601PC). The method was adapted from Santos [4].

3. Results and discussion

Figure 1 shows the yields for galacto-oligosaccharides production for batch and continuous process. Analysing this Figure, we can observe that the continuous process allowed double the total GOS yield. This can be explained by the fact that, the concentration of lactose is increased in this process, favouring a balance between the transgalactosylation reaction and the hydrolysis reaction. In the batch process, the GOS production is high only at the beginning, where the lactose concentration is still high, after which only the hydrolysis reaction is favoured.

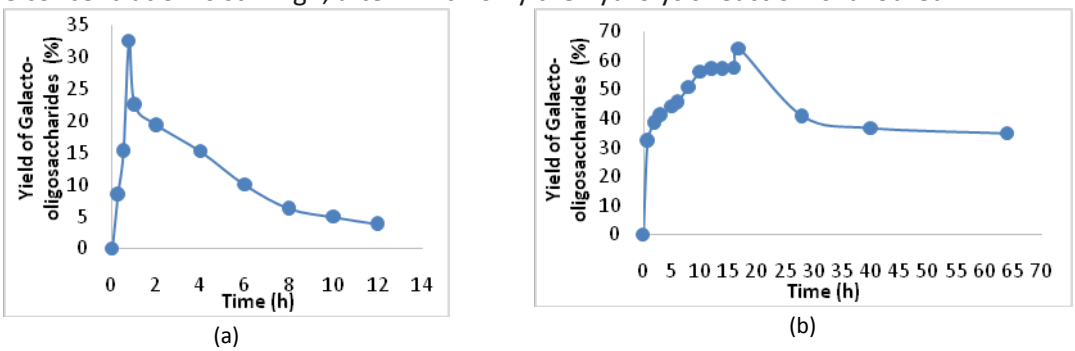

Figure 1. Yields of galacto-oligosaccharides. (a) Batch process, (b) Continuous Process.

4. Conclusions

This work shows that is possible to reach high total concentrations of dissolved sugars (>50% w/w) at moderate reaction temperatures without reduction in GOS yield by considering the synthesis of GOS in continuous process operation. This strategy allowed obtained an optimal final concentration of GOS higher than the one obtained in batch reactor operation.

Highlights

- The volatile compounds produced by the yeast strains were identified and quantified using SPME-GC-MS.
- Selection of yeast strains with potential to develop starter cultures for cocoa bean fermentation.

1. Introduction

Fermentation is one of the most important steps in the post-harvest process of cocoa, because many of the organoleptic perceptions that will directly impact the quality of the final product are developed in this stage by the action of microorganisms [1]. Among the main microorganisms involved in this process are the yeasts, lactic and acetic bacteria. The yeasts are the microorganism that plays the most important role in the production of volatile organic compounds [2]. The most common metabolites produced are esters which are related to fruit notes, alcohols with floral aromas and aldehydes and ketones with walnuts or almonds [3].

For those reasons is imperative to have more control over the fermentation; and one of the recently proposed alternatives is the use of starter cultures. These starter cultures are made from yeasts isolated from typical cocoa fermentations that have had the effect of producing cocoa paste with fine or flavor characteristics. The use of this approach would not only reduce the fermentation time [4], but also the variability between production lots; ensuring the uniformity of the product in markets that increasingly require more traceability [5]. The main objective of this work is to select yeast isolates that represent potential sources for producing volatile compounds related to desirable perceptions in cocoa beans.

2. Methods

1. The isolation of yeast from fermentation box was done as following: Sampling cocoa beans during fermentation process until cocoa bean was well fermented; once it was

done the sample was diluted serially in order to get single colonies for isolation in Sabouraud media.

2. The growth of yeast and volatile compound production was following by UFC and SPME – GC – MS, respectively. Briefly, the isolated yeast was inoculated in a Sabouraud media and then the growth of yeast was development until reach a 10^6 UFC. After that, the media was placed into a hermetically sealed vial where was developed the solid phase microextraction using the procedure described by Palencia [5]. Then, the identification and quantification of volatile compounds produced by the yeasts was carried out by GC-MS and GC-FID respectively using the HP5 column 30m x 0.25µm x 0.25µm [5].

Finally, the concentration profile obtained was analyzed in order to determine which yeasts have the best potential to produce aroma compounds. Yeast with highest yields in volatile compounds were selected for starter culture development.

3. Results and discussion

Four yeast were selected for the future starter culture development according to aroma profiles produced by each of them identifying and quantifying by using GC. Some volatile compounds produced by selected yeast can be mentioned as follow: alcohols, esters, aldehydes which are related with sensorial perception of floral, fruit, nutty; respectively.

Interestingly, the yeast 111 was be able to produce high concentration of isoamyl ester; this finding would be used for developing cocoa fermentations in order to produce cocoa mass with fruit characteristics, which aren't typically produced in Colombia.

4. Conclusions

In this work there were isolated 90 native yeasts and it was selected 4 of them with potential to use in cocoa fermentations. Remarkably, it was found a yeast with potential to produce high concentration of esters which open the possibility to a development fermentation process to produce Colombian cacao with new sensorial profiles.

Thermostable cellulase and xylanase activity from *Sulfolobus shibatae* of potential application in lignocellulosic bioethanol production

Angela Boyce, Gary Walsh*

Department of Chemical Sciences and Bernal Institute, School of Natural Sciences, University of Limerick, Limerick, Ireland.

**Corresponding author: gary.walsh@ul.ie*

Highlights

- In xylan-containing media at 75°C, *S. shibatae* produces cellulase and xylanase.
- The crude enzymes display optimum activity at 100°C and are thermostable.
- The crude enzymes display activity on pretreated straw lignocellulose at 90°C.
- Potential application in hydrolysis of lignocellulose for bioethanol production.

1. Introduction

Enzymes produced by thermophilic microorganisms are of growing interest in industrial applications due to their activity and stability at high temperatures [1]. Amid environmental concerns in relation to the use of fossil fuels, one such industrial application is in the enzymatic hydrolysis of lignocellulosic biomass to produce bioethanol, which can be used as an alternative transportation fuel. The enzymatic hydrolysis of lignocellulose is currently undertaken at 40-50°C and process improvements are necessary to achieve competitive bioethanol production [2]. Increasing the hydrolysis temperature by using thermostable enzymes active at higher temperatures offers several potential advantages including: higher reaction rates, improved hydrolysis performance, decreased hydrolysis times, increased substrate solubility and lower viscosity, reduced risk of contamination and lower cooling costs following thermal pretreatment [2,3]. The identification and characterization of novel thermostable lignocellulose-degrading enzymes suitable for this application is therefore of interest. This study describes the production and initial characterisation of thermostable cellulase and xylanase activities from the archaea *Sulfolobus shibatae* with emphasis on determining potential suitability for lignocellulosic bioethanol production.

2. Methods

Sulfolobus shibatae B12 (DSM 5389) was grown at 75°C in *Sulfolobus* medium [4] containing 0.05% (w/v) yeast extract and 0.1 % (w/v) xylan. After 8 days, the cells were removed by centrifugation and the resulting supernatant (crude enzyme) was concentrated by ultrafiltration using a 10 kDa membrane. Enzyme activity was determined by measuring the amount of reducing sugars released from carboxymethyl cellulose (CMC) or xylan using the dinitrosalicyclic acid method [5].

3. Results and discussion

The thermophilic archaea *Sulfolobus shibatae* was found to produce thermostable cellulase and xylanase activities when grown in xylan-containing media. Upon determination of the effect of

temperature on enzyme activity using CMC as substrate, maximum activity was observed at 100°C with over 70% of maximum activity observed in the temperature range 90-105°C (Figure 1). The crude xylanase activity also had an optimum temperature of 100°C with over 70% of maximum activity observed in the temperature range 85-105°C. Maximum activity on both CMC and xylan was observed at pH 4.

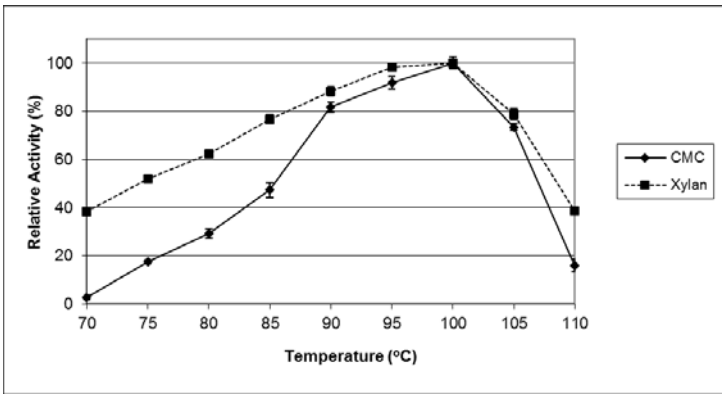

Figure 1. Effect of temperature on the crude enzyme activity from *S. shibatae* on the substrates CMC and xylan. Data expressed as a percentage of maximum activity.

Upon assessment of enzyme thermal stability, 86% of original activity on CMC and 64% of original activity on xylan was detected after incubation of crude enzyme at 80°C for 30 hours. At 95°C, the crude enzyme retained 44% and 23% of original activity on CMC and xylan, respectively, after 24 hours and at 100°C, 63% of original activity on CMC was detected after 30 minutes compared to 41% of original activity on xylan.

The crude enzyme produced by *S. shibatae* was capable of hydrolysing pretreated straw lignocellulose. After 6 hours at 90°C, the amount of reducing sugars released at pH 3.5 was approximately twofold the amount released in the corresponding control samples without enzyme. The crude enzyme also rapidly decreased the viscosity of CMC solution at 90 and 95°C.

4. Conclusions

The properties of the crude cellulase and xylanase activities produced by *S. shibatae*, in particular the high activity and stability observed at high temperatures and ability to hydrolyse straw lignocellulose at high temperature, strongly indicate potential suitability for use in the production of cellulosic bioethanol. While further studies are necessary to confirm industrial applicability, potential uses include the prehydrolysis/liquefaction of pretreated lignocellulose and/or as a component of thermostable enzyme cocktails for hydrolysis of pretreated lignocellulose to fermentable sugars. Moreover, these enzymes may also be of interest in other biotechnological processes undertaken at high temperatures.

RETRO-TECHNO-ECONOMIC-ENVIRONMENTAL ANALYSIS (RTEEA) APPLIED TO FIRST- AND SECOND-GENERATION ETHANOL PRODUCTION

Highlights

- Global sensitivity analysis shows that environmental and economic metrics can be divided in two groups.
- Economic metric (NPV) is influenced mainly by the hydrolysis step.
- Environmental metrics are significantly influenced by the pretreatment stage.

1. Introduction

Economic and environmental analysis is an important field in (bio)process engineering, supporting R&D decisions. Process Systems Engineering tools (PSE) allied with techno-economic analysis (TEA) and life-cycle assessment (LCA) can be used to verify process feasibility, to identify possible bottlenecks and optimal operating conditions, among other possibilities.TEA and LCA are usually used to assess the economic and environmental performance of defined process conditions, both structural and operational. RTEA [1] is a novel approach that turns this problem upside down: rather than evaluating the TEA for a predefined processes setup, it provides goals to be pursued by R&D teams, in order to seek feasible operational conditions, based on simulations of the overall process. In this work, RTEA was expanded to RTEEA (Retro-Techno-Economic-Environmental Analysis), incorporating life cycle assessment. RTEEA was applied to the first- and second-generation (1G/2G) ethanol production from sugarcane, using economic and environmental metrics to define feasible regions. Global sensitivity analysis (GSA) was used to identify, with statistical support, critical process variables [2].

2. Methods

RTEEA is constituted by four steps: construction of a base case, incorporation of TEA and LCA analysis into the simulation of the process, selection of key variables through global sensitivity analysis and delimitation feasible spaces. The 1G/2G anhydrous ethanol production from sugarcane industrial process was modelled as described by Longati et al (2018). The energy consumption of the plant was optimized through pinch analysis of the process main stream. In this case study, the Net Present Value (NPV) was chosen as the economic metric. The CML-IA baseline V3.04 (World 2000) method was used to perform the life cycle impact assessment (LCIA). The environmental metrics are derived from LCIA. An initial set of variables was chosen using previous knowledge of the process for the global sensitivity analysis through the Sobol method [2]. The main and total

Sobol indexes were used to select the process variables. To perform the retro-techno-economic-environmental analysis, it is essential that the variables chosen for analysis are process constraints. If this is not the case, other specified variable, correlated with the desire one, must be freed in order to keep null the degree of freedom of the whole-plant model. The TEA and LCA equations that equal the chosen metrics with a threshold value must be solved together with the model equations of the process (energy and mass balances, thermodynamic relations and so on). In this case study, these equations were NPV = 0 and the CML method environmental indicators of the 1G stand-alone process. The chosen process constraints that satisfy those equations are the output of RTEEA.
The platform for the simulations was the software EMSO, which is an equation-oriented simulator.

3. Results and discussion

Among more than twenty-seven thousand process variables are present in the biorefinery model. Therefore, an initial ad-hoc selection of variables, based on previous knowledge, had to be made to obtain a treatable set of variables to be spanned by the global sensitivity analysis. The process variables chosen for this case study are related to the steps of bagasse pretreatment, cellulose enzymatic hydrolysis reactor, and xylose fermentation, in the 2G sector of the plant. These steps are still not industrially consolidated, and the information that RTEEA provides may be useful for R&D teams. The GSA pointed out that there are two distinct groups, that encompass various metrics. The first one, composed of the net present value, global warming potential, and photo-oxidation, is mainly influenced by enzyme load and cellulose conversion in the saccharification reactor. The second group, composed of all other metrics, is mainly influenced by the solid mass fraction in the pretreatment stage, and by the cellulose-to-glucose conversion.

4. Conclusions

In this work, environmental techno-economic analyses were coupled to derive targets for R&D teams, at early stages of the process development. The RTEEA methodology, an extension of RTEA, was able to identify the process variables that show significant influence on economic and environmental performance of the process, to obtain their threshold values, and to make explicit their relations. A case study was used to demonstrate the methodology capabilities: 1G-2G bioethanol production using sugar cane as feedstock. With this methodology, new goals and directions for process development can be quickly defined.

EFFECT OF CALCIUM AND XYLOOLIGOSACCHARIDES ON XILOSE ISOMERASE ACTIVITY FOR ISOMERIZATION OF XYLOSE TO XYLULOSE

Felipe A. S. Corradini[1], Thais S. Milessi-Esteves[1], Roberto C. Giordano[1], Raquel L. C. Giordano[1*]

Highlights

- Kinetic parameters of the enzymatic xylose-to-xylulose isomerization were estimated.
- Ca^{2+} ions are competitive inhibitors of the isomerization enzymatic reaction.
- Xylobiose inhibition is only important at high concentrations.

1. Introduction

Xylose isomerase (XI) catalyzes the reversible isomerization of xylose to xylulose and of glucose to fructose. Its molecular mass is around 173 kDa, formed by four identical subunits of approximately 47 kDa each. Bivalent ions (Mg^{2+}, Mn^{2+} and Co^{2+}) act as important cofactors of the enzyme, some of them being essential components in the reaction medium in order to keep the isomerase activity. XI is one of the enzymes with the highest market demand in the food industry, used for the production of high-fructose corn syrup (HFCS) through the isomerization of glucose to fructose. Due to this industrial application of XI, the kinetics of this reaction was well investigated.

On the other hand, there are few reports in the literature about the enzymatic xylose-xylulose isomerization, most of them between the years 1980-1990, and related to the application of the reaction in the simultaneous isomerization and fermentation of xylose (Simultaneous Isomerization and Fermentation, SIF). These studies aimed at the production of 2G ethanol from hemicellulose, through fermentation of xylulose by *Sacharomyces cerevisiae*, the microorganism conventionally used in the 1G ethanol production. However, the genetic modification of *S. cerevisiae* to allow *in-vivo* isomerization in order to achieve the direct fermentation of xylose was almost the only studied route in the following 20 years. This approach is still not implemented in the industry, so the SIF process study was resumed [1]. Furthermore, XI was also used as a component in a biocatalyst for ethanol production from xylo-oligomers, the Simultaneous Hydrolysis, Isomerization and Fermentation process (SHIF) [2]. In the SHIF process, xylanases hydrolyze xylo-oligomers to xylose, which is then isomerized to xylulose by XI, and xylulose is converted to ethanol by non-modified *S. cerevisiae*. The biocatalyst also contains calcium carbonate in order to control the intra-particle pH. Xylobiose and Ca^{2+} ions are potential inhibitors of the isomerization of xylose to xylulose in the SHIF process. Within this context, the kinetics of this reaction is investigated here.

2. Methods

2.1 Xilose isomerase activity assay: initial velocity of xylulose formation is determined using 5 mL of substrate solution (2 mol.L^{-1} xylose in 50 mmol.L^{-1} tris-maleate buffer pH 7.0 containing 50 mmol.L^{-1} $MgCl_2.6H_2O$ and 2.5 mmol.L^{-1} $CoCl_2.6H_2O$), at 60 °C. Xylulose was quantified using the cysteine-carbazol method [3].

2.2 Preparation of xylobiose rich solution according to [4]. Beechwood xylan solution (50 g.L^{-1} in 50 mM sodium citrate buffer pH 5.5) was hydrolyzed by soluble xylanase NS22036. Xylo-oligosaccharides concentration was determined via HPLC using a SugarPak I column (Waters, Milford, USA).

2.3 Influence of substrate, Ca^{2+} ions and xylobiose (X_2) on the rate of reaction at 35 °C: concentrations were varied, for xylose (15-300 g.L^{-1}), Ca^{2+} ions (0-16 g.L^{-1}) and X_2 (0 - 9.1 g.L^{-1}).

3. Results and discussion

A Michaelis-Menten model with competitive inhibition represented well the influence of Ca^{2+}. The kinetic model describes the competition between Ca^{2+} and Mg^{2+} ions for the metal site within the active site of XI.

Isomerization rates were slightly affected by the presence of X_2 at substrate concentration of 45 g.L^{-1}. Inhibitory effects were better perceived at higher substrate concentrations, keeping the amount of X_2 fixed. A Michaelis-Menten rate expression with uncompetitive inhibition fitted well to the experimental data.

4. Conclusions

This work showed that Ca^{2+} competes with Mg^{2+} for the metal site in the enzyme structure. X_2 is a uncompetitive inhibitor of the reaction, affecting the reaction rates more severely at higher substrate concentrations.

Highlights

- GO-G aerogels were synthetized by microwave assited reaction
- The aerogels have a high blood absorption capacity (over 70%)
- The blood cells were retained by aerogels

1. Introduction

Actually, the developing of science and nanotechnology has allowed the synthesis of new materials with biomedical applications. Among them, the graphene and its oxidated forms, such as graphene oxide (GO), have been used in this area for their biological, chemical, physical and mechanical properties [1]. An important application of this material is to be functionalized with biocompatible polymers, as gelatin (G),to obtainGO-G aerogels.These aerogels are materials that present low density, high surface area,and porous structures [2]. Based in this properties, it is possible use them in the biomedical field,as a hemostatic agent, in the control of profuse bleeding generated in wounds. The aim of this study was synthesized GO-G aerogels by microwave assisted reaction, to evaluate their surface properties and hemostatic performance, in order to validate its use as a hemostatic agent.

2. Methods

The GO-G aerogels were developed to different synthesis conditions (pH and GO-G ratio) [1], to analyze the influence of these factors on the physicochemical properties of the biomaterials synthesized. Subsequently, the capacity absorption of the synthesized aerogels on phosphate-buffered saline (PBS) was determined, simulating of pH wound conditions. The internal structure of the synthesized aerogels was evaluated by scanning electron microscope (SEM), to observe the blood cell adhesion to the structure of these materials. Also, a droplet of fresh blood was dropped onto the GO-G aerogels surface at different exposure times (30 to 240 seconds) to evaluate the process of blood absorption. Finally, the blood absorption capacity assays and *in vitro* dynamic whole-blood clotting by absorbance determination were developed [3] using 50 microliters of fresh blood to conditions similar to the previous ones, was carried out to evaluate the hemostatic performance of these aerogels.

3. Results and discussion

Among the developed aerogels, those synthesized at basic conditions and a greater proportion of gelatin had the higher PBS absorption capacity (up to 65%), indicating that these materials could have a better interaction with external media such as blood. Also, the SEM images showed that there was an adhesion of red blood cells in the materials synthesized (see Figure 1) and this phenomenon increased proportional to the content of GO in the aerogels synthesized, as seen in the Figure 1b); regardless of pH conditions used in the synthesis. This phenomenon can explain due the interactions between GO and blood components, favoring the hemostatic performance of these aerogels. Finally, all the synthesized aerogels, had blood absorption capacities higher tan 70%, in a maximum time of 240 seconds, which can favor the control of profuse bleeding and validate that use as possible hemostatic agent.

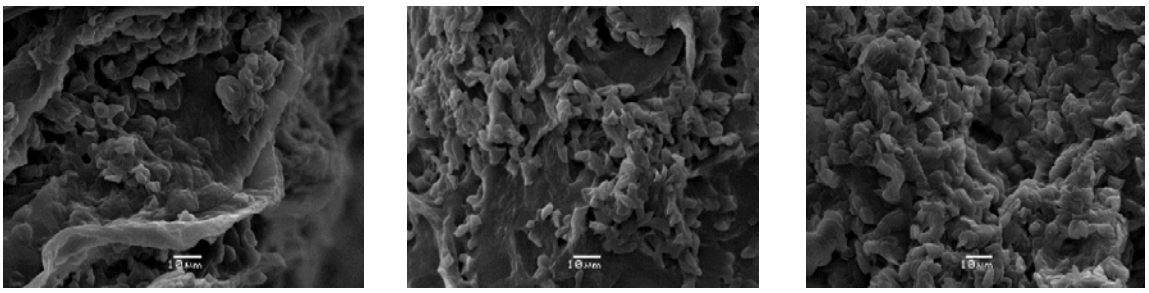

Figure 1 SEM images a) GO-G aerogels at basic pH and 1:15 GO-G ratio, b) GO-G aerogels at acid pH and 1:10 GO-G ratio, c) GO-G aerogels at neutral pH and 2:25 GO-G ratio.

4. Conclusions

The studied showed the possibility of the use of GO-G aerogels as hemostatic agents according to the internal structure and blood absorption capacity reported.

Highlights

- Screening of six various carriers for immobilization of *β*-galactosidase.
- Tyrosol adsorption on carriers and calculation of Langmuir parameters.
- Synthesis of tyrosol β-galactoside by immobilized biocatalyst.
- Study of operational stability of immobilized biocatalyst on one selected resin.

1. Introduction

Nature produces a vast variety of glycosides with interesting biological properties which could be used in pharmaceutical and cosmetics industry. However, demand for naturally occurring glycosides in reasonable quantities and purity requires their synthesis, either chemical or enzymatic. Enzymatic synthesis represents an effective and direct alternative to the synthesis of glycosides thanks to the stereo- and regioselectivity of enzyme. Enzymatic synthesis of glycosides is carried out using hydrolytic enzymes such as glucosidases, fructosidases and galactosidases. These enzymes possess both hydrolytic and transferase activity, but the ratio of these activities depends on the source of enzyme. Glycosides containing tyrosol or hydroxytyrosol group possess bioactive properties. Tyrosol *β*-galactoside owns many advantageous properties for humans, such as antioxidant, anti-fatigue and anti-hypoxia effects. This study is focused on enzymatic synthesis of tyrosol *β*-galactoside by immobilized *β*-galactosidase from *A. oryzae*. Immobilization was conducted on various commercial resins. All studied resins were used for the enzymatic synthesis of tyrosol *β*-galactoside. Furthermore, adsorption of tyrosol on the resins were measured at two different temperatures and subsequently Langmuir parameters were calculated. Based on the results, one immobilization resin was chosen for study of operation stability in repeated batch experiments.

2. Methods

The investigated resins were Dowex Marathon MSA (Dowex), Lifetech™ ECR1508 (1508), Lifetech™ ECR8309M (Amino C2), Lifetech™ ECR8409M (Amino C6), Lifetech™ ECR8209M (Epoxy) and Lifetech™ ECR8285M (Epoxy Butyl). Before immobilization and adsorption measurement was each resin prepared according to immobilization protocol from supplier. Enzymatic synthesis of tyrosol *β*-galactoside and adsorption of tyrosol on resins were carried out as batch experiments. Samples from adsorption measurements were analyzed by the diode array spectrophotometer HP 8452A (Hewlett Packard, USA) at a wavelength of 275 nm. The HPLC system Agilent 1200 (Agilent Technologies, USA) with diode array detector and a Zorbax Eclipse XDB C-18 column with a guard

column was used to determine the concentrations of tyrosol and tyrosol *β*-galactoside in diluted samples from enzymatic synthesis.

3. Results and discussion

The primary aim of this study was to prepare an immobilized biocatalyst suitable for the synthesis of tyrosol *β*-galactoside. At first, tyrosol adsorption was measured for each studied resin and isotherms at 37°C are illustrated in Figure 1. Carriers 1508 and Dowex are based on non-polar, hydrophobic matrices containing benzene rings, however Amino and Epoxy, Epoxy Butyl carriers are made from more hydrophilic and polar methacrylate resins. Since tyrosol contains a non-polar benzene ring it has a greater binding capacity on non-polar particles. It is clear from the results that Amino C2 and C6 carriers are the most polar particles and therefore they adsorb the least amount of tyrosol which results in the greatest amount of tyrosol available in the reaction solution for synthesis of tyrosol *β*-galactoside.

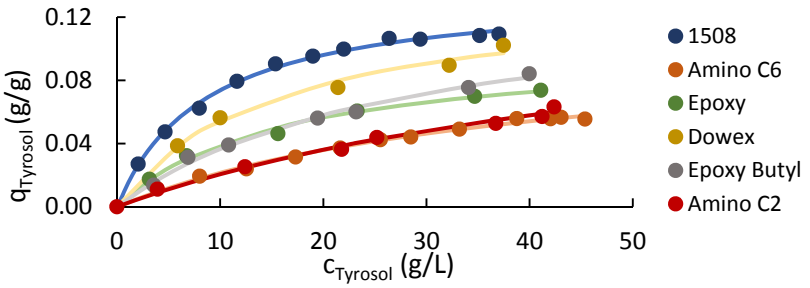

Figure 1. Adsorption isotherms for studied carriers at 37°C. Points represent experimental data, lines represent calculated Langmuir isotherms.

Subsequently, free *β*-galactosidase was immobilized on all studied carriers and was used for synthesis of tyrosol *β*-galactoside from lactose and tyrosol. Experiments were carried out with two different amounts of enzyme. Evident hydrolysis of product was observed for higher amounts of enzyme which is typical for transglucosylation. [1, 2] The highest volumetric productivities and yields were achieved with Amino and Epoxy resins. Epoxy resins were afterwards used for the study of operational stability in fourteen repeated cycles. The formation of tyrosol *β*-galactoside was kept nearly constant during all cycles. The differences among individual runs were within the experimental error. Epoxy resins exhibit covalent binding with enzyme which resulted in high operational stability and no leakage of the enzyme out of the matrix.

4. Conclusions

This work provides the screening of immobilization carriers suitable for enzymatic synthesis of tyrosol *β*-galactoside. Hydrophilic, polar resins and resins with covalent bonding results as the best immobilization carriers for tyrosol galactoside synthesis.

Highlights

- Protocol on the metagenome extraction for various types of soil was standardized.
- Type and pH of buffer and reaction time were the most statistically significant.
- Quality of DNA extracted from new soil can be calculated from the formula.

1. Introduction

As is well known, the total environmental DNA (=Metagenome) is a key material in the biotechnology field with high added Value. Although many related researches were performed, much remains unclear about the factors affecting the quality of the extracted metagenome. Therefore, optimal methods or major factors for the direct isolation of high-quality DNA from various environments should be developed. So we introduce elaborate statistical techniques and use various bioinformatics tools to improve the extraction protocol and visualize the results. Seven variables from the adjustable parameters present in the protocol were selected, and the most statistically significant factors were the type of buffer, the pH of the buffer, the reaction time and the rate of centrifugation. The process design space and simulation about major factors and profiling was visualized. Our results provide a foundation for future research into clarifying the biodiversity in a specific soil microbial ecosystem, identification and mechanism of active genes and metabolites derived from metagenomes.

2. Methods

Considering some metagenomic DNA extraction protocols of recent related studies, we selected 14 various factors related to chemical reaction, physical force and soil sample. For experimental design, We first used the factorial-complete randomize design, factorial fractional design and taguchi method to check the main effects of some variables on the quality of the extracted DNA and their interaction effects with the samples. Since these statistical models needed some modifications, we customized the analysis design featuring the diversification of attributes and application of quality by design (QbD) and design of experiments (DOE). In data processing, missing values occurred when data collection having some bad influence on the results were dealt with by the 'Multiple imputation' technique. And then we carried out the simple correlation test, cluster analysis, cross tabulation analysis, Logistic regression analysis, conjoint analysis and principle components analysis to get the significant variables and their attributes related to the high quality metagenome. Finally, the simulation, profiling and process design space were performed to find the range of conditions for new soil sample in the future.

3. Results and discussion

Table 1. Summary of the cross tabulation, multiple regression and the cluster analysis related to the optimal group.

Desert				Forest				Marsh			
Variable		Comparative evaluation of attributes		Variable		Comparative evaluation of attributes		Variable		Comparative evaluation of attributes	
		Attribute	Optimized condition			Attribute	Optimized condition			Attribute	Optimized condition
RT (hr)	T (31.6%)	7, 8	4 ~ 8	RT (hr)	T (30.8%)	7 ~ 8	7 ~ 8	RT (hr)	T (75%)	4 ~ 6	6
	S (91%)	>= 4			S (63.2%)	7 ~ 9			S (61.6%)	6 ~ 8	
CFG (rpm)	T (42.1%)	11,000, 12,000	11,000 ~ 12,000	CFG (rpm)	T (53.9%)	5,000 ~ 6,000	5,000 ~ 6,000	CFG (rpm)	T (75%)	5,000 ~ 6,000	5,000 ~ 6,000
	C (55.6%)	11,000			S (79%)	5,000 ~ 10,000			S (53.9%)	5,000 ~ 6,000	
	S (91%)	>= 9,000			.	.			.	.	
pH	T	.	7.0 ~ 7.4	pH	T (53.9%)	7.4 ~ 8.2	7.4 ~ 8.2	pH	T (100%)	7.4 ~ 7.8	7.8
	C (100%)	>= 7.8			S (63.2%)	8.2 ~ 9.0			S (84.7%)	7.8 ~ 9.0	
	S (91%)	<= 7.4			.	.			.	.	
DT (hr)	T (81.8%)	<= 1.5	<= 1					RTemp (°C)	T (50%)	55	55 ~ 60
	C (55.6%)	<= 1							S (61.1%)	60 ~ 75	

The analysis of the size (S), concentration (C), and both (T) of the extracted DNA was conducted. Although the some variable preferred different range of attributes by type of soil, the most of the variables had similar range of attributes. Within the experimental range, when the pH of the buffer is used with 8.0 for 7 hour and the rate of centrifugation was at 6,000rpm, generally high-quality metagenomic DNA was extracted.

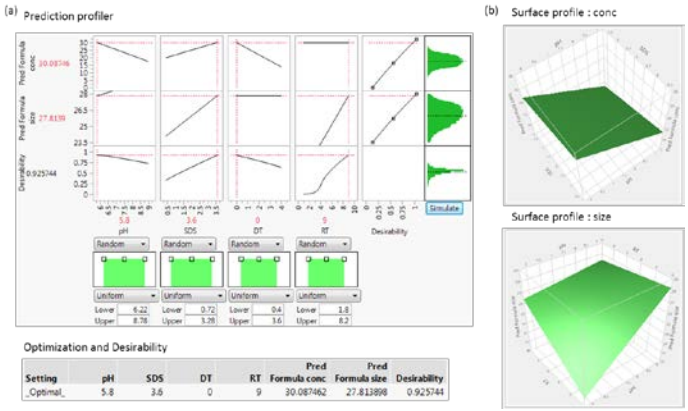

Figure. 1. Optimization and simulation of variables with significant probability (a) The results of the prediction profiler, optimization; (b) The results of the surface profiler: 'conc' variable with pH and SDS, 'size' variable with pH and RT

When the forest soil sample is used, it was predicted that the condition to maximize both the concentration and size of the extracted DNA was to use a buffer (pH 5.8), SDS (3.6%) for 9 hour with no drying time.

4. Conclusions

The metagenome extraction protocol that can be applied to various environments was established through the statistical process based on six selected variables and their attributes. Using three representative types of sample, we present a range of major factors that can be adjusted to extract high-quality metagenomes from new soil samples. The visualization of adjustable range of major variables through the simulation and profiling makes inference of immediate results possible. And the efficiency of extracting high-quality metagenomes from various environments, creating libraries and exploring metagenomes is three times better than those of previous protocol.

Biosynthesis performance of phenyllactic acid during fermentation and whole-cell conversion with *Lactobacillus paracasei* strain

Qining Wang, Yixuan fang, Rui Xu, Songhong Zhang, Lingyu Zhu, Junxian Yun

College of Mechanical Engineering, Zhejiang University of Technology, Hangzhou 310032, China

**Corresponding author: yunjx@zjut.edu.cn*

Highlights

- Effective strain of *L*actobacillus *paracasei* for the synthesis of phenyllactic acid
- Cell concentration of 3.2 $g \cdot L^{-1}$ in the fermentation
- Different biocatalytic properties of the cells obtained at different time in the logarithmic phase
- Concentrations of phenyllactic acid of 0.6-0.7 $g \cdot L^{-1}$ with the conversion ratio of 0.3-0.38

1. Introduction

Phenyllactic acid (PLA) is a kind of high-value organic acids with broad-spectrum antibacterial properties and could be used to synthesize the new bio-based materials of poly(phenyllactic acid)s [1-4]. The biosynthesis method for preparing PLA is a more sustainable method than chemical synthesis due to its advantages like more moderate reaction conditions and higher efficiency. In this work, the preparation of PLA by microbial synthesis was achieved via the highly efficient strain screening from Chinese traditional pickles, the microbial fermentation synthesis and whole-cell transformation synthesis process.

2. Methods

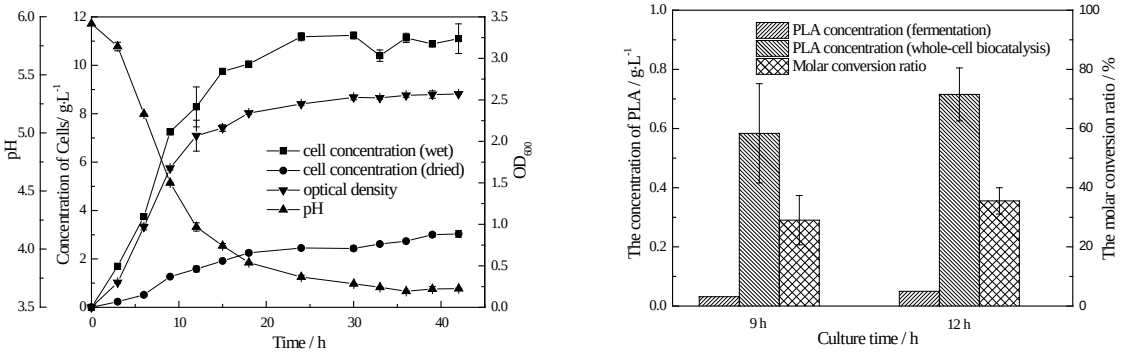
L. paracasei 16C3 strain was isolated from Chinese traditional pickles, identified by 16S rRNA gene sequence and deposited as the patent strain at the China Center for Type Culture Collection. The growth performance and fermentation production of PLA of this strain in the MRS medium with the static culture and the biosynthesis of PLA using this strain as the whole-cell biocatalyst and phenylalanine (Phe) as the precursor, were investigated experimentally.

The changing of pH was measured by a pH meter (FE20, Mettler-Toledo Ltd., Switzerland). Concentrations of PLA in the fermentation broth and bioconversion broth were analyzed by high performance liquid chromatography (HPLC) using Agilent 1260 infinity system equipped with DAD detector at the wavelength of 210 nm.

3. Results and discussion

The results showed that the maximum cell concentration of about 3.2 $g \cdot L^{-1}$ in the fermentation broth was achieved, as shown in Figure 1(a). The broth pH decreased with time increasing at the logarithmic phase (3 to 15h), indicating that the Intracellular metabolism was active, and some metabolites such as organic acids were produced into the broth. No significant

decrease was observed in the stable phase (30 to 44h), indicating that the activity of cells and enzymes in the broth at this stage were stable.



(a) (b)

Figure 1. (a) Cell growth and pH change for *L. paracasei* 16C3 in MRS broth during fermentation process with 30 mL flasks at 35℃. (b) Concentrations of PLA and conversion ratios with cells at different culture time as the whole-cell biocatalysis compared with those obtained at the fermentation. Bioconversion conditions was 2 g• L^{-1} glucose, buffer pH 8.0, 2 g• L^{-1} Phe, 300 g• L^{-1} permeabilized cells and 35°C shaker temperature.

With the cells obtained at different time in the logarithmic phase as the whole-cell biocatalysts, the strain *L. paracasei* 16C3 has different biocatalytic properties, as shown in Figure 1(b). It was found that the bioconversion concentration of PLA was positively correlated with the culture time. The cells cultured about 12 h at the logarithmic phase displayed more effective biocatalytic capacity. The concentration of phenyllactic acid of 0.7 g·L^{-1} with the conversion ratio of 0.38 was achieved, which was high that that with the cells cultured about 9 h, i.e., 0.6 g·L^{-1} with the conversion ratio of 0.3. Moreover, the concentration of PLA with whole-cell biocatalysis from Phe was ten times that produced in the fermentation broth. At the same time, Phe could be the suitable substrates for PLA in bioconversion replaced phenylpyruvate due to the low-cost, stable and water-soluble advantages.

4. Conclusions

L. paracasei 16C3 is an interesting strain for the production of PLA by using Phe as the key substrate by whole-cell bioconversion. The culture time of the cells is one of important parameters influencing the whole-cell biocatalytic properties.

Highlights

- *Flavobacterium frigidarium* is a promising source of zeaxanthin
- Oxygen supply enhanced the zeaxanthin production
- Evaluation of different concentrations of nutrients for the zeaxanthin production

1. Introduction

Carotenoids are the most diverse pigments present in nature. They are used in pharmaceutical, cosmetic and food industry as colorants and antioxidants. Traditional production of carotenoids is by chemical synthesis. However, the increasing negative perception of synthetic additives, demands an alternative such as the biotechnological production of these compounds. Bacterial production of carotenoids is still not competitive compared to chemical synthesis due to the high production cost and lower yields. Flavobacterium species are known as source of carotenoids, being zeaxanthin the principal product [1]. The oxygen supply to the culture is an important factor as oxygen is a precursor in the biochemical pathway for the conversion of β-carotene and β-cryptoxanthin in zeaxanthin. The aim of this work was to optimize the formulation of a media culture to produce zeaxanthin and scale-up the process in a laboratory scale fermenter using an Antarctic *Flavobacterium* sp.

2. Methods

A strain of *Flavobacterium frigidarium* [2] was used as source of carotenoids. The effects of three media components (peptone, yeast extract and NaCl) were studied by a factorial design 2^3 with four central points (Table 1). Media composition was as follows: peptone 2 or 12 g/L, yeast extract 2 or 12 g/L, NaCl 6 or 24 g/L, glucose 6 g/L, $CaCl_2$ 0.3 g/L, $MgSO_4.7H_2O$ 3.4 g/L, urea 0.5 g/L and 400 µL/L of a micronutrient solution. The central point contained: peptone and yeast extract 7 g/L, and NaCl 15 g/L. The strain was cultured in 1-L Erlenmeyer flasks with 300 mL medium in an orbital shaker at 20°C and 200 rpm. The responses studied were zeaxanthin content ($\mu g/g_{biomass}$), zeaxanthin production (g/L), total carotenoid content ($\mu g/g_{biomass}$) and total carotenoid concentration (g/L). Biomass concentration was measured by OD at 600 nm. After 48 hours of growth, cells were harvested by centrifugation. Pellets were washed with distilled water, frozen at

-80°C and lyophilized. Evaluation of dissolved oxygen influence was studied in a bioreactor Biostat A Plus (Sartorius) with 3 L of working volume at 20°C and pH 7. Dissolved oxygen was monitored and maintained above 20% of O_2 saturation of the medium during the bioprocess. Biomass and carotenoid contents were monitored every 12 hours. After 72 hours of growth, cells were harvested and processed as explained previously. Carotenoid quantification was carried out by HPLC-DAD as previously described [2].

3. Results and discussion

The factorial design results are presented in Table 1. The highest zeaxanthin production was achieved in run 5 reaching (256 ± 19) µg/L. However, total carotenoid concentration was maximized in experimental conditions corresponding to the central point.

Run	Factor (g/L)			Content (µg/$g_{biomass}$)		Concentration (µg/L)	
	NaCl	Peptone	Yeast extract	Zeaxanthin	Total carotenoid	Zeaxanthin	Total carotenoid
1	6	2	2	47 ± 3	119 ± 6	112 ± 6	290 ± 13
2	6	2	12	27 ± 1	110 ± 2	111 ± 3	466 ± 6
3	6	12	2	43 ± 2	117 ± 5	132 ± 7	368 ±15
4	6	12	12	14 ± 1	64 ± 1	5 7 ± 1	273 ± 1
5	24	2	2	99 ± 7	172 ± 10	256 ± 19	455 ± 27
6	24	2	12	37 ± 3	109 ± 4	144 ± 10	435 ± 17
7	24	12	2	30 ± 2	92 ± 4	74 ± 6	233 ± 10
8	24	12	12	12 ± 1	56 ± 1	41 ± 1	192 ± 1
9	15	7	7	45 ± 2	121 ± 4	192 ± 9	521 ± 17
10	15	7	7	40 ± 1	110 ± 2	179 ± 2	495 ± 9
11	15	7	7	38 ± 2	111 ± 4	176 ± 9	509 ± 18
12	15	7	7	38 ± 2	107 ± 3	177 ± 7	501 ±12

Table 1. Zeaxanthin and total carotenoid production in shaken flasks

As high levels of oxygen have been widely reported as enhancer of zeaxanthin production, both media were tested in fermenter to study the conversion of β-carotene and β-cryptoxanthin in zeaxanthin. In media 5, zeaxanthin and total carotenoid concentration were similar in shaken flasks and fermenter experiments, reaching in the latest (296 ± 5) µg/L and (443 ± 10) µg/L, respectively. It indicates that in this media, oxygen was not limiting for the production. However, in the central point media culture, total carotenoid production increased to (2358 ± 80) µg/L, with an almost complete conversion to zeaxanthin (2067 ± 70) µg/L. The oxygen supply had an important impact in the carotenoid production as it influences both biomass and zeaxanthin and carotenoid production. Biomass increased from (4.6 ± 0.1) g/L to (5.8 ± 0.1) g/L and zeaxanthin and carotenoid content resulted in (356 ± 12) µg/$g_{biomass}$ and (407 ± 14) µg/ $g_{biomass}$ respectively, 8-fold and 3- fold higher than in shaken flasks.

4. Conclusions

The results showed that the strain could increase the zeaxanthin concentration by 11-fold, showing the dependence of zeaxanthin production with media composition and oxygen supply.

Highlights

- Properties of Capto MMC and Capto Phenyl for rhEPO purification were investigated
- Presence of ionic and hydrophobic interactions at Capto MMC was confirmed
- Non-conventional elution methods must be used
- Strong hydrophobic character of the rhEPO was observed

1. Introduction

Erythropoietin (EPO) is a glycoprotein hormone regulating the production of red blood cells in the organism. EPO is an important and expensive medicinal product. Therefore many purification procedures were developed to obtain pure recombinant human erythropoietin (rhEPO) suitable for clinical use. Conventional methods include the combination of common chromatography purification techniques as ion-exchange, hydrophobic, reverse-phase and size-exclusion chromatography. Some researchers purified EPO by affinity and immunoaffinity chromatography [1, 2, 3]. In this work we compared the properties of a multimodal (Capto MMC) and a strong hydrophobic (Capto Phenyl) chromatography resin during the purification of rhEPO from biological material.

2. Methods

The multimodal adsorbent Capto MMC and the hydrophobic adsorbent Capto Phenyl were obtained from GE Healthcare. rhEPO was produced by human embryonic kidney cell 293 line. The post-culture medium was directly used without any further treatment for the purification experiments. Batch experiments were performed to facilitate the optimization of separation conditions. Flow experiments were carried out using the FPLC system ÄKTA Purifier (GE Healthcare, Uppsala, Sweden). The separation was carried out under the optimized conditions according to batch experiments. The concentration of rhEPO was determined by indirect ELISA assay [4]. The protein concentration was measured according to a standard BCA protein assay protocol [5].

3. Results and discussion

For both tested chromatography resins batch experiments were performed to find the best adsorption and elution conditions. In case of Capto MMC, a larger portion of rhEPO was adsorbed using 50 mM citrate-phosphate buffer with pH 6 supplemented with 300 mM NaCl. Under these

conditions, the binding of contaminant proteins was reduced. Multimodal resins have both ion-exchange and hydrophobic functional groups and this makes the elution of the adsorbed proteins more difficult. Practically no rhEPO was eluted, when the ionic strength of the buffer was increased. 56 % of rhEPO was recovered by simultaneous change of pH and ionic strength of the buffer. The yield of rhEPO was significantly improved by chaotropic agent, arginine. This behavior of the rhEPO confirmed that at multimodal resins, both ionic and hydrophobic interactions can participate in the binding of proteins.

Flow experiments were carried out under the optimized conditions. The adsorption of rhEPO was good, only 3 % of rhEPO was not adsorbed on the resin. The elution was carried out using 50 mM Tris-HCl buffer at pH 7 supplemented with 1 M arginine. During the purification, more than 50 % of contaminating proteins was removed and 80 % of rhEPO was recovered. In a single bind-elute step, the concentration of rhEPO increased nineteenfold compared to that in the feed.

In case of Capto Phenyl, the best rhEPO adsorption was observed at 1.5 M NaCl concentration. The pH of the post-culture medium was adjusted to 6. The adsorption of rhEPO was also enhanced by $(NH_4)_2SO_4$ but due to a possible precipitation of proteins caused by high concentration of $(NH_4)_2SO_4$, the further purification was carried out at the presence of NaCl. Due to the strong hydrophobicity of the resin, commonly used elution procedures during hydrophobic interaction chromatography were not effective. Practically no rhEPO was recovered by reducing the ionic strength of the buffer and only 25 % of the adsorbed rhEPO was eluted by increasing the pH of the elution buffer to 9 and addition of 6 M urea. Good recovery was achieved when organic solvents as ethanol and isopropanol were used.

Flow experiments provided similar results as at Capto MMC. Many of the contaminating proteins left the column during the adsorption and washing phase, while only 5 % of the rhEPO was lost during this stage. Most rhEPO was recovered when 50 % ethanol or 30 % isopropanol in 20 mM Tris-HCl buffer with pH 9 was used for the elution.

4. Conclusions

In this work was investigated the possible application of a multimodal resin Capto MMC and a hydrophobic resin Capto Phenyl for rhEPO purification. In both cases many contaminating proteins were removed in a single bind-elute mode and highly concentrated rhEPO was obtained. According to the results Capto MMC is more suitable for rhEPO purification. Organic solvents, used to recover rhEPO at Capto Phenyl can cause denaturation of the target protein and loss of activity.

Highlights

- Adsorption properties of various types of chromatographic adsorbents were tested.
- Good selectivity of a strong multimodal anion exchanger has been achieved.
- Influence of pH and ionic strength on adsorption was studied.

1. Introduction

Monoterpene glycosides play a fundamental role as significant aroma precursors of volatile monoterpenes. They contribute to some of the most important aroma characteristics of wine. These flavor compounds can be released by enzymatic hydrolysis catalyzed by glycosidases to enhance beverage aroma and flavor. The hydrolysis firstly requires the action of a particular enzyme (α-L-arabinosidase, β-D-apiosidase, α-L-rutinosidas, β-D-xylosidase), and secondly the liberated monoglucoside is than hydrolysed by a β-D-glucosidase. Even though one of the most abundant glycosides in fruit juice are apiosylglycosides, there is no pure β-D-apiosidase on the market. This enzyme is often present as a part of commercial enzyme preparations produced by fungi [1].

2. Methods

Static adsorption experiments were performed with six different chromatographic adsorbents. Among the examined adsorbents was one weak anion exchanger (SEPABEDAS-FPDA), three strong anion exchangers (ESHMUNO Q, CAPTO Q, PRAESTO Q), one salt-tolerant anion exchanger (TOYOPEARL NH2-750F) and one strong multimodal anion exchanger (CAPTO Adhere). Column experiments were carried out with the selected adsorbents using the FPLC system ÄKTA Purifier (GE Healthcare, Uppsala, Sweden). Tricorn 5/50 columns were used for the flow experiments.

3. Results and discussion

The purpose of this work was to purify β-apiosidase from an enzyme preparation produced by fungi. The aim of the batch experiments was to observe the behavior of each adsorbent during the adsorption. The effect of pH and salt concentration was examined too. Based on the obtained selectivities, which gave information about the purification of apiosidase from proteins and contaminating glucosidase, three chromatographic adsorbents were selected for flow

experiments. Column experiments were carried out under optimized condition with strong anion exchanger ESHMUNO Q, salt-resistant anion exchanger TOYOPEARL NH2-750F and multimodal anion exchanger CAPTO Adhere. The most promising results were obtained using the multimodal adsorbent CAPTO Adhere. The separation was performed in 25 mM Tris-HCl buffer with pH 9 and 300 mM NaCl and the desorption was conducted by a linear gradient of this solution and a salt-free citrate phosphate buffer with pH 5. Compared to other adsorbents, CAPTO Adhere offered the highest purification factors from proteins (15.6) and glucosidase (5.9).

4. Conclusions

The aim of the work was to study the equilibrium characteristics of adsorbents for chromatographic purification and further characterization of glycoside used in production of terpenes.

Highlights

- High starch accumulation by microalgae
- Controlled torus PBR with dissolved oxygen and pH regulation
- Physiological adaptation to nitrogen deficiency

1. Introduction

Chlamydomonas reinhardtii is a green microalgae known to accumulate large amounts of starch in nitrogen-limited conditions, up to 50% of its mass content expressed in dry weight of cells (%DW) that could be used as a feedstock for next generation of biofuels production [1]. In autotrophic nitrogen-starved cultures of *C. reinhardtii*, several physiological changes take place in order to adapt their mass content in pigment content and accumulate starch [2]. Starch accumulation in nitrogen starved cells can be affected by other factors such as anoxic conditions [3], light energy availability [1] and inoculum physiological state. The objective of this work is study of starch accumulation dynamic in nitrogen-starved *C. reinhardtii*, in controlled conditions of O_2 dissolved (OD), pH and light availability, prior to a modelling study with a view to develop an optimized starch production protocol in nitrogen-limiting conditions.

2. Methods

A wild type strain of *C. reinhardtii* (137H) has been cultivated in autotrophic nitrogen-limited conditions, using Suoeka medium with NH_4Cl concentration of 1,87mM, in a torus-shaped PBR, equipped with a pH-temperature and DO sensor, as well as mass spectrometer for gas analyses. The pH of the microalgae culture and inoculum was regulated at 7.5 with gaseous CO_2 injection. DO has been regulated with 4.5% O_2 - 95.5% N_2 gas mixture injection flowrate. Limited-growth cultures were performed in batch and at different incident light intensities. Inoculum has been cultivated in 1L air-lift PBR in non-limiting autotropic conditions. The local fluence rate was calculated along batch cultures using the 2-flux model and the radiative properties of culture were determined experimentally using the methodology developed by Pilon *et al*. [4]. Biotic and abiotic phases have been analyzed measuring the dynamic evolution of key nutriments and intermediate metabolites, as well as the analysis of the produced gases.

3. Results and discussion

For nitrogen-limited growth cultures of *C.reinhardtii*, an NH_4Cl initial load of 1.87mM was used to sustain biosynthesis up to 0.25g/L of biomass under standard growth conditions, according to the known stoichiometry. This amount is close to the value obtained during the first 20 hours of culture in concordance with the depletion of NH_4^+ measured (Fig 1A). After that point, an increase in the starch content was observed and a maximum accumulation of 53% was finally obtained after 70 hours of cultivation (Fig. 1A). A stop of cell growth seems to occur at 32 h of culture, once the number of cells remained relatively constant. In contrast, the nitrogen depletion in the medium lead to a remobilization of the total proteins, while reducing their content to 20% (Fig 1A). In the other hand, the pigments content decreased once the NH_4^+ vanished. The total pigments content was stabilized around 1%. This results in a change within the pigment distribution compared to a standard growth culture without any mineral deprivation. The radiative properties were estimated leading to the calculation the energy light profile within the cultivation system during the starch accumulation phase (70h). This assessment showed that light was not a limiting factor since a fluence value was estimated at 21umol/m^2s at the bottom of the PBR (Fig 1B). Throughout the experiment, the dissolved O_2 was regulated to 130% in oxygen saturation in the air, in order to avoid anoxic conditions. Nonetheless, after 63 hours the dissolved oxygen falls as a consequence of low photosynthetic activity (Fig 1C).

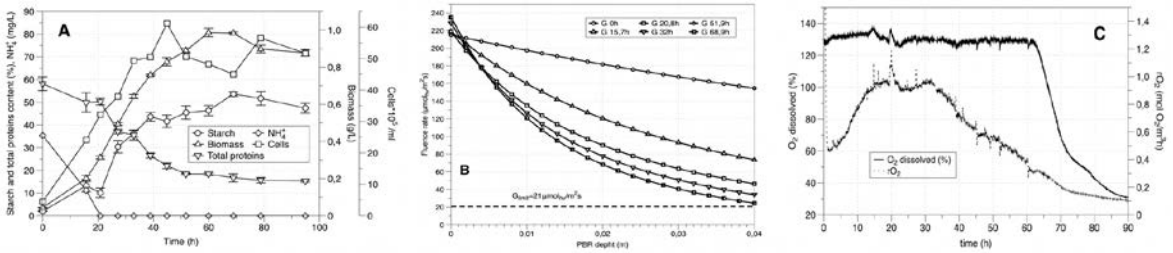

Figure 1. A. physiology response to nitrogen starvation, B. Fluence rate in batch culture q_0= 200umol/m^2s, C. Dissolved oxygen and rO_2 evolution.

4. Conclusions

The use of a controlled torus PBR allowed the study of starch accumulation dynamic after a nitrogen deficiency, where neither light transfer nor dissolved gases (CO_2, DO) influenced the storage of starch. A maximum starch content of 53% was obtained after 70 hours of cultivation. The physiological impact of nitrogen deficiency also led to the remobilization of 30% of the total protein content and to the adaptation in the content and distribution of pigments. This work will lead to the development of a biochemically structured model for starch storage in *C. reinhardtii*.

Effect of Hofmeister series ions on BSA and DNA adsorption on salt-tolerant interaction chromatography (STIC) membrane

Tomáš Kurák, Milan Polakovič*

Department of Chemical and Biochemical Engineering, Institute of Chemical and Environmental Engineering, Faculty of Chemical and Food Technology, Slovak University of Technology, Radlinského 9, 81237 Bratislava, Slovakia

**Corresponding author: milan.polakovic@stuba.sk*

Highlights

- Single- and bi-component adsorption of BSA and DNA was studied.
- Salt type and concentration has significant effect on binding capacity on salt tolerant membrane
- DNA adsorption on STIC had similar behavior to that of multimodal adsorbents

1. Introduction

Most mAb purification processes include at least one ion exchange chromatography step. Salt tolerant adsorbents are novel materials which are a useful complement to conventional ion exchangers and hydrophobic resins. They maintain binding capacity even in higher salt concentration. This leads to a reduction in the number of operations in downstream separation train. Moreover this opens space for seeking good selectivity in wider salt concentration range.

2. Methods

Model macromolecules used in adsorption experiments were BSA and salmon DNA. Thermodynamics of protein binding was studied for single-component solutions of BSA or DNA and their binary mixture. Experiments were carried out using 96 well plates filled with Sartobind STIC membrane adsorbent. Loading solutions passed through membrane in the well by centrifugal force or a single well was used as a membrane module using the FPLC system ÄKTA (GE Healthcare, Uppsala, Sweden). Four different buffers (phosphate, tris, bis tris, bis tris propane) were chosen to examine effect of pH on protein binding. The influence of salt type and ionic strength was examined for a spectrum of anions (SO42-, HPO42-, Cl-, SCN-,F-) and cations (NH4+, Na+, Mg2+, K+)

3. Results and discussion

Firstly, the influence of pH and buffer type was examined. It was shown that pH affects the binding capacity of both BSA and DNA similarly as in case of conventional anion exchangers. It was however observed that the buffers containing polyvalent salt inhibited strongly binding of BSA but they enhanced adsorption of DNA. Secondly, the influence of salt type and ionic strength on the binding capacity was examined for several anions and cations. The selected ions span the whole Hofmeister series so salts with both chaotropic or kosmotropic effects were investigated here. Chaotropic salts decreased BSA binding capacity with increasing ionic strength but not as rapidly as polyvalent kosmotropic salts (Fig. 1). On the other hand, increasing salt concentration, even of

polyvalent salts, had different effect on DNA adsorption. Binding capacity had a maximum at certain salt concentration. The observed effect can have more general implications for the application of multimodal adsorbents in protein purification. This behaviour can be used to optimize separation conditions (e.g. salt concentration, buffer system and pH).

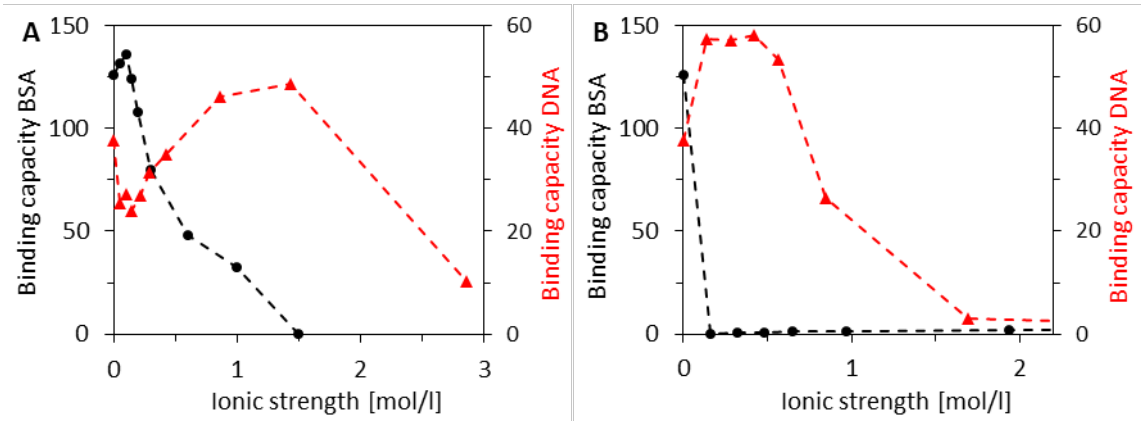

Figure 1. Influence of ionic strength on BSA and DNA binding capacity in the presence of (A) NaCl (B) Na2SO4

4. Conclusions

This work helps to clarify the effect of the composition of the mobile phase on the adsorption of single and bi-component solutions on the salt tolerant membrane adsorbent. The results of the influence of buffer and salt types, pH, and ionic strength on the adsorption equilibrium of BSA and salmon DNA on the Sartobind STIC membrane contribute to understanding of process performance and optimal design of chromatographic separation processes.

Hydrogen production in a pressurized photobioreactor: phototrophic bacterium *Rhodobacter capsulatus*

Jean-Pierre MAGNIN[1,2], Jonathan DESEURE[1,2*],
[1] *Univ. Grenoble Alpes, CNRS, Grenoble INP, LEPMI, 38000 Grenoble, France;*
[2] *Univ. Savoie Mont Blanc, LEPMI, 73000 Chambéry, France*

Highlights

- Biohydrogen production
- photo-fermentation, *Rhodobacter capsulatus*,
- Wastewater valorization
- Partial changing pathway from growth into survival for Rhodobacter capsulatus

1. Introduction

Energy consumption from fossil feed-stocks increases with human growth and economic growth of emerging countries and lead to the CO_2 formation and consequently to climate changing [1]. Therefore, the large-scale transition from fossil fuel to hydrogen fuel and renewable hydrogen technology can substantially improve air quality and reduce climate change [2]. Biological energy such as photobiohydrogen exhibits a positive global warming potential, low acidification potential, relevant social cost of carbon and a low potential production cost [3]. To make economically possible the use of biohydrogen as energetic vector, high purity of produced hydrogen shall be reached using a pressurized tank process to gas storage. Therefore, the main disadvantage of hydrogen is the difficulty of inexpensive easy storing and dispensing of the hydrogen gas. Direct compression of biohydrogen is a benefit to reach the widespread commercial applications. In the present work, hydrogen production process was achieved on anaerobic photosynthesis using the purple non-sulphur bacterium *Rhodobacter capsulatus*. The bacterial culture was carried out in a photo-bioreactor operated in a closed vessel or opened vessel, using lactate as a carbon source and LED illumination is provided. In previous work [4], we have observed when the gas pressure increases with the bacterial growth (in closed vessel), the pressurized hydrogen production is improved (80%) versus atmospheric hydrogen production.

3. Results and discussion

In present work , we have exhibited the opportunity to obtain pressurized hydrogen close to 1o bar by photofermentation of lactate. We have observed an unexpected enhancement of bio- hydrogen production by the phototrophic bacterium *Rhodobacter capsulatus* in a pressurized photobioreactor: the amount of produced hydrogen from synthetic media (lactate (35 mmol L^{-1}) glutamate (5mmol L^{-1})) under pressurized vessel is multiplied by 1.8 versus atmospheric vessel. Hydrogen purity has overcome 90 % with lactate conversion rate was up to 70 %. It is suspected that the energetic demand of *Rhodobacter capsulatus* increases during culture under pressurized

condition and improves hydrogen production. We have observed that the addition of nitrogen sources can drive the lactate conversion rate. In our cultures, the partial changing pathway is possible from growth to survival; this mechanism could explain the lower growth in the closed vessel than in the open vessel. Therefore, during culture under pressurized conditions, stress appears, and this stress increases the energetic demand and improves hydrogen production. However, we do not know the nature of this stress, and we do not have a hypothesis regarding its origin.

4. Conclusions

The hydrogen production in closed vessel is multiply by 1.8 versus atmospheric opened vessel. Numerous advantages due to the high operating pressure can be itemized:

i) Self-compression of produced hydrogen
ii) Easier control of fed bath or continuous operation
iii) Lower risk of contamination
iv) Easier storage

Synergistic interaction of co-encapsulated *Saccharomyces cerevisiae* and *Metarhizium brunneum* used for biological pest control

Katharina Hermann[1,2], Pascal Humbert[1], Anant Patel[1]

1 Bielefeld University of Applied Sciences, WG Fermentation and Formulation of Biologicals and Chemicals, Faculty of Engineering Sciences and Mathematics, Interaktion 1, 33619 Bielefeld, Germany; 2 Bielefeld University, WG Multiscale Bioengineering, Technical faculty, Universitätsstraße 25, 33615 Bielefeld, Germany

Highlights

- Calcium alginate-based formulation acts as microfermenter for the entomopathogenic fungus *M. brunneum*
- Co-encapsulation of *S. cerevisiae* improves sporulation of *M. brunneum*
- Co-encapsulation of *S. cerevisiae* and *M. brunneum* leads to steep oxygen gradients in alginate beads as revealed by microelectrode measurement

1. Introduction

In the last few years wireworm damage has become an increasing problem in both conventional and organic potato cultivation. Wireworms are polyphagous soil dwelling larvae of click beetles (*Agriotes spp*.) and even low populations lead to severe economic losses since they can live up to five years in soil. Wireworms use CO_2 gradients established in soil by plant roots to locate potential hosts. However, effective plant protection products are currently not available since chemical insecticides have recently been restricted or abandoned. Consequently there is a tremendous need for alternative biological control options. In previous work, a biological bead formulation for wireworm control was developed, based on an attract-and-kill approach that exploits the insect's behavior [1-4]. The calcium alginate beads contain both *Saccharomyces cerevisiae* that produce CO_2 as an attractant and the entomopathogenic fungus *Metarhizium brunneum Cb15 III* acting as the kill component. Additionally, a nutrient supply is added. When the beads are placed in soil, they absorb its moisture, thereby initiating the CO_2 production process as well as the growth of fungus out of the beads. Virulent aerial conidia are formed on the bead's surface. Therefore the co-formulation represents a "microfermenter" [5] that needs to be investigated in more detail. Co-cultivation can alter cell growth [6] and, moreover, lead to morphological and physiological changes possibly resulting in attenuated virulence induced by contact-dependent interaction [7]. Hence, the main objective was to investigate the synergistic interaction of *Saccharomyces cerevisiae* and *Metarhizium brunneum* inside the bead.

2. Methods

M. brunneum was grown in submerged culture for 48 h at 25 °C and 150 rpm in shaking flasks with baffles. Mycelial biomass and blastospores were separated by vacuum filtration.

The encapsulation suspension was prepared by mixing sodium alginate and sterile native corn starch. Then, *S. cerevisiae* and *M. brunneum* biomass were added. For bead formation, the suspension was dripped into a sterile $CaCl_2$ solution. Diameter of beads was 4-5 mm. Subsequently, beads were dried, resulting in a bead diameter of 3 mm.

Formed aerial conidia were rinsed off from the bead surface with a 0,1% Tween 80 solution and conidial concentrations were determined by counting conidia with a Thoma cell counting chamber

Microelectrodes (Unisense, Denmark) with a diameter of 50 µm were used measuring oxygen-, pH- and temperature gradients. For this, beads were fixed, and microelectrodes inserted stepwise (100 µm) into the beads with a manual micromanipulator.

3. Results and discussion

We found that co-encapsulation of *S. cerevisiae* enhanced the sporulation of *M. brunneum* from the beads significantly (Figure 1), probably serving as nitrogen source, since they consist of 80% nitrogen.

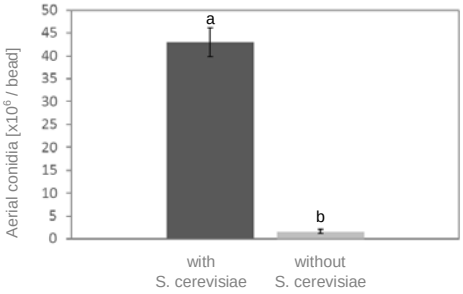

Figure 1: Sporulation of M. brunneum on alginate beads with and without S. cerevisiae. Different letters above bars indicate significant differences based on t-test at p < 0.05 (means ± SD, n = 4).

Further analysis revealed steep oxygen gradients when *S. cerevisiae* is added to the formulation (Figure 2), indicating oxygen limitations in the center. Diffusion limitation in alginate beads can limit cell growth and lead to metabolic changes [8, 9]

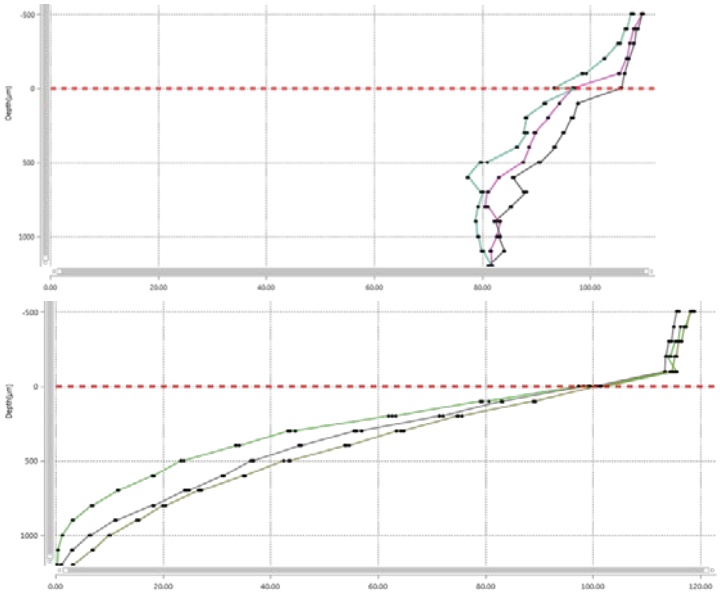

Figure 2: Oxygen gradients in alginate beads loaded with starch and M. brunneum (top) and with starch, M. brunneum and S. cerevisiae (bottom). Abscissa in mV. Red dotted line indicates bead surface.

4. Conclusions

Preliminary results indicate a biological impact of co-encapsulation on fungal development, especially sporulation. A novel method for bead analysis was established in order to examine the physicochemical and biochemical processes. Future work will focus on small-scale submerged co-cultivation (BioLector Pro).
The influence of oxygen limitations will be examined and circumvented by reducing both bead diameter and cell concentration in order to improve efficacy.

Development of biocatalysts for application in integrated process of lactose hydrolysis and glucose isomerization aiming the production of prebiotics

Carlos A. C. Girão Neto[1], Natan C. G. e Silva[1], Marcele M. S. Vasconcelos[1], Luciana R. B. Gonçalves[1], Maria V. P. Rocha[1]

[1] *Department of Chemical Engineering, Universidade Federal do Ceará, Brazil*

Highlights

- The coating of supports with polyethylenimine improves the immobilization parameters.
- The polyethylenimine biocatalysts were very effective in the hydrolysis of lactose.
- High conversion of glucose into fructose was obtained.

1. Introduction

β-galactosidase enzyme (E.C. 3.2.1.23) is widely used in the dairy industry for the hydrolysis of lactose, but over the years it has also increased its use as a catalyst for the synthesis of galactooligosaccharides (GOS) by favoring transgalactosylation reactions, having these GOS a recognized prebiotic function (Urrutia *et al.*, 2018). Besides that, studies have been carried out with the purpose of isomerizing the glucose formed in the hydrolysis reactions to fructose by glucose isomerase enzyme (GI) (E.C. 5.3.1.18) and the obtained fructose can be used as one of the substrates in the transgalactosylation reactions. These enzymes, when immobilized, can be much more effective because some enzymatic characteristics can be improved, such as the stability and activity, specificity or selectivity, and even its purity, besides the possibility of reusing the biocatalysts. The coating of supports has been proposed to extend its useful life, for example, the coating with a multifunctional polymer called polyethylenimine (PEI). This, in turn, involves the enzyme and suits its structure, giving greater stability, especially for multimeric enzymes like β-gal, and also protects from environmental variations, such as temperature, as well as to the aggressive effects of the activating agent (Bolivar *et al.*, 2009; Garcia-Galan, Barbosa and Fernandez-Lafuente, 2013). Therefore, the present work aims initially to evaluate the effects of coating the supports with PEI on the immobilization of β-gal from *Kluyveromyces lactis*, and then to determine the catalytic efficiency of these biocatalysts in the lactose hydrolysis. In parallel, it was evaluated the conversion of the formed glucose into fructose using GI from *Streptomyces murinus*, in order to obtain a product that can be used in the synthesis of prebiotics.

2. Methods

2.1. Immobilization of the [2]-galactosidase: β-gal (E.C. 3.2.1.23) from *Kluyveromyces lactis* was immobilized on chitosan gel (2 % w/v) activated with two different activation agents: glutaraldehyde (0.8 % v/v) according to Albuquerque *et al.* (2018) and glycidol adapted from Guisán (1988), and then the supports were coated with polyethylenimine - PEI (10 % w/v) adapted from Pessela *et al.* (2005). 10 mg of protein per gram of support was used in the immobilization and the process was performed at pH 7.0 and 25 °C in 100 mM potassium phosphate (KH_2PO_4) buffer, containing 0.1 mM $MnCl_2$ and 0.2 mM $MgCl_2$, under gentle agitation on a rotary shaker. The immobilization parameters were determined.

2.2. Catalytic Efficiency of Biocatalysts: The hydrolysis reactions were evaluated for 1.5 hours using a synthetic solution containing 66.7 g/L lactose, under stirring, pH 7.0 and 50 °C. After this process, the [2]-gal enzyme was removed and it was added 0.1 g of immobilized GI (E.C. 5.3.1.18) from *Streptomyces murinus*, 8 mL of KH_2PO_4 buffer, 2 mL of 0.5 mol/L $MgSO_4$, 1 mL of 0.01 mol/L $Co(NO_3)_2$, and the isomerization reactions were evaluated for 4.5 hours under stirring, pH 7.5 and 70 °C. Samples were taken to determine the carbohydrate concentration (lactose, glucose, galactose and fructose) by High Performance Liquid Chromatography (Albuquerque *et al.*, 2018).

3. Results and discussion

The coating of supports with PEI considerably improved the immobilization parameters (Table 1), presenting higher results than those obtained by Albuquerque *et al.* (2018), which used the same immobilization conditions of the present study, but without coating the supports. It was expected since the PEI layer allows a very strong immobilization via multipoint adsorption, besides involving the enzyme and conforming to its structure, avoiding loss of activity due to conformational changes and thus conferring a greater stability to the biocatalyst (Pessela *et al.*, 2005).

Table 1. Immobilization parameters and efficiency of the integrated process of lactose hydrolysis and glucose isomerization by immobilized β-gal and immobilized GI, respectively.

Biocatalyst	Immobilization yield (%)	Activity offered (U/g)	Derivative activity (U/g)	Recovered activity (%)	Conversion of lactose (%)	Conversion of glucose (%)
A	97.45	210.28	95.26	45.30	63.96	36.02
B	92.74	175.36	142.96	81.52	71.72	21.18

β-gal immobilized on: (A) Chitosan activated with glutaraldehyde and coated with PEI; (B) Chitosan activated with glycidol and coated with PEI.

For the hydrolysis of lactose into glucose and galactose, the biocatalyst B showed the closest result at obtained by the soluble enzyme (88 %), after 2 hours of reaction and under the same conditions used (Albuquerque *et al.*, 2018). Biocatalyst B showed the highest conversion of lactose, which was expected since it had a superior enzymatic activity (142.96 U/g). At the end of this process, the reaction media containing the biocatalysts A and B showed concentrations of 44.9 g/L or 50.35 g/L of glucose/galactose and 24.04 g/L or 18.86 g/L of lactose, respectively. For the isomerization reactions, the highest conversion obtained was 36.02 %, an excellent result when compared to that obtained by Yu *et al.* (2011) (45 %), after 16 hours of reaction and using an enzyme dosage of 2 g. However, the reaction medium from biocatalyst B contained higher concentrations of glucose and galactose, and this may have affected the performance of the GI, leading to a lower conversion.

4. Conclusion

The coating of the supports with polyethylenimine improved the immobilization process of β-galactosidases. In addition, these biocatalysts were efficient for the hydrolysis of lactose, and it was possible to convert the obtained glucose into fructose through the isomerization reactions, thus proving that the use of this integrated process is possibly promising to produce prebiotics.

Highlights

- Psychrotolerant strains from King George Island, Antarctica
- Identification of carotenoids by chromatographic analysis
- *Chryseobacterium marinum* potential source for carotenoids production

1. Introduction

Carotenoids are among the most diverse natural products. They are synthesized de novo by many organisms, mainly plants and microorganisms. They absorb light between 400 to 550 nm, which gives them their yellow-orange color [1]. In fact, as antioxidant compounds, carotenoids have relevant biological functions in quenching of singlet oxygen, light capture and photosynthesis protection. There is currently much interest in biological active compounds derived from natural resources due to the high costs and waste materials associated to the chemical synthesis.
Antarctic microorganisms are exposed to extreme environmental conditions as weather, drastic light changes, nutrient scarcity, and high seasonal ultraviolet radiation incidence increased by the ozone depletion over Antarctica [2, 3, 4]. The isolation and characterization of extreme habitats microorganisms has become more important lately as a mean of identifying adaptations of microorganisms to these extreme conditions, with potential biotechnological application such as carotenoid production. This study involved 20 psychrotolerant strains isolated from sampling events carried out during the Uruguayan Antarctic Expedition (December, 2014) along Fildes Peninsula, King George Island, Antarctica.

2. Methods

Strains characterization and selection: Single colonies that exhibited yellow/orange coloration were subculture in TSA plates. The pigmented colonies were replicated until a pure culture was reached. Strains were conserved at -80°C on glass beads with 20% glycerol in Tryptic Soy Broth. Strains were characterized, influence of temperature on cell growth at 10°C, 25°C and 37°C on TSA. Identification of the strains was done by 16S rRNA analysis [5].

Culture conditions for biomass and pigment production: A factorial experimental design 2^2 was used to evaluate the relative importance of glucose and peptone for biomass production and carotenoids content. Statistica trial version software was used for analysis. Bacterial strains were cultured in 500 mL Erlenmeyer flasks with 150 mL medium in an orbital shaker at 20°C and 200 rpm. The culture media included: yeast extract 2.0 g/L, NaCl 5.0 g/L, K_2HPO_4 2.5 g/L, glucose (15 g/L, 10 g/L or 5 g/L), and peptone (11g/L , 6.5 g/L or 2g/L). For each nutrient variable, a high (+), a low (-) concentration and three center points were tested. After 48 h culture growth, cells were harvested by centrifugation. Cell pellets were stored at -80°C and lyophilized (VirTis BenchTop 2 K Freeze Dryer, SP Industries Inc.).

Pigment extraction and characterization: Approximately 0,05 g of lyophilized biomass was extracted with 4 mL of methanol until bleaching. The extract was dried under a nitrogen stream and dissolved in acetone for chromatographic analysis. Detection was performed at 450 nm.

3. Results and discussion

Phylogenetic analysis sorted the isolated strain as *Chryseobacterium marinum,* a Gram – negative, yellow, rod-shaped aerobic bacterium. The absorption spectrum of the methanol- extracted pigment of *Chryseobacterium marinum* displayed a typical carotenoid spectrum in the visible range with maximum absorbance at 450 nm. Identification of carotenoids was carried out according to the strain producing pigments and the retention time (RT) in the C18 column and was confirmed through coelution with *β*-carotene, *β*-cryptoxanthin and zeaxanthin standards.
Evaluation of nutritional effects in biomass and carotenoids production: Peptone showed either a positive effect in the biomass growth and pigment content. Meanwhile glucose showed a negative effect in the biomass production and in the pigment production. Maximum growth and zeaxanthin concentration were obtained after 48.5h growth at 20° C, pH 7.0, in a medium containing 5 g/L glucose and 11 g/L peptone. Under these conditions, the concentration of total carotenoids from *Chryseobacterium marinum* was 15,1 mg/L. Surfaces responses are showed in Figure 1. Even though, *Chryseobacterium sp.* showed potential as microbial source for producing carotenoids, the carotenoid yield and composition can still be maximized by optimization of the bioprocess.

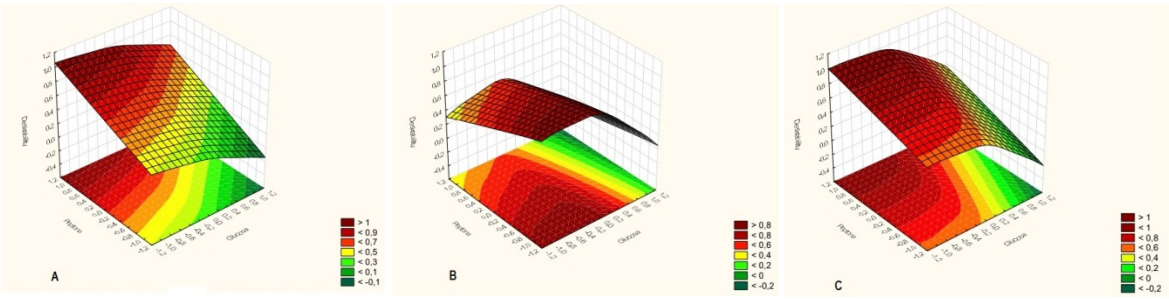

Figure 1. Surface-response graphs generated from the 2^2 statistical factorial design, utilizing peptone and glucose influence on the response factors: (A) Biomass, (B) Carotenoids content and (C) Zeaxanthin production.

4. Conclusions

As reported for the genus *Chryseobacterium: β*-carotene, *β*-cryptoxanthin and zeaxanthin were detected. Carotenoids identified from Antarctic bacteria constitute an alternative for further biotechnological application towards a more sustainable way of pigments production.

Highlights

- Antioxidant recovery can be improved by enzymatic treatment
- Enzymes can be inhibited by solvent presence during the extraction process.
- Ethanol 10% allow to maintain enzyme activity almost in a 50%

1. Introduction

Antioxidants are substances that limit the oxidation of several molecules. They are present in fruit and vegetables (pulp, seeds, and skins) (Laroze *et al*. 2010). Extraction of antioxidant compounds depends of several factors. Also, different treatments are used to improve the bioactive compounds extraction, such as the use of plant cell wall degrading enzymes. Few works report enzymatic treatment of vegetable material to improve the antioxidant recovery (Kim *et al.*, 2005; Li *et al.*, 2006; Pinelo *et al.*, 2008; Kapasakalidis *et al.*, 2009; Maier *et al.*, 2008; Laroze *et al*., 2010). In most of them, enzyme incorporation increases the presence of phenolic compounds and its antioxidant activity; however, results depend of several variables, including enzyme inhibition (Kim *et al.,* 2011; Ximenes et al., 2011). Also, authors as Bezerra and Dias (2005) reports that organic solvent as ethanol produce enzyme denaturation. Due to this fact enzyme application during antioxidant compounds extraction with solvents must be not efficient. **The aim** of this work was to evaluate the effect of organic solvent in the enzymatic activity of commercial formulations which are used in the treatment of agro-industrial solid waste to improve the antioxidant compounds extraction.

2. Methods

Enzymes: Commercial enzymes (Grindamyl CA 150 from Danisco; Macer 8 FJ from Biocatalyst; Celluclast 1.5L and Cellubrix L from Novozymes) were characterized about their enzymatic activity.
Enzymatic activity determination: Two types of enzyme activities assays were done. A) Cellulolytic activity was established using carboxymethylcellulose (CMC) as substrate according to Ghose (1987). B) Polygalacturonase activity (pectinase activity), was determined by Ros *et al* (1992) method. The enzymes were dissolved in buffer and then, different amount of solvent was added.
Extraction of phenolic compounds with antioxidant activity: A solid/solvent ratio of 1/10 w/v was used in the extraction of phenolic compounds from Maqui berry pomace, which was used as model raw material because its high antioxidant compound content. Enzymes were dissolved in water, added to the solid, blended, and the solvent was incorporate then. Solid and extracting solvent were put at 50°C during 6 hours under magnetically stirring. Extract was recovery by filtration.

Antioxidant presence: Total polyphenolic compounds (TPC) were determined by Folin-Ciocalteu method, according to Conde *et al.* (2009). **Antioxidant activity** (AA) was determined by two methods (1) The 2,2-diphenyl-1-picrylhydrazyl = 2,2-diphenyl-1-(2,4,6-trinitrophenyl) hydrazyl) (DPPH) radical scavenging capacity was measured according to Laroze *et al.* (2000), and (2) the 2,2'-azino-bis(3-ethylbenzthiazoline-6-sulphonic acid) (ABTS) assay according to Conde *et al.* (2009).

3. Results and discussion

Figure 1 shows the effect of several proportion of ethanol on the enzymatic activity of 4 commercial catalysts. As it is possible to observed in all the cases the presence of ethanol decreases drastically the enzyme activity. Only when 10% of ethanol was used the cellulolytic activity was maintained over 50% of the original value. Then, this solvent (ethanol 10%) was used to probe the enzymatic extraction of phenolic compounds from maqui berry pomace. The Figure 2 shows an increment on the extraction of phenolic compounds from maqui berry pomace and its antioxidant activity when enzymes as Macer 8FJ and Celluclast were used, in comparison to control.

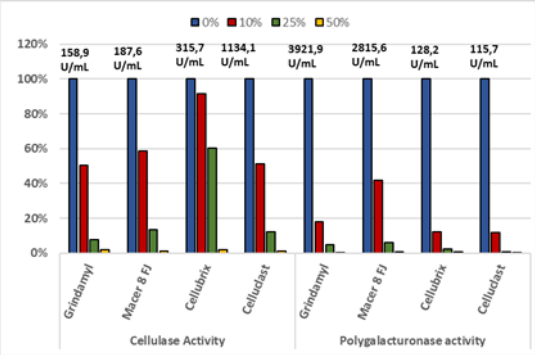

Figure 1. Enzymatic activity of commercial catalyst in ethanol presence.

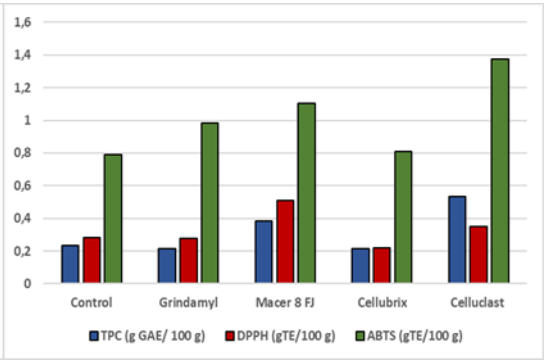

Figure 2: Recovery of phenolic compounds with antioxidant activity using an enzymatic treatment.

4. Conclusions

The extraction of antioxidant compounds is improved when mixtures of organic solvents with water are used, in comparison to only water extraction. In addition, the use of enzymes is an attractive alternative to improve the extraction, but its activity is deeply affected by the presence of organic solvent. Despite that, it is possible to find an amount of solvent that allows the enzymes to act and at the same time improve extraction. Then, catalysts as Celluclast 1.5L and Macer 8FJ allows to increase the efficiency of extraction of phenolic compounds with antioxidant activity from Maqui pomace up to 100%, considering as extraction solvent a 10% of aqueous ethanol.

Highlights

- Rapid biofilm formation was observed at low succinic acid concntrations.
- Biofilms were patchy at high succinic acid concentrations and struggled to grow.
- Biofilms developed at high SA concentrations were much less viable in comparison.

1. Introduction

The wild type bacterium *Actinobacillus succinogenes* requires no introduction as a promising biocatalyst for industrial biotechnological production of succinic acid—a reputable platform chemical [1]. Continuous fermentation of *A. succinogenes* unavoidably results in biofilm formation, leading to high cell densities responsible for high succinic acid titers and volumetric productivities reported in literature [2]. This study looked at the impact that acid metabolite build-up in the fermenter has on the overall biofilm development and its viability.

2. Methods

Actinobacillus succinogenes 130Z (DSM No. 22257; ATCC No. 55618) was grown on a glucose substrate in a novel continuous fermenter suitable for sterile and multiple biofilm sampling. Biofilm was cultivated on plastic coupons at both high (16 g L^{-1} succinic acid) and low metabolite (8.6 g L^{-1} succinic acid) build-up conditions by adjusting the fermenter dilution rate. Sampled coupons were stained with Baclight LIVE/DEAD bacterial viability (Thermo Fisher Scientific, USA) stains before acquiring multiple image z-stacks using a Zeiss LSM 880 laser scanning confocal microscope (Zeiss, Germany) at random locations on the coupons. Acquired image z-stacks were analysed using Comstat2 to calculate descriptive biofilm parameters for objective characterisation of the biofilm.

3. Results and discussion

Biofilm formation was rapid when cultivated under low succinic acid (SA) titres, contrary to high SA titre conditions where the biofilm struggled to grow. As such, complete surface coverage was achieved at low SA cultivation whereas a patchy biofilm structure resulted from growth at high SA titre conditions, Figure 1. Furthermore, quantitative analysis showed an average biomass thickness increase from 10 µm on the first day to 30 µm by the third day of sampling for low SA biofilm cultivation in comparison to a 12 µm - 15 µm increase for biofilms cultivated at high SA titres Figure 2b. In addition, elongated bacilli cells were observed at high SA titre biofilm cultivation which may possibly have been a response to stressful conditions, Figure 1b.

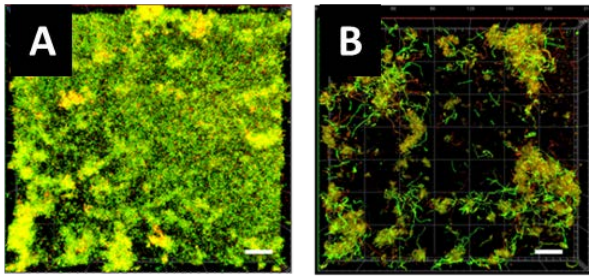

Figure 1. Biofilm images on day 1 of sampling for cultivation at low SA titers (A) and at high succinic acid titers (B). Scale bars indicates 20 µm.

A ratio (viability factor) of the mean intensity of the green fluorescence (for "live" cells) to the mean intensity of the red fluorescence (for "dead" cells) for all the z-stacks collected on a specific day of sampling was computed, which allowed an observation how the overall biofilm viability varied as the biofilm developed, Figure 2a. At low SA titres, the developed biofilm consisted of increasing "live" cells as shown by the increasing viability factor, whereas high SA titre biofilms became increasingly less viable, Figure 2a. The results thus showed that high SA acid titre conditions do not only slow down biofilm development but causes significant loss of biofilm viability.

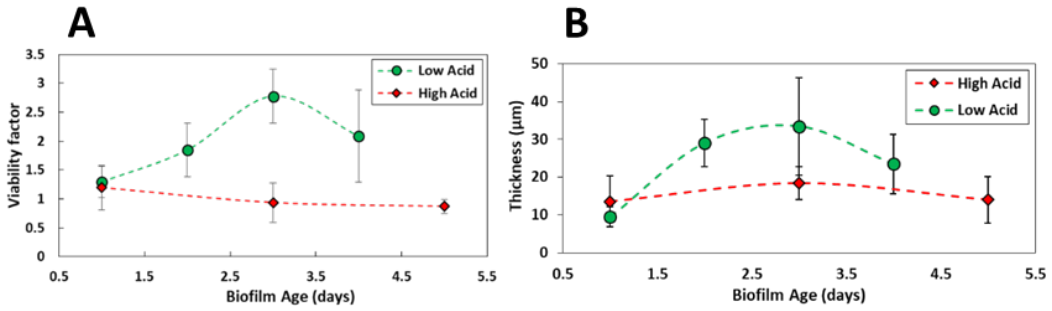

Figure 2. The viability profiles (A) and thickness profiles (B) of biofilms cultivated at both low and high SA acid concentrations.

4. Conclusions

Biofilms developed at both low and high SA titres were compared. High SA acid conditions slowed biofilm growth and resulted in a loss of biofilm viability whereas rapid biofilm growth was experienced at low SA titre conditions with increased biofilm viability.

Highlights:

- Strong constitutive promoter TEF for overexpression of GSH1 and GSH2 genes.
- Overproduction of glutathione by yeast Yarrowia lipolytica
- Exploitation of alternative subtrates (Inulin)
- Strain can use inulin to produce more yield of glutathione

1. Introduction

The tripeptide glutathione (Gamma-L-Glutamyl-L-Cysteinylglycine) is the most abundant low-molecular-weight intracellular thiol. It plays important roles in cellular redox balance, nutrient metabolism and regulation of cellular mechanism. Glutathione, that could exist as a reduced (GSH) and oxidized (GSSG) state, is synthesised in a two step process. Firstly, glutamate and cysteine are ligated by an gamma-glutamylcysteine synthase (gamma-GCS, EC 6.3.2.2) encoded by GSH1 gene to form a L-gamma-glutamyl-L-cysteine. In a second step a L-gamma-glutamylcysteine-glycine gamma ligase (GS or GSH synthetase, EC 6.3.2.3) encoded by gene GSH2 link a glycin residue on the dipeptide. The yeast *Y. lipolytica*, considered as an emerging industrial chassis was used as a cell factory to produce glutathione from raw material

2. Methods

First, we overexpress GSH1 and GSH2 genes under the control of pTEF, a strong constitutive promoter. The most overexpressing strain was obtained for further manipulation. This yielded to a significant increase (69%) of glutathione production.

In a second step, we genetically adapt the producing strain to different cheap raw sugar-sources, including glycerol, inulin, lactose and starch. Among them, inulin revealed the most suited for glutathione synthesis. The production titre was increased by 61 % as compared to glucose media used as a reference.

3. Results and discussion

In this study, strong constitutive promoter pTEF were used to overexpress genes encoding the two enzymes (L-cysteine gamma-ligase and glutathione synthase) which catalyse the synthesis

of GSH in *Yarrowia lipolytica*. Several strains which can overexpress GSH1 or GSH2 or both of them have been successfully obtained. The newly constructed strains for glutathione overproduction show different comparing to control.

Following the successfulness of GSH-overexpressed genes, after removing leucine and uracil markers, this strain was used as a host for further modifications for exploiting cheap feedstock as main carbon source. We focused on glycerol (overexpression of GUT1 and GUT2 genes), lactose (overexpression of beta-galactosidase gene), starch (overexpression of alpha and gluco-amylase genes) and inulin (overexpression of inulinase encoding gene). Among those feedstocks, inulin yielded to higher amount of glutathione comparing to others.

4. Conclusion

The successful construction of strain that can consume cheap raw materials such as organic waste or by-products from other food processing sectors (cheese making, prebiotic producing, soap making and so on) and produce more glutathione, a higher value compounds have been achieved.

Highlights

- Development of an acoustic sensor to detect breast cancer cells (MCF-7).
- Folate-modified S-layer lattice as antibody-presenting biosensing matrix
- Highly expressed folate receptor on the cell membrane of some cancer cell lines.

1. Introduction

Designing an interface matrix with good biocompatibility for efficient detection of target cancer cells is a critical step in biosensor fabrication[1,2]. Antibody alternatives are attracting more attention to overcome limitations associated with antibody-based bioreceptors, such as high cost and density and orientation of the antibodies on the sensor surface. Exploiting biomaterials capable to present ligand molecules in an optimal density and orientation leads to the fabrication of biosensors with good selectivity and sensitivity. Excellent matrices are monomolecular arrays of protein subunits forming surface layers (S-layers), which are the common structure of the outer cell envelope on almost all archaea and many bacteria[3]. In this study, S-layer proteins were modified with folate to target the overexpressed folate receptors on breast cancer cells (MCF-7). Acoustic detection of MCF-7 was assessed using quartz crystal microbalance with dissipation (QCM-D) monitoring.

2. Methods

Folate was bound to the isolated S-layer protein SbpA from *Lysinibacillus sphaericus* CCM 2177[2]. The QCM-D measurements were run for modified SbpA and MCF-7 cells at 27 and 37 ± 0.02◦C, respectively. To evaluate the efficiency of the developed biosensor, suspensions of MCF-7 cells at different cell densities (1×10^4, 1×10^5, and 5×10^5 cells/mL) were exposed to the folate-modified S-layer lattice.

3. Results and discussion

The fabricated acoustic biosensor showed the efficient recognition of MCF-7 cells in situ and in real-time with a detection limit of 1 × 10^5 cells/mL. The direct recognition of MCF-7 cells on the developed QCM-D sensor was evaluated by monitoring the shifts in the frequency (ΔF) and dissipation (ΔD) (Figure 1). The obtained results revealed a strong shift in ΔF, which is due to the binding of the MCF-7 cells to the sensor surface. Moreover, the recognition of the folate presented on the S-layer lattice by the folate receptors of the MCF-7 cells correlated directly with the MCF-7 cell density. It is known that the cell capture efficiency remarkably increases when the sensing layer has low thickness. Besides the small thickness of the S-layer lattice nanostructure, functionalization with folate instead of adding an extra antibody layer reduces the thickness of the biosensing layer. Moreover, immobilization of antibodies in proper orientation is not a matter because folate was used as an antibody alternative to detect breast cancer cells. However, the nature of the sensor surface has highly affected the interaction between the functionalized sensor and MCF-7 as cell attachment was influenced by the hydrophilicity and wettability of the modified S-layer lattice.

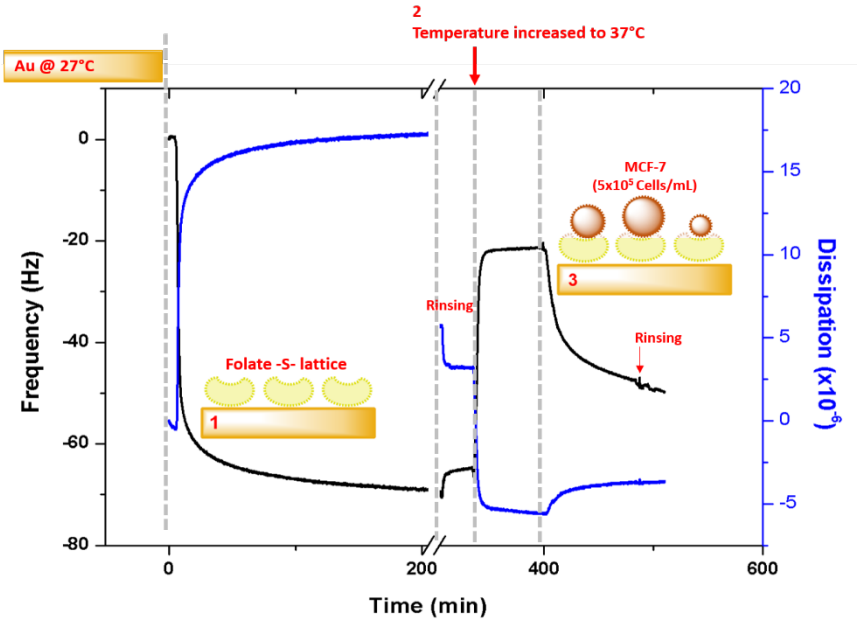

Figure 1. Development of folate-S-lattice platform and the subsequent capturing of MCF-7 cells on MCQ-D sensor.

4. Conclusions

A careful selection of biomaterials that can be assembled together to decorate sensor surfaces can improve the selectivity and sensitivity of diagnostic biosensors. S-layer proteins can be advantageous biomaterials due to their ability to self-assemble to form a nanostructure lattice, which can be easily functionalized with folate to develop functional sensors. The developed biosensor with the folate-modified S-layer lattice as alternative antibody scaffold exhibited well performance for breast cancer detection that can be exploited in future to test the cellular response to chemotherapeutic agents.

Highlights

- Phenolic compounds recognized as relevant building blocks.
- ABS were efficiently applied on their fractionation.
- CPC was efficiently applied on the scale-up of the process.

1. Introduction

Phenolic compounds are ubiquitous biomolecules exhibiting a wide range of physiological properties, with a wide range of different applications. In this work, aqueous biphasic systems (ABS) formed by polyethylene glycol and sodium polyacrylate, and electrolytes (inorganic salts or ionic liquids) were applied for the purification of caffeic, ferulic and protocatechuic acids, vanillin and syringaldehyde. The up-scale of the technology was assessed by successfully applying a centrifugal partition chromatography (CPC).

2. Methods

All materials and methods used are reported in detail in our previous work [1].

3. Results and discussion

Phenolic compounds are relevant biomass building blocks described by their many applications as the most versatile and important industrial organic chemicals. In this sense, these products are considered as economically attractive. In this work, polymer-based ABS (with PEG 8000 + NaPA 8000) using ionic liquids or inorganic salts as electrolytes, were studied in the separation of five model phenolic compounds (caffeic, ferulic and protocatechuic acids, and vanillin and syringaldehyde), all originated from lignocellulosic depolymerisation. The selection of the best ABS and its optimization was performed, followed by its application in CPC to reinforce the technique scale-up. After the development and characterization of the integrated process to fractionate the mixture of phenolic compounds, an environmental evaluation was done considering the carbon footprint as the main output. After the identification of the best ABS platform to separate each phenolic compound (PEG 8000/NaPA 8000/NaCl), its use in CPC followed. After optimizing the CPC operational conditions, it was also proved the success of the scale-up process, since, not only the results defined for the batch system were obtained but also the final process (Figure 1) developed

showed to be simultaneously efficient and of low carbon footprint (36% of carbon footprint reduction for the best scenario explored). In this context, high recovery values were obtained, respectively, 87%, 84% and 65% for caffeic, ferulic and protocatechuic acids, and 82% for the aldehyde-rich fraction (composed of vanillin and syringaldehyde).

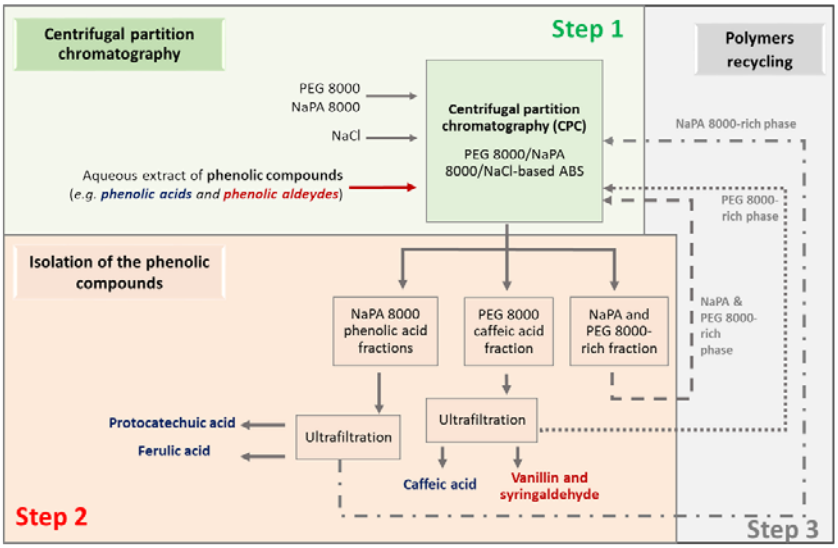

Figure 1. Schematic representation of the process developed. Adapted from [1].

4. Conclusions

An efficient and low carbon footprint up-scale process using CPC was successfully developed to separate phenolic compounds, showing its applicability for the processing of real matrices like agro-forestry and biomass wastes.

Highlights

- The gene expression profile exhibited great differences between both conditions.
- An increment in gene expression under acetate growth was observed.
- EutD and PrcP could be part of the underground metabolism through alternative enzymatic activities.

1. Introduction

Escherichia coli (*E. coli*) metabolism carbon fluxes are an important factor to take into account, since this bacteria is widely employed as a model organism in industrial and biotechnological processes. In this sense, *E. coli* can metabolize diverse carbon sources such as acetate, which is a poor carbon source, or glucose. Under glucose limitation conditions, *E. coli* develops carbon stress responses [1], so this bacteria exhibits an expansion in gene expression [2], the emergence of new pathways and alternative enzymatic activities. Thereby, diverse activities and new pathways could be part of underground reactions which may be connected to the existing network, increasing the potential of employing diverse and new carbon sources [3].

2. Methods

In this work, a gene expression study through a streptavidin-biotin-based microarray assay has been carried out to know the differences between the genetic global expression in *E. coli* K12 MG1655 growing in minimal medium M9 supplemented with glucose or acetate as carbon source. High density arrays "GeneChip E. coli Genome 2.0 Arrays" (P / N 900550, Affymetrix, Incorporated) were used

3. Results and discussion

The transcription profiles of *E. coli* K12 MG1655 growing in acetate supplemented medium exhibited great differences in gene expression respect to the strain growing in glucose supplemented medium. This behavior may be attributable to the increase in the number of genes expressed which allow a large scale carbon-scavenging to metabolize “low quality” carbon source [2]. The adaptation process may involve a refined regulatory response to only activate genes of acetate metabolism (*acs*, *ackA*, *actP*), but we observed an increment in the expression of genes, which belong to other pathways, such as the glyoxylate shunt, methylglyoxylate shunt, TCA cycle,

and gluconeogenic flux, suggesting that these pathways are at least partially controlled at the transcriptional level. Furthermore, *eutD* and *prcP* genes were overexpressed in acetate growing. These two genes belong to the ethanolamine and propionate metabolism, respectively, so in acetate growing EutD and PrcP must present other alternative enzymatic activities and could be part of the underground metabolism reactions.

4. Conclusions

The gene expression change in acetate compared to glucose was used to assess the metabolic flux distribution in key pathways. Furthermore, the results suggest difficulties to identify adaptive mechanisms only through examination of expression changes, since there are other mechanisms that regulate metabolism, such as post-translational regulation, enzyme kinetics and allosteric control.

Highlights

- ANN applied to chromatography in the biopharmaceutical DSP.
- ANN training based on a generative *in silico* model.
- The calibration approach is versatile and scalable.
- RMSEPs compared to a standard PLS could be reduced by 14% to 40%.

1. Introduction

Biopharmaceutics are the fastest growing sector of the modern pharmaceutical industry. Nowadays, seven out of the ten most valuable pharmaceutical products are biopharmaceutics [1]. During the downstream processing (DSP) of biopharmaceuticals, chromatography is the main workhorse. While in production mainly univariate signals are used to monitor chromatographic steps, recently the benefits of multivariate spectroscopic methods for process monitoring have been demonstrated [2]. Data analysis was up to now mostly limited to linear methods such as partial least-squares (PLS) models. Machine learning provides much more powerful methods such as artificial neural networks (ANN). However, ANNs generally need a vast amount of data to be reliably calibrated. In wet lab experiments, this amount of data is difficult to obtain. To circumvent this problem, we developed an approach relying on a generative model to yield artificial process sensor data and the corresponding reference concentrations. Based on this data, the ANN could be successfully trained.

2. Methods

Experimental data from a publication by Brestrich et al. [3] were used in this study. Briefly, preparative chromatography experiments were performed on an Äkta Purifier 10 system (GE Healthcare, Chalfont St. Giles, UK) equipped with a diode array detector (optical pathlength 0.4mm) UltiMate 3000 DAD (Thermo Fisher Scientific, Waltham, US) with a HiTrap 7x25 mm column prepacked with SP Sepharose FF (both GE Healthcare). Experiments were performed for a ternary separation of ribonuclease A, cytochrome c and lysozyme (all Sigma Aldrich, St. Louis, US). Chromatographic separations were modeled with ChromX (GoSilico GmbH, Karlsruhe, Germany).

For generating the *in silico* dataset, first, the mechanistic chromatography model was calibrated based on multiple calibration runs. Simultaneously, a database for spectroscopic data including the relevant reference analytics was established. Next, the design space of the process was randomly sampled yielding 10,000 process chromatograms with simulated concentration traces resulting in

780,000 concentration vectors. For each concentration vector, the database was sampled for the nearest neighbors (Euclidean-distance). Scaled sensor responses were then obtained by multiple linear regression and subsequent matrix multiplication of concentration vectors and spectral matrices. On the obtained dataset, ANNs with different geometries were calibrated with the ANN framework Keras [4]. The regression models were tested on an independent chromatography run.

3. Results and discussion

A workflow was established for calibrating ANNs based on generative approach consisting of a mechanistic chromatography model and a spectral database. The generative approach allows to easily scale the calibration dataset. It thus circumvents some of the issues of using ANNs for process data. Most importantly, overfitting ANNs is reduced. A further benefit of the established workflow is the easy scalability of the spectral database. Thus, the database can easily be extended without significantly complicating calculations. Finally, the workflow captures non-linearities in the sensor response due to the local linear regression.

Based on the generated *in silico* data, two ANNs were calibrated. While a classical (dense) ANN geometry was on par with a reference PLS model, a convolutional ANN surpassed the PLS model in all calculated root mean squared error of calibration (RMSEC) and prediction (RMSEP, see Table 1). The results demonstrate the potential that lies in the application of more complex regression models compared to PLS.

Table 1. Results from the different calibrated models. Best results in each column are underlined.

	Ribonuclease A		Cytochrome c		Lysozyme	
	RMSEC / (g/L)	**RMSEP / (g/L)**	**RMSEC / (g/L)**	**RMSEP / (g/L)**	**RMSEC / (g/L)**	**RMSEP / (g/L)**
PLS	0.0126	0.0149	0.0135	0.0098	0.0132	0.0116
Classical ANN	0.0176	0.0150	0.0122	0.0096	0.0140	0.0108
Convolutional ANN	0.0090	0.0130	0.0065	0.0059	0.0084	0.0073

4. Conclusions

We investigated on a generative *in silico* approach to calibrate ANNs for PAT applications. A workflow was established involving the calibration of a mechanistic model, spectroscopic database establishment, Monte-Carlo-based process sampling, spectra generation, and ANN model calibration. Based on the proposed approach, a convoluational ANN performed 15% to 40% better on an independent chromatography experiment compared to a standard PLS model. The results demonstrate significant potential of the generative approach to ANN calibration.

Highlights

- The extraction of STEAP1 was optimized to increase the concentration of total protein.
- A reproducible strategy for STEAP1 isolation and buffers composition were established.
- STEAP1 was isolated by HIC in a single step and co-eluted with residual of contaminants.

1. Introduction

The Six-Transmembrane Epithelial Antigen of the Prostate 1 (STEAP1) is a cell-surface antigen overexpressed in several types of cancer, namely in prostate cancer [1]. In normal cells the levels of STEAP1 are low or absent [1, 2]. Considering its secondary structure and location in the cell membrane, it has been suggested a role in intercellular communication between tumor cells [2, 3]. These features highlight STEAP1 as a promising therapeutic target. The main goal of this work is to express high levels of STEAP1 protein from LNCaP cells and isolate the target protein in a native form by traditional hydrophobic interaction matrices.

2. Methods

LNCaP cells were maintained in a humidified chamber with controlled atmosphere until 90-100% confluence. These cells were lysed onto RIPA buffer or an in-house buffer for nuclear and cytosolic extraction of proteins. This procedure was fully optimized regarding the volume of buffers and the concentration of proteins to further enhance the yield of the isolation process and immunoblot experiments. Total protein samples were loaded onto a butyl sepharose column and the manipulation of ionic strength was used to promote a complete retention of proteins to the matrix and a selective fractionation of impurities. The purification step was monitored by SDS-PAGE and STEAP1 was detected in dot-blot analysis or a single band in western blot with approximately 39 KDa [1]. Mass spectrometry was also used to confirm the identity of the target protein. Lastly, circular dichroism was used to infer if the concentration of ammonium sulphate effectively influences the arrangement of secondary structure of STEAP1 or promote interactions between the target protein and unspecific compounds.

3. Results and discussion

Once STEAP1 is overexpressed in LNCaP, we extracted total protein and also both cytosolic and nuclear fractions. The western blot analysis showed an increased expression of STEAP1 in cytosolic fraction, with similar levels to total protein extracts. These aliquots were applied in the chromatographic studies. The main results demonstrated that STEAP1 was fully captured in butyl sepharose matrix since the concentration of ammonium sulphate in the binding buffer was 1500 mM and 2000 mM. However, the elution profile denoted low selectivity, once STEAP1 was detected at similar levels in distinct steps of the elution salt gradient, namely 10 mM Tris-HCl and H_2O. Likewise, these samples presented a considerable background of impurities that co-elute with the target protein. Interestingly, STEAP1 was not retained at 1000 mM and 1250 mM of salt. This result could be explained considering the presence of a non-ionic detergent in the lysis buffer which condition the exposure of the hydrophobic domains of the predictive six-transmembrane structure of STEAP1. This phenomenon clearly affected the interaction of the target protein with the chromatographic matrix and explains the reason behind the significant retention of several impurities at lower concentrations of ammonium sulphate. Otherwise, as the salt concentration in the binding buffer increases, the interactions between STEAP1 and butyl sepharose are consequently promoted. Nevertheless, these findings were valuable because it was conceivable to isolate STEAP1 in a single chromatographic step with residual amount of interfering biomolecules.

4. Conclusions

This work established for the first time a reproducible chromatographic procedure for the isolation of human STEAP1 with high expression levels and significant grade of purity. These optimized conditions will allow that samples containing the target protein may be further used for a detailed biochemical and structural characterization of STEAP1 and later development of molecules that were able to block its oncogenic functions.

Highlights

- High boron concentrations
- Microbial diversity
- Metagenomics approach
- Bioinformatic analysis
- Environmental biotechnology potential

1. Introduction

Boron can be directly and indirectly involved in different functions and mechanisms in many different organisms. There is some information about this area in literature [1, 2, 3, 4]. Moreover, boron may be toxic to living cell at high concentration [5]. However, some special microorganisms can easily survive in regions with high boron concentrations and these microbes have potential at environmental biotechnology field [6, 7, 8]. Researchers are interested in microorganisms living in high boron content because of their metabolic characteristics. Classical microbiological cultural techniques are not always useful to determinate of microbial species in extreme conditions due to their extreme characteristics and there is no study about specifying microbial diversity by molecular techniques. Therefore, in this study, metagenomics approach as next generation sequencing was used to present of microbial community in area with high concentration boron.

2. Methods

Two different environmental water samples were taken from two places with boron contaminated field in Balıkesir-Bigadiç and Eskişehir-Kırka Works. Metal contents of these samples were determined. The experimental studies were started with the total DNA extraction and metagenomics analysis method was performed. 16S amplicon sequencing in Illumina Miseq Platform was practiced to keep all of microorganisms survive in sampling areas. Metadata of microorganisms was analyzed bioinformatically by QIIME 1.

3. Results and discussion

According to chemical analysis; B, Li, Na, S and Sr contents in Kırka samples were found higher than water samples of Bigadiç. Metagenomics data is shown in Table 1.

Table 1. Dominant genera in sampling areas

Sampling area	Dominant genera
K1 (Kırka boron mine drainage, station 1)	*Rhodobaca, Gloeobacter, Luteolibacter, Fluviicola, Verrumicrobium, Bacteriovorax*
K2 (Kırka boron mine drainage, station 2)	*Rhodobaca, Gloeobacter, Luteolibacter, Verrumicrobium*
B1 (Bigadiç boron mine drainage, station 1)	*Pseudanabaena, Gloeobacter, Hyphomonas, Algoriphagus, Rhodobacter, Anaerospora*
B2 (Bigadiç boron mine drainage, station 2)	*Rhodobacter, Hydrogenophaga, Roseococcus, Anaerospora*

4. Conclusions

This study will provide information about inhabiting microorganisms which are able to tolerate high boron. In future studies, these organisms can be used for environmental biotechnology field.

Biological hydrogen production by *Rhodopseudomonas palustris*: comparison of a packed bed and fluidised bed photobioreactor systems.

Brandon Ross[1], Robert Pott[1] *

1 Department of Process Engineering, Stellenbosch University, South Africa

**Corresponding author:* rpott@sun.ac.za

Highlights

- *R. palustris* used in the photobioreactor systems is immobilised in a transparent PVA cryogel
- A packed bed bioreactor and a fluidised bed bioreactor will be compared based on specific hydrogen production
- It is expected that the fluidised bed will outperform the packed bed.

1. Introduction

Biological hydrogen production is a promising replacement for the current modes of hydrogen production seen in industry today. However, key issues with the process still need to be solved before such processes can be scaled up to industrial levels. The use of photosynthetic bacteria such as *Rhodopseudomonas palustris* to produce hydrogen has shown to have a low environmental impact but the required energy input is greater than the energy derived from the hydrogen produced. Therefore, to increase the efficiency of the biohydrogen production process the ratio of energy consumed to energy produced must be improved.

The scalability of processes using photosynthetic bacteria to produce biohydrogen relies on the optimisation of the process parameters, of which the immobilisation of the photosynthetic bacteria in a poly vinyl-alcohol (PVA) based hydrogel by entrapment has been identified as covering several of these key areas. These areas include but are not limited to: i) protection from physio-chemical challenges, ii) cryptic growth, iii) higher biomass concentration than in planktonic systems, iv) reduced number of cell divisions resulting in metabolic energy being focused on product formation [2].

The immobilisation of such bacteria then raises the question, what bioreactor configuration suites photosynthetic biohydrogen production when using immobilised bacteria. Not many configurations have been proposed, let alone investigated, for the use of immobilised photosynthetic bacteria due to most immobilisation matrices being opaque. Thus, two reactor systems were designed to investigate the hydrogen production performance, namely a packed bed photobioreactor (PBPBR) and a fluidised bed photobioreactor (FBPBR).

2. Methods

R. palustris was immobilised in transparent PVA cryogel where the PVA solution was 10% (w/v) PVA dissolved in a 50% (v/v) glycerol-water solution. The PBPBR and FBPBR were designed to allow the synthetic waste stream to pass through the bed of immobilsed bacteria with a 100% recycle stream to operate as a batch system with all hydrogen produced collected off the headspace of the

photobioreactors. The Hydrogen production by immobilised *R. palustris* was compared to planktonic cultures in the same photobioreactor system.

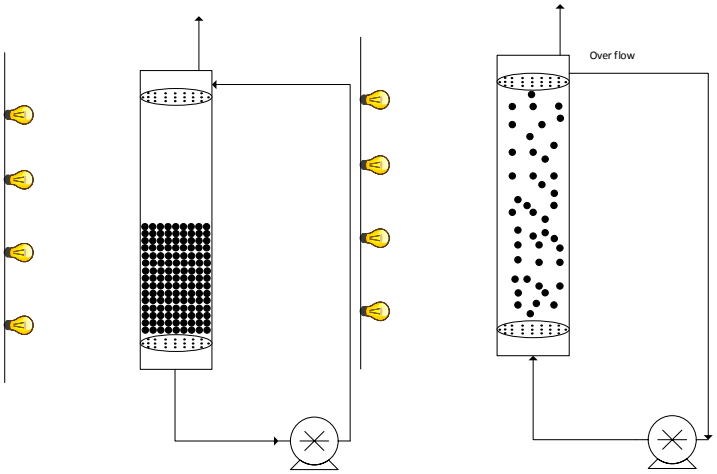

Figure 1. PBPBR and FBPBR experimental setup

3. Results and discussion

It is anticipated that the fluidised bed photobioreactor will outperform the packed bed photobioreactor with respect to the specific hydrogen production (specific in terms of both biomass loading and volume of the reactor). This is due to the motion of the fluidised bed increasing the amount of light that each PVA cryogel bead that contains the immobilised bacteria receives. Full results will be available from the 30th of May 2019.

4. Conclusions

We present a proven design for photobioreactors that can be used in conjunction with transparent immobilised *R. palustris*. Preliminary studies with planktonic media in the photobioreactors proved the viability of the system with regards to production and collection of biohydrogen. Further conclusions with regards to the hydrogen production in the PBPBR and the FBPBR will be drawn once all results have been obtained.

X-Ray Tomography evaluation of Microbially Induced Calcite Precipitation (MICP) in mortar cubes

Diana Tamayo-Figueroa[1*], Henry Omar-Meneses[2], Pedro Brandão[3]

1 Doctorado Biotecnología, Instituto de Biotecnología (IBUN), Facultad de Ciencias, Universidad Nacional de Colombia, Bogotá, Colombia; 2 Clínica para Pequeños Animales, Departamento de Salud Animal, Facultad de Medicina, Veterinaria y Zootectnia , Universidad Nacional de Colombia, Bogotá, Colombia; 3 Grupo de Estudios para la Remediación y Mitigación de Impactos Negativos al Ambiente (G.E.R.M.I.N.A.), Laboratorio de Microbiología Ambiental y Aplicada, Departamento de Química, Facultad de Ciencias, Universidad Nacional de Colombia, Bogotá, Colombia.

**Corresponding author: dptamayof@unal.edu.co*

Highlights

- A non-destructive methodology to follow crack repair by MICP is reported.
- MICP treatment showed a higher $CaCO_3$ filling effect when compared to control.
- MICP activity allowed 18-27% of $CaCO_3$ filling of mortar cube holes after 9 weeks.

1. Introduction

Cement based materials are widely used for construction but their durability is affected by cracking, a common phenomenon in this type of materials [1]. The use of microorganisms that induce calcite (calcium carbonate) precipitation (MICP) has been proposed as an alternative crack repair technology [2]. In this process microbial metabolism increases environmental alkalinity that favours $CaCO_3$ precipitation [3]. This phenomenon is an extremely strain-specific (bio)chemical reaction and depends on urease diversity, ion strength, cell density, and medium pH [4]. Current methodologies used to track crack repairs do not provide a clear picture of the system behaviour while the repair occurs, especially in internal cracks, and usually it is necessary to destroy test specimens. This work reports the use of X-ray tomography to evaluate calcium carbonate filling of different size holes in mortar cubes, due to crystals precipitation by *Arthrobacter crystallopoietes* KNUC403, a bacteria previously isolated from a concrete structure [5].

2. Methods

Mortar cubes: For each treatment, a standard mortar mixture was prepared. A ratio of 1:2.75 (cement:sand) was used maintaining a water:cement ratio of 0.52. Curing time was 7 d. Four holes with different diameter sizes (in cm: 0.476, 0.635, 0.794, and 0.952) were made in the mortar cubes. Three replicas were made for each hole size.

Biological treatment of mortar cubes: Two treatments with (B) or without cells (C) were carried out to assess $CaCO_3$ production by *A. crystallopoietes* KNUC403 using X-ray tomography. Treatment B consisted in the addition of bacterial biomass + Urea-$Ca(NO_3)_2$ media to each hole, while control treatment C consisted in the addition of Urea-$Ca(NO_3)_2$ only to each hole. The addition of culture medium, with or without microorganisms, to the mortar cubes was performed every seven days. The mortar cubes were incubated at 30 °C.

X-ray tomography analysis: Mortar cubes holes depth variation was evaluated regularly in a Philips Helical tomograph (Tmoscan AV) by simple cuts with 2 mm thickness, a tube rotation of 2 s, a kilovoltage at 120 Kv, 140 MA, a window level of 3500 and a window width of 1100.

3. Results and discussion

X-ray tomography allowed to monitor the difference in the mortar cubes hole filling processes between treatments, a situation related to the production of $CaCO_3$ by MICP. This technique allowed to measure the change in the holes depth without destroying the sample or altering its mechanical properties (Figure 1), which could be useful to track the repair of material failures. After 9 weeks, the calcium carbonate filling percentage of the different hole sizes evaluated showed differences between the two treatments (Table 1). It is evident that after the experimental time period treatment B showed filling values between 18 and 27% compared to control treatment C with values lower than 8%, reaffirming the feasibility of using X-ray tomography as a strategy to monitor and control crack repair in cement-based materials. The fact that the filling percentage for the different hole sizes is similar for treatment B suggests that microbial behaviour has been affected by the available oxygen, a factor that may influence the amount of precipitated $CaCO_3$. This should be addressed in future studies. Mechanical and permeability tests will be performed to the mortar cubes of both treatments when a filling percentage close to 50% is obtained.

Figure 1. Image obtained by X-ray tomography showing the measurements of width and depth of different holes in mortar cube. Hole diameter sizes: 1 - 0.476 cm; 2 - 0.635 cm; 3 - 0.794 cm; 4 - 0.952 cm.

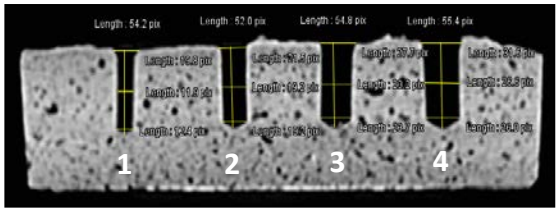

Table 1. Calcium carbonate filling percentage of four different hole sizes in mortar cubes without (C) or with (B) bacterial (*A. crystallopoietes* KNUC403) biomass treatment, after 9 weeks of incubation. Hole diameter sizes: 1 - 0.476 cm; 2 - 0.635 cm; 3 - 0.794 cm; 4 - 0.952 cm.

Hole size	Treatment C [Urea-$Ca(NO_3)_2$ media only]	Treatment B [*A. crystallopoietes KNUC403* + Urea-$Ca(NO_3)_2$ media]
1	2,31%	19,95%
2	3,73%	18,29%
3	2,33%	27,37%
4	7,91%	19,36%

4. Conclusions

X-ray tomography showed a positive effect of using *A. crystallopoietes* KNUC403 on the $CaCO_3$ filling of holes in mortar cubes as compared to control without cells. The technique allows to track the filling of holes in cement-based materials without the need to alter the mechanical properties of the material. This permits to follow-up the repair of superficial and internal cracks on this type of materials using MICP.

Highlights

- Quantitative and label-free analysis of single, living microbial cells via MS
- Determination of uptake and production rates of single cells

1. Introduction

Microbial cells can be used as biocatalysts for complex syntheses of chemicals and energy carriers at physiological conditions and with high efficiency. Although microbial cells have been applied for thousands of years for the production of value-added compounds, there is still little quantitative knowledge about the contribution of the minimal catalytic unit, the single cell, to the macroscopic output of bioprocesses.[1] Up to now, mainly optical analyses have been applied for disclosing a remarkable heterogeneity in cellular features like gene expression, regulatory mechanisms or growth.[2,3] However, absolute numbers on uptake and production rates in single cells are inexistent.[4]

We demonstrate how the label-free quantification of catalytic performance in single cells can be

2. Methods

We applied chip-coupled microfluidics (negative dielectrophoresis cell traps and microdroplets) for analyzing the production of L-lysine by *Corynebacterium glutamicum* via mass spectrometry.

3. Results and discussion

achieved with chip-coupled mass spectrometry.[5] The presented approaches are capable of directly resolving catalytic heterogeneities. This knowledge is key for understanding and improving the efficiency of bioprocesses.

With microfluidic cultivation formats, such as the Envirostat or microdroplets, single cells are isolated and trapped under defined extracellular reaction conditions.[6] By interfacing microfluidic reactor formats with high-sensitivity mass spectrometry, the quantitative analysis of molecules produced by single cells is now possible for the first time. The concept is demonstrated with L-lysine-producing single cells of *Corynebacterium glutamicum*.

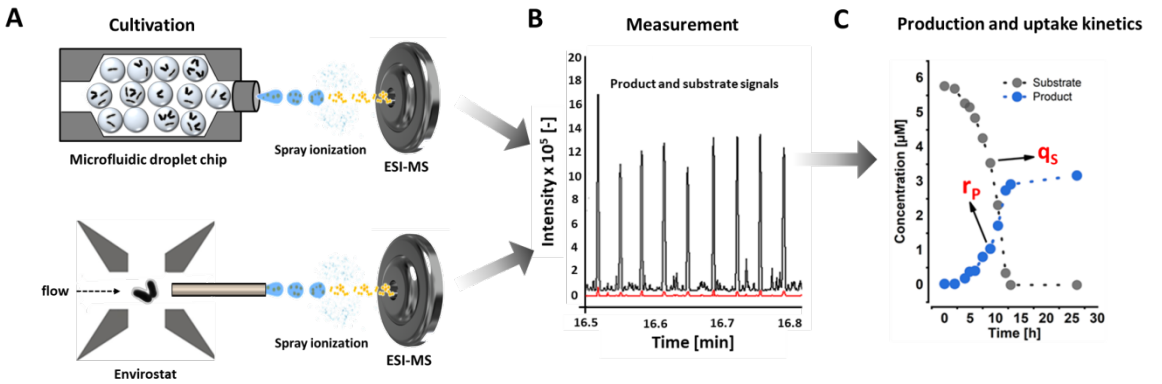

Figure 1. Cultivation and measurement of substrate and product concentrations in microfluidic cultivation setups. A) On-chip cell encapsulation in droplets and deterministic trapping of single cells and small co-cultures with the Envirostat. The analytes in the aqueous medium are ionized via ESI and transferred to the MS. B) Substrate and product concentrations are quantified with isotopically-labelled standards spiked the cultivation media. C) From the uptake and production profiles, production kinetics r_P and uptake kinetics q_S of single cells and small populations are determined.

4. Conclusions

Our approach enables the characterization of the catalytic structure of microbial populations based on single cell activity data and opens the door towards novel approaches for population modeling and improving biocatalytic processes.

Highlights

- Supercritical CO_2 extraction can be employed for recovery of lipophilic products
- Residual biomass is rich in antioxidant products
- Phycobiliprotein rich extracts can be obtained by ultrasonic treatments
- A stream of products with various applications can be recovered from this biomass

1. Introduction

Cyanobacteria are ubiquitous photosynthetic bacteria that can have significant effects on the water quality as well as the functioning of aquatic ecosystems [1]. The massive proliferation of cyanobacteria can lead to excessive surface water blooms in heavily eutrophicated systems [2]. During the last decade's appearance of this kind of cyanobacterial blooms has also been verified in the Curonian lagoon [3]. This region, which is listed in UNESCO's world heritage sites, provides many ecosystem services, and thus, it is a crucial area for recreation, tourism, and aquaculture.

Recent reports suggest that removal of wild cyanobacterial blooms from the Curonian lagoon as a management measure, should be considered and prioritized [3]. To turn this threat into gain herein we envisioned the utilization of a wild cyanobacterial bloom as a feedstock within a biorefinery concept. Towards this end, fractionation of this biomass was achieved with high-pressure and or conventional extraction techniques This underutilized biomass could be considered as a source of products with potential biotechnological, food, agrochemical and pharmaceutical applications

2. Methods

For the optimization of SFE-CO extraction, a central composite design (CCD) and response surface methodology (RSM) were used. Fatty acid methyl esters were identified and quantified by means of GC-FID. Tocopherol content was assessed by HPLC with a fluorescence detection. Phycobiliprotein rich extracts were obtained by conventional techniques (freeze-thaw cycles, homogenization, solid-liquid extraction). Ultrasound-assisted extraction in combination with conventional techniques was further optimized with a CCD-RSM for the highest phycocyanin,

allophycocyanin, phycoerythrin and total phycobiliprotein yields. Residual biomass was further treated either with pressurized liquid extraction (PLE) or conventional techniques to obtain antioxidant rich extracts. *In vitro* antioxidant capacity of obtained extracts was evaluated with the Folin-Ciocalteu, DPPH and ABTS assays. Functional properties of obtained extracts were further evaluated for their ability to inhibit catalase, superoxide dismutase and acetylcholinesterase activity. Preliminary phytochemical characterization was achieved by means of UPLC-ESI-TOF-MS.

3. Results and discussion

For the SFE-CO_2 CCD-RSM indicated 42.5 MPa, 55 °C and 120 min of extraction as optimal conditions, under which SFE-CO_2 yielded 4.43 g/100 g DW of non-polar extract characterized by the presence of α-linoleic acid and α-tocopherol [4]. Under optimal extraction conditions, the SFE-CO_2 proved to be faster and more efficient compared to conventional hexane extraction [4]. In a next step, isolation of aqueous phycobiliprotein rich extracts was based on several conventional techniques in combination with optimized ultrasound-assisted extraction. The highest total phycobiliprotein yields were observed for samples, treated with homogenization followed by application of 8.75 min of ultrasounds at 84% amplitude [5]. During the next steps, residual biomass was further treated with increasing polarity solvents either by conventional or pressurized liquid extraction techniques. The acetone, ethanol and water extracts showed a strong antioxidant capacity in various radical scavenging assays. Moreover, the obtained extracts showed inhibitory effects against biologically relevant enzymes. In a last step, preliminary phytochemical composition of obtained extracts as assessed by means of UPLC-ESI-TOF-MS revealed the presence of a number of natural pigments as well as auxins, compounds that could be potentially utilized as biofertilizers.

4. Conclusions

In conclusion, the potential of wild cyanobacteria for recovery of a stream of products within a biorefinery concept were shown. Wildly harvested *Aphanizomenon flos-aquae* biomass could be considered as a feedstock for recovery of products with potential food, nutraceuticals, biotechnological and agricultural applications. Further studies focusing on life-cycle assessment and techno-economic feasibility of the developed biorefinery schemes would be of further interest in this field.

Highlights

- Each biochar possessed increased microbial activity after aging
- Increased biological activity was associated with decreased available nutrients
- Initial specific surface area highly affected the aging-mediated changes

1. Introduction

Biochar (BC) is a solid by-product of biomass combustion under oxygen limited conditions, known as pyrolysis [1]. Biochar proved to be useful as soil amendment [2], and considered effective in carbon sequestration and reduction of agricultural greenhouse gas emissions [1,2], contaminant and heavy metal removal, and other applications [1,2]. Biochar effects as soil amendment do not only depend on soil properties, biochar production conditions, but also on a variety of temporal processes in the environment, called "aging", including abiotic and biotic redox reactions, interactions with microbes, organic matter, minerals and solutes in the soil environment [3]. Progressive aging alters biochar quantity and quality [4]. This paper evaluates the effects of simulated conditions of artificial biological aging on the physicochemical, biological, ecotoxicological properties of five biochar types compared to their properties before aging. The aim is to support efficient long-term utilization of biochar in soil focusing also on the potential environmental risks posed to soil biota.

2. Methods

Triplicate samples of five biochar (BC) types were "aged" by placing samples in 750 mL glass containers so that three calcareous sandy soil layers alternated with the biochar layers. The biochar types were the following: grain husk and paper fibre sludge BC (A1), wood screenings BC (B1), woodchips BC (F1), herbal pomace BC (H1), miscanthus BC (M2). The containers were covered with perforated aluminium foil, so that drying could not occur over 11 weeks; microcosms were watered every 3 week with 20 mL microbial inoculant optimized for calcareous soil. Aerobic conditions were provided by glass capillary tubes inserted into the layers. After 11 weeks the biochar and soil layers were carefully separated and removed. The biochars before and after aging were examined by an integrated methodology, including physicochemical (pH, electric conductivity (EC), specific surface area (BET), loss on ignition (LOI), water holding capacity (WHC), permanganate oxidizable carbon (POXC), cation exchange capacity (CEC), organic matter (OM), plant available nutrients (NPK), heavy metals, metalloids, other elements), biological (aerobic heterotrophic cell counts) and ecotoxicological methods (*Sinapis alba* shoot- and root inhibition test, *Folsomia candida* mortality tests*).*

3. Results and discussion

Significant differences between biochars before and after aging were determined by one-way Analysis of Variance (ANOVA) using StatSoft® Statistica 13.1. Table 1 shows the summary of the main effects of biochar aging compared to before aging.

Table 1 Summary of the main effects of biochar aging.

Biochar type	*pH*	*EC*	*LOI*	*WHC*	*BET*	*Pore vol.*	*POXC*	*OM*	*NO_3-N*	*P_2O_5 / K_2O*	*CEC*	*CFU Bacteria*	*Plant growth*
A1	-	-	-	-	-	-	-	-	-	-	-	+	-
B1	-	-	-	-	-	-	-	-	+	-	0	+	+
F1	-	-	-	-	-	-	-	-	+	-	-	+	+
H1	-	-	-	0	0	0	-	-	+	-	-	+	0!
M2	0	-	-	-	-	-	-	-	+	-	-	+	-

– significant decrease | – decrease | + significant increase | + increase | ! ecotoxicity | 0 no effect

Each biochar underwent changes through the aging process, especially regarding nutrients and biological activity. The accelerated biological aging resulted in higher microbial activity in case of all biochars depending on their surface areas (BET). The highest increase (more than two-fold) was found for M2 and F1 biochars with the largest (BET). BET values of biochars correlated with the aerobic heterotrophic cell counts (CFU) of weathered biochars. The total N content of each biochar decreased - except A1 with the highest initial NO_3-N content – while there was an increase in the available nitrate due to the increased bacterial activity. Most of biochars exhibited significant decrease (~40–60%) in the pH, OM and permanganate oxidizable (labile) carbon content (POXC) as well as in available K and P upon aging. These changes were accompanied by decreases in biochar CEC however previous studies reported higher CEC of biochar after aging. We assume that enhanced bacterial activity triggers microbial OM production and sorption of OM, resulting in a range of new organic functional groups affecting CEC.

4. Conclusions

Based on our results the specific surface area of non-aged biochars highly affected the aging-mediated changes. Percentage decrease in available nutrients and labile carbon was the lowest while the decrease in CEC was the highest in the case of M2 biochar with the highest specific surface area suggesting that M2 would be the most efficient and stable charcoal on the long term. Artificial biological aging of biochar represents a promising model for studying weathering effects. Further comparative evaluation of the outcomes of biochar aging in the soil matrix under real field conditions is planned.

Highlights

- Bionanofiber composited membrane was successfully prepared.
- Maximum stress was increased in chitosan nanofiber composited membrane.
- The chitosan nanofiber composted membrane was dramatically decreased compared with alginate-Ca membrane.

1. Introduction

Oceanic bio-polymer have been expected as environmental compatible materials for medical, food and industrial application. Sodium alginate was a typical oceanic bio-polymer and it was sustainably and abundantly produced from kelps. It was widely cultivated in worldwide ocean. Gelling character of sodium alginate by the aid of metal ion exchange was extensively applied to form gel particles and membranes. Molecular size of alginate chain was hardly controlled because of natural bio-products. Biomass nanofiber have been researched for their use in biodegradable packaging due to their renewable, low cost and low density. More recently, this have been reinforced into biopolymers to produced green nanocomposite membrane, with improved thermal, mechanical and oxygen barrier properties.

Membrane separation processes are attractive because of their low energy cost and contaminant-free final product. Interest in using natural materials for the membrane body has increased because of their biocompatibility and environment-friendly disposal.

2. Methods

2.1 Preparation of bio-nanofiber composited membrane

Calcium alginate based composite membrane was cooperated with Chitosan nanofiber (Chi-NF). Aqueous solution of sodium alginate (10 g/L) was prepared by dissolving in pure water. Desirable amount of chitosan nanofiber (Chi-NF) or carboxymethyl cellulose nanofiber (CMC-NF) was added into alginate aqueous solution and mixed magnetic stirrer. The solution was poured into a glass petri dish, and then dried in a thermostat-controlled oven for 12 h at 333 K. Dried sodium alginate with mixed Chi-NF in the petri dish was immersed into the $CaCl_2$ solution (0.1 mol/L) for 20 min. The membrane was washed with pure water to remove excess metal ion.

(a) Alginate-Ca membrane (b) Chi-NF composited membrane (c)CMC-NF composited membrane

Figure 1 Image of alginate-Ca membrane composited nanofiber.

2.2 Mechanical strength

A rheometer was used to measure the mechanical strength of the swollen membranes. The swollen membranes were cut into sample pieces (1 × 4 cm), which were then stretched at a speed of 1 mm/s using the reheometer. The mechanical properties were evaluated in terms of both the maximum stress (δ) when the membrane ruptured.

3. Results and discussion

Figure 2 shows the effect of the maximum stain with the mass fraction of chitosan nanofiber and carboxymethyl cellulose nanofiber in the algnate-Ca membrane. The maximum stress was slightly increased with increasing of mass fraction of chitosan nanofiber until f_{NF}=30%. In contrast, the maximum strain was gradully decreased. The clearance between alginate polymer chains and chitosan nanofiber became narrow with increasing the mass frtion of ChiNF. Chitosan is in higher deacetylation, and has by many amino groups. Deacetlyation contributed to making many hydrogen bonds and prducing stronger mechanical characterics of chiotsan.

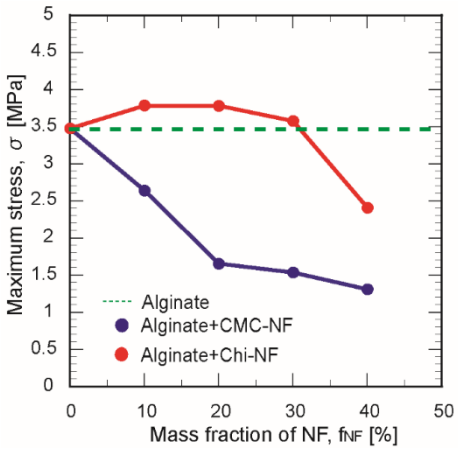

Figure 2 Effect of mass fraction of nanofiber on maximum stress.

4. Conclusions

A stable membrane made of calcium alginate with multiple domains of bio nanofiber was successfully prepared. Maximum stress of membrane a rupture for Chi-NF composited membrane was increased.

Highlights

- Endoglucanase (EG) possesses higher stability in presence of effectors in compare with cellobiohydrolase (CBH).
- Cellulases stability well correlates with the results of saccharification of aspen wood (AW).

1. Introduction

The main obstacle in the bioconversion of wood is its resistance to enzymatic hydrolysis. Existing pretreatment methods aimed at increasing the reactivity of wood (reducing the degree of crystallinity and lignin content, increasing the available surface area, etc.) remain imperfect in terms of "green chemistry" [1]. The use of ionic liquids (ILs) does not lead to the formation of toxic products; in addition, they are easily regenerated, practically non-volatile, non-combustible, and dissolve many inorganic and organic compounds and gases well [2]. However, the best ILs are extremely expensive for use in industry. In recent years, seawater and its concentrates have been considered an affordable and cheap alternative to ILs [3].

The use of any pretreatment of cellulosic raw materials with its subsequent saccharification should imply the presence of an enzyme complex of cellulases, including cellobiohydrolase (CBH), endoglucanase (EG) and β-glucosidase (BG) that are intact to chemical residue and capable of deep destruction of cellulose. We have previously shown that CBH from the *Tricoderma viride* was more sensitive to the presence of hydrophobic ILs with a long alkyl substituent (1-octyl-3-methylimidazolinium chloride), and EG activity was sensitive to short ([bmim]Cl) while *Aspergillus niger* β-glucosidase was the most stable of the enzymes in the presence of ILs in concentrations of 1, 5 and 10 g/l [4]. In this work, we studied the effect of [Bmim]Br, [Choline]Cl and seawater on the catalytic activity of the cellulase complex from fungus *Penicillium verruculosum*. We simulated the technological process of saccharification of pretreated aspen wood (AW) under conditions of varying degrees of washing from the corresponding reagent.

2. Method

Saccharification of AW (80 g/l in the reaction mixture) was performed under the action of cellulase enzymatic preparation (CEP, 10 mg/g or 0.8 mg/ml of the reaction mixture) with an excess of β-glucosidase activity (0.6 mg/g or 0.048 mg/ml of the reaction mixture) in 2 ml test tubes in a temperature-controlled shaker. The hydrolysis process was carried out in the presence of 0.1 g/l of

ampicillin in 0.1 M Na-acetate buffer pH 5.0 and 40 ° C. To study the effect of effectors, [Bmim] Br, [choline] Cl, (20, 10, 5, 2 and 1% in the reaction mixture) or seawater (200, 100, 50, 20 and 10%) were added to the reaction mixture. During the process, aliquots were taken, in which the glucose concentration was determined.

3. Results and discussion

The presence of 1% [Bmim] Br, 1-2% [Choline] Cl in the reaction mixture did not affect the stability of the EG and CBH. The effect of ILs on cellulases at high concentrations was different: after 48 hours, the EG activity decreased to 75% and 15% in the presence of [Choline]Cl and [Bmim]Br, respectively. The activity of CBH in the presence of [Choline]Cl decreased 2 times, and was not detected after 3 h of incubation in 20% [Bmim]Br. Seawater taken in studied concentartions did not affect the stability of the enzymes (data are not shown). The presence of effectors had little effect on the results of hydrolysis using AW as a substrate (Fig.1). The yield of glucose after 48 hours of hydrolysis in presence of 20% [Bmim] Br or 20% [Choline]Cl was 47 and 67% of the control, with 10% ILs - 72 and 76%, with 5% ILs - 77 and 80%, with 2% ILs - 85 and 91%, with 1% IL - 94 and 100%, respectively. In the presence of 200% seawater, the glucose yield was 74% of the control, at 100% - 87%, in more dilute solutions of seawater, the glucose yield values close to the control were obtained.

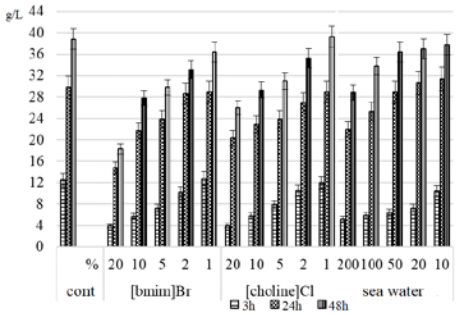

Figure 1. The yield of glucose (g/l) under enzymatic hydrolysis of milled AW (80 g/l) using CEP (10 mg of protein/1 g of substrate) and β-glucosidase (0.6 mg of protein / 1g of substrate) in the presence of ILs and seawater of various concentrations; 50 ° C, 0.1 M Na-acetate buffer with pH 5.0.

4. Conclusions

Pretreatment of aspen wood using ILs or seawater can adversely affect the reactivity and stability of the enzyme complex as a whole or its individual components, therefore the creation of new enzyme preparations that are tolerant to IL exposure is a promising task of industrial biotechnology.

This research was funded by Ministry of Science and High Education (MON) of Russia, project identification number: RFMEFI61617X0081.

Highlights

- Lytic polysaccharide monooxigenase (PMO) significantly boosts the hydrolytic activity of *Penicillium verruculosum* cellulases;
- New strains with optimized ratio of endoglucanases, cellobiohydrolases, β-glucosidases, and PMO were created;

1. Introduction

The use of renewable raw materials, such as agricultural by-products, is becoming increasingly important as a starting material for new biotech products. Agricultural and forestry materials, including (ligno) cellulose or starch, are first converted to sugars, which are later converted to chemicals, bioplastics, biofuels, and pharmaceuticals by fermentation [1]. Cellulose conversion occurs under the action of a complex of cellulolytic enzymes, which include exo-1,4-β-glucanase (CBH), endo-1,4-β-glucanase (EG) and β-glucosidase(BG). Cellobiohydrolases catalyze the degradation of the crystalline sections of cellulose, sequentially, by the processive mechanism, cleaving cellobiose from the ends of the polysaccharide chain. Endoglucanases catalyze the hydrolysis of amorphous sites of cellulose, splitting internal 1,4- β-glucosidic bonds by a disordered mechanism, thereby reducing the degree of substrate polymerization and creating new sites for the action of cellobiohydrolases. β-glucosidases hydrolyze cellobiose and cellooligosaccharides to the final product - glucose [2, 3]. Lytic polysaccharide monooxygenases (LPMO) catalyze oxidative cleavage of cellulose and cello-oligosaccharides. LPMOs are able to oxidise the C–H bond of the glycoside linkage connecting the sugar units in polysaccharides, which ultimately leads to cleavage of the glycoside link and hence boost generation of fermentable sugars. These enzymes are secreted by various fungal strains and are important components of enzyme cocktails used for industrial biomass conversion [4,5]. Improvement of the properties of new enzyme coctails and fine tuning of biocatalytical processes of cellulose-to-biofuels can lead to ecologically friendly and cost-efficient alternatives to fossil-based technologies.

LPMO from *Penicillium verruculosum* was overexpressed in the same fungal strain. The LPMO enzyme preparations with the “basal” cellulolytic enzyme complex, which contains EGs, CBHs, and bG were produced. The yield of fermentable sugars was 45 and 30% higher in microcrystalline cellulose (MCC) and pretreated aspen wood (AW) hydrolysis for some preparations.

2. Methods

LPMO was overexpressed in *Penicillium verruculosum* fungal strain; the number of strains, carrying 5-67% of LPMO were produced. Saccharification of MCC and AW (100 g/l in the reaction mixture) was performed under the action of basal cellulase enzymatic complex (CEC) and CEC+LPMO, normalized by protein to 5 mg/g of substrate or 0.5 mg/ml in the reaction mixture. The reaction conditions: 50mM sodium acetate pH 5.0, 40°C, 5mM of gallic acid was added as an electron donor for LPMO. Samples for reducing sugars and glucose assay were taken after 6, 24, and 48 hours of hydrolysis.

3. Results and discussion

MCC and AW was efficiently hydrolyzed by *Penicillium verruculosum* enzyme preparations with 5-12% of cloned LPMO, while the efficiency decreases dramatically for preparations with higher content of LPMO (Fig. 1). The yield of reducing sugars was ~10% higher in case of AW to compare to MCC. The yield of glucose was also higher with LPMO-enriched enzyme preparations, while the xylose yield remains approximately the same.

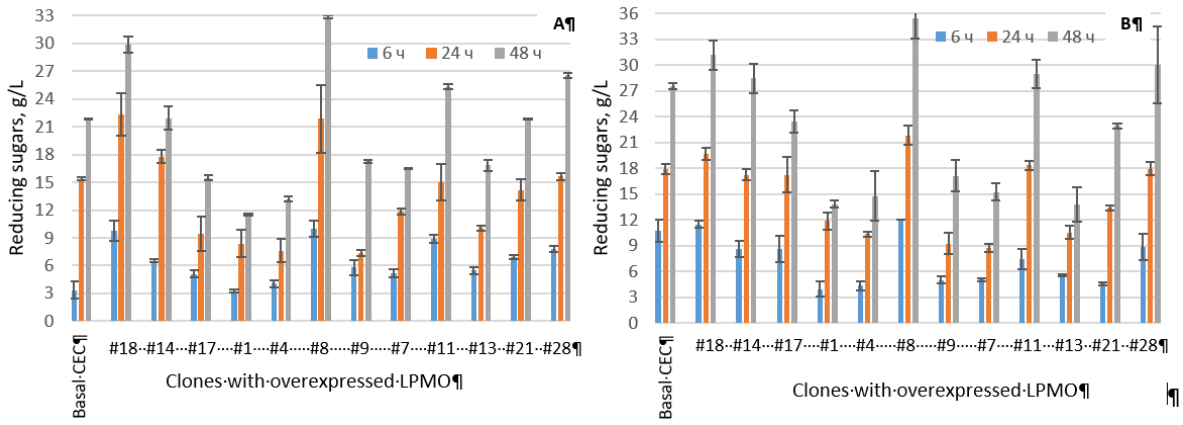

Figure 1. Reducing sugars release after 6, 24, and 48 hours hydrolysis of microcrystalline cellulose (A) and pretreated aspen wood (B) by different LPMO-enriched enzyme preparations. Substrate concentration 100 g/L, protein concentration 5 mg/g of substrate, 40 °C, pH 5,0.

4. Conclusions

New high productive *Penicillium* fungal strains with overexpression of LPMO were developed. The yield of reducing sugars as well as glucose were up to 45% higher for enzyme preparations with 5-12% of LPMO to compare to *Penicillium* basal cellulase enzyme complex. The level of total reducing sugars was approx. 10% higher in case of pretreated aspen wood hydrolysis to compare to microcrystalline cellulose. The content of LPMO does not affect much the level of xylose release in case of aspen wood.

Acknowledgments: the project is supported by Russian Fond of Basic Research, #18-54-80027\18

Characterization of liquid-solid adsorption processes in recirculated differential bed (RDB) and spinning basket (SB) set-ups

Simon Crelier[1], Bryan Boisset, Rémy Dufresne, Djano Kandaswamy

[1] *University of Applied Sciences and Arts Western Switzerland, CH-1950 Sion*

**Corresponding author: simon.crelier@hevs.ch*

Highlights

- RDB configuration enables an accurate control of experimental conditions
- Contrary to empirical models, mass transfer-based approaches enable a proper scaling-up of adsorption steps
- RDB configuration has been used successfully with various model systems
- SB configuration enables a more efficient liquid-solid mass transfer than RDB

1. Introduction

Liquid-solid adsorption is at the core of many industrial processes. The phenomenon is relatively easy to investigate at laboratory scale in a stirred vessel, but a proper design and dimensioning requires the acquisition of reliable equilibrium and kinetic data under well-mastered and characterized experimental conditions.

Similarly, the use of empirical rate laws (e.g. pseudo-2nd order, Elovich) to describe the kinetics of adsorption makes a proper scale-up of the adsorption step difficult. This is mainly because these models' parameters are difficult to relate to those commonly used in process engineering such as mass transfer- or diffusion coefficient-related dimensionless numbers.

As a consequence very few of the promising applications that are described in the literature are developed further up to pilot scale operation, not to mention industrial implementation.

We propose here a simple approach that does not require any complex equipment, but nevertheless enables a systematic investigation of the adsorption process and a proper transfer to larger scale. It is based on the use of a recirculated differential bed such as the one described in Figure 1. This set-up allows a precise control of working conditions and an easy determination of process relevant parameters.

This approach has been successfully applied in our laboratory to various model systems. These include the adsorption of Methylene Blue or Allura Red on granulated activated charcoal (GAC), of copper ions on Amberlite IR 120, of 4-nitrophenol or cephalosporin on Amberlite XAD 16, and of BSA or IgG on chromatographic resins.

2. Methods

Measurements were performed at room temperature (20±1 °C). A known volume V_{liq} of a solution of adsorbate with an initial concentration C_0 was contacted with a mass m_{sor} of sorbent.

The residual concentration of adsorbate in the liquid phase, C(t), was determined as a function of contacting time by spectrophotometry, ICP-MS or measurement of a colored complex. The corresponding adsorbed concentrations q(t) were calculated using the mass balance of Eq. 1:

$$q(t) = \frac{V_{liq}}{m_{sor}} \cdot (C_0 - C(t)) \qquad \text{Eq. 1}$$

3. Results and discussion

A short selection of results is shown here. The Recirculated Differential Bed configuration is shown on Figure 1 below. 400 mL of methylene blue solution (C_0=12 mg/L) was pumped at various flow rates Q_{rec} over a shallow fixed bed with 51.2 mg GAC (mean particle diameter 190 µm). The results are shown in Figure 2.

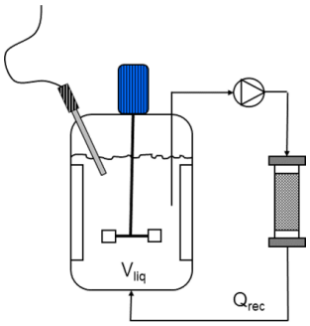

Figure 1. The RDB configuration

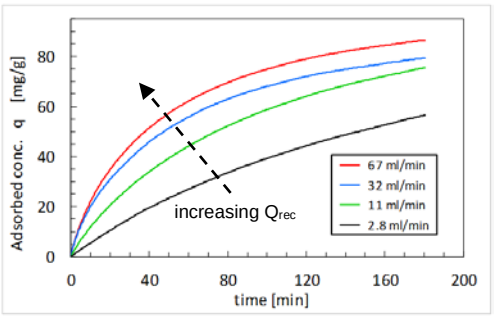

Figure 2. Adsorption kinetics of MB on GAC at various flow rates

External mass transfer coefficient k_l was estimated from the initial slope of the C(t) kinetics curves, as described in [1]. The k_l values ranged from $1.73 \cdot 10^{-5}$ m/s at 2.8 ml/min to $1.18 \cdot 10^{-4}$ m/s at 67 ml/min. This suggests a significant contribution of external mass transfer to the overall adsorption process, as described in [2].

External mass transfer coefficients were also measured with the spinning basket from SpinChem AB (Umeå, Sweden) during the adsorption of methylene blue (12 mg/L) on GAC (mean part. diam. 300 µm). The values of k_l also increased with increasing rotation speed and they varied between $2.71 \cdot 10^{-4}$ m/s at 100 rpm and $7.17 \cdot 10^{-4}$ m/s at 300 rpm.

4. Conclusions

Although the spinning basket contactor enables to reach higher external mass transfer coefficients, the spinning rate is more difficult to relate to hydrodynamic parameters such as Reynolds number, due to a more complex flow pattern. In this respect and although less efficient, the recirculated differential bed gives a better control of operating conditions for characterization and scale-up.

Highlights

- Solid State Fermentation
- Two-zones model approach.
- Hidrodynamics.
- Heat transfer.

1. Introduction

Solid state fermentation in recent years is booming in the biotechnology industry, due to the potential to produce value-added metabolites in different industries, for example; enzymes, biofuels, food additives, precursor molecules for chemical and pharmaceutical industries, among others [1].But nevertheless; in this type of systems, one of the biggest problems for scaling systems is the heat transfer, Due to the temperature gradients that are generated in the bioreactor, some reports mention gradients of up to 10 ºC [2], this is due to the exotherm of the biological reactions in the fermenter. Several authors have made characterizations of heat transfer; however, we still do not have a reliable methodology to scale the process. This could be due to not considering the effect of hydrodynamics when characterizing the heat transport parameters.

Due to the above, the objective of this work was to characterize the hydrodynamics and the effect it presents in the transport of heat in a tray bioreactor to produce proteases (SSF) under abiotic conditions.

2. Methods

The characterization of the system was carried out in a bioreactor of trays packed with agroindustrial waste (fruit, vegetable and soybean paste).

2.1 Hydrodynamic characterization.

2.1.1 Pressure Drop

To characterize hydrodynamics, pressure drops were determined in the system by varying the aeration flow (VkgM) using two high precision manometers at the inlet and at the bioreactor outlet.

2.1.2 Profile Velocity

To determine the velocity profiles, two hydrodynamic models were used, which are based on the system pressure drop, vacuum fraction, air properties (density, viscosity). The hydrodynamic user models were Navier-Stokes-Darcy-Forchheimer (NSDF) and Two-zones model (developed in the research group). The NSDF model has been proven in previous works that adequately reproduces

the velocity profiles obtained through experimental data, therefore it was used as a basis to compare with the Two-zones model.

2.1 Characterization of heat transfer.

2.1.1. Temperature gradients

The temperature was determined in transient state in different sampling ports along the bioreactor generating wide gradients that allow greater certainty when determining the parameters of heat transport (effective conductivity and the coefficient of heat transfer in the wall). said parameters were estimated by coupling hydrodynamics using Two-zones model.

3. Results and discussion

Figure 1a shows the experimental pressure drops in the system at different aeration flows (VkgM), in figure 1b the velocity profiles (cm s^{-1}) are shown using both hydrodynamic models and figure 1c shows the temperature profile in the bioreactor, this was with constant aeration flow and bath temperature.

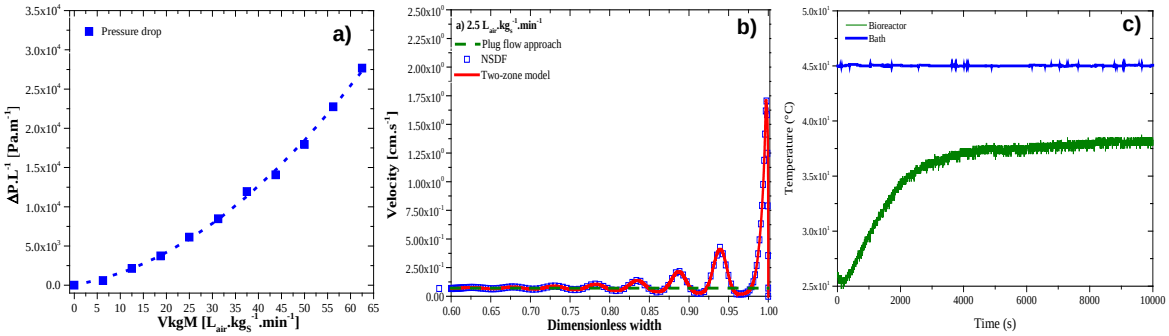

Figure 1. Experimental and theorical results in the system

As shown in Figure 1b, the velocity profiles obtained in the Two-zones model are practically identical to those obtained by means of NSDF (difference less than 3%), which gives us certainty about the results, together with the advantage that under the same computing conditions the processing time is reduced by 3000 times. The hydrodynamics was coupled to the estimation of the heat transfer parameters with the abiotic experimental data. The effective thermal conductivity and wall heat transfer coefficient present a value of ca. $9.49*10^{-3}$ W m^{-1} K^{-1} and $3.68*10^{-1}$ W m^{-2} K^{-1}

4. Conclusions

The Two-zones model allows reliable speed profiles to be obtained, greatly reducing the computation time, on the other hand the coupling of hydrodynamics to the heat transfer model allows to have a greater certainty of the heat transfer parameters and realizes all these analyzes under biotic conditions allow us to determine the effect of the bioreactor in the fermentation.

Isolation and characterization of halophiles microorganisms from solar salterns of Trapani, Sicily.

Valeria Villanova[1], Christian Galasso[2], Serena Lima[1], Alberto Brucato[1], Francesca Scargiali[1].

[1] Università degli studi di Palermo, Dipartimento d'Ingegneria, viale delle Scienze, edificio 6, 90128, Palermo (Italy). [2] Stazione Zoologica Anton Dohrn, Villa Comunale, 80121 Naples, Italy.

Highlights

- Halophiles microorganisms are very interesting for biotechnological applications.
- These organisms were isolated and characterized from solar salterns in Sicily.
- Tested samples showed potential cosmetic applications.

1. Introduction

Halophiles are those organisms that can grow optimally at high salt concentrations and, hence populate hypersaline environments such solar salterns, salt lakes and Dead sea.
Hypersaline environments are inhabited by various microorganisms belong to all the three domains of living organisms: Archaea (*e.g.* Halophiles), Bacteria (*e.g.* cyanobacteria) and Eukarya (*e.g.* microalgae). The most known and representative microalgae that can be found in high salt concentration are two species of the flagellates green algae *Dunaliella*: *D. viridis* e *D. salina*. The latter is one of the most studied microalgae for their ability to accumulate large amount (up to 14% of dried biomass) of *β*-carotene under extreme environmental [1]. Although *D. viridis* does not accumulate that large amount of *β*-carotene, it can produce oxygenated carotenoids and grow faster than *D. salina* [2]. Similarly to *Dunaliella* species many diatoms, can tolerate high salt concentration and have been found in both solar salterns and very saline and polluted lakes [3]. Moreover, amongst hypersaline bacteria we can find both photosynthetic and heterotrophic bacteria*: i)* the cyanobacteria *Cyanothece* and *ii) Salinibacter rubens*. Several strains of *Cyanothece* group isolated from hypersaline habitats have been characterized for the production of exopolysaccharide (EPS) with biotechnological application [4]. Moreover, halophiles organisms under stress condition such as high salinity and high light intensity accumulated large amount of carotenoids in order to protect the cell against light damage and oxidative stress. Due to the accumulation of these carotenoids, the solar salterns during the summer season are frequently pink-red colored [5]. These carotenoids show beneficial effects for human health, hence the production of halophilic microorganisms' carotenoids is of increasing interest for the blue economy.

2. Methods

The sampling site was the natural area "Saline di Trapani e Paceco", formed by several pans dedicated to the extraction of sea salt in the province of Trapani, city on the west coast of Sicily. Here, the different salt concentration in these pans allows the proliferation of different halophiles microorganisms visible by changing color from white to pink or red. These organisms were isolated with serial dilution methods in both liquid and solid artificial seawater with different salt

concentration (from 20 to 200 g/L of NaCl). The species identification of isolates halophiles were done by Colony PCR using different molecular markers (*i.e.* 16s, ITS, 18S). The cells were grown under different culture conditions in order to stimulate the production of secondary metabolites. High light intensity and salinity (*i.e.* 100 µmol m^{-2} s^{-1} and 200 g/L NaCl) was used as stress condition to stimulate the synthesis of interesting molecules (*e.g.* carotenoids) that can have a beneficial effect on humans. At the end of growth experiment, the cells were collected by centrifugation and the pellet was freeze-dried. Freeze-dried biomass was extracted with an hydroalcoholic solution (Eth/H_2O 3/1, v/v) and the obtained cell extracts were tested in biological assay including antitumor and cell repair activity on human cell.

3. Results and discussion

New strains of microorganisms (bacteria and microalgae) have been isolated from red and pink coloured pan present in the saltworks of "Saline di Trapani e Paceco": *D. viridis*, *Nitzschia dubiiformis, Salinibacter rubens* and *Cyanothece sp.* All the cell extracts did not show any antitumor activity on human cell (*i.e.* HT29 and PC3) at all tested concentration. *D. viridis* extracts from low light and salinity condition showed cytotoxic effects on human epithelial cell BEAS-2 cells increasing with high concentration. The same effect was not showed in the *D. viridis* grown under high light and salinity condition probably for the production of secondary metabolites with beneficial effect. Almost all samples showed a moderate repair activity on human epithelial cell line BEAS 2B, especially at medium and low concentrations (*i.e.* 10 and 1 µg ml^{-1}).

4. Conclusions

This research aims to promote the sustainable production of biomass with high biological value, thanks to the selection of halophiles microorganisms. Here, new strains of hypersaline microorganisms (bacteria and microalgae) were isolated from solar salterns at the natural reserve of "Saline di Trapani e Paceco". Thanks to the use of several molecular markers, it was possible to identify the species of isolated microorganisms. Cell extracts did not show significant cytotoxicity neither on normal nor tumour mammalian cells tested. Almost all samples showed a moderate repair activity showing a potential use of these strains in cosmetics.

Microalgae bio-products application for nutraceutical sector and cosmetics ingredients

Casella Patrizia [1], Rimauro Juri[1], Iovine Angela[1,2], Mehariya Sanjeet[1,2], Musmarra Dino[2], Molino Antonio[1,*]

1 Italian National Agency for New Technologies, Energy and Sustainable Economic Development (ENEA), Territorial and Production System Sustainability Department, CR Portici Piazzale Enrico Fermi, 1 - 80055, Portici, Italy; 2 Department of Engineering, University of Campania "Luigi Vanvitelli", Via Roma, 29 - 81031 Aversa, Italy

**Corresponding author: antonio.molino@enea.it*

Highlights

- Cosmetics and nutraceutical ingredients as beta-carotene, astaxanthin, methyl linoleate, palmitate, and eicosapantenoic acid are produced from microalgae
- Their extraction by CO_2-SFE was improved to obtain a good standard for nutraceutical and cosmetic application

1. Introduction

Microalgae are promising sources of high value compounds such as carotenoids, beta-carotene, lutein and astaxanthin, and fatty acids, (É3 and É6) that can find application in the growing sectors of nutraceuticals and cosmetics. Nutraceutical sector lies halfway between pharmaceuticals and nutrition, where natural compounds as vitamins, minerals, antioxidants are necessary as ingredients and active principles. Cosmetics industry is a very rich field that has also seen an ever-increasing trend in the demand for natural origin ingredients.

Among microalgae bio-products, beta-carotene is considered an excellent ingredient in nutraceuticals for its pro-vitamin A function, while astaxanthin in the form of oleoresin produced by the microalgae *Haematococcus pluvialis* is currently authorized as a novel food for its antioxidant properties [1]. In addition, the oils produced by the microalgae species *Ulkenia sp.* and *Schizochytrium sp.* have been authorised as novel foods and as sources of omega-3s (EPA and DHA). Lutein, on the other hand, is required as a supplement for its properties against degenerative macular disease. In cosmetic sector, ingredients as beta-carotene and lutein are used as colouring agents and skin conditioning, and polyunsaturated fatty acids (methyl linoleate and palmitate as both skin conditioning and emollient agents.

As part of the European project VALUEMAG (Valuable Products from Algae Using new Magnetic Cultivation and Extraction Techniques), the microalgae *Dunaliella salina*, *Scenedesmus almeriensis*, *Haematococcus pluvialis*, and *Nannochloropsis sp.* were selected for their ability to produce high value compounds such as beta-carotene, lutein and astaxanthin, and polyunsaturated fatty acids (PUFAs). The objective of the this work is to investigate the extraction of these bio-products by supercritical fluid extraction using CO_2 as extraction fluids (CO_2-SFE) and to evaluate the characteristics of extracted compounds compared to the characteristics of the

products currently authorized as novel foods and ingredients in nutraceutical and cosmetic industry.

2. Methods

The complete methodological approach is shown in the figure 1. Microalgae were cultivated testing a six-meter height Soft Magnetic Cone (SOMAC), a magnetic conic photobioreactor. Supercritical fluid extraction (CO_2-SFE) was tested varying temperature (°C), pressure (bar) and CO_2 flow rate (g/min) to extract carotenoids and fatty acids polyunsaturated from *Dunaliella salina*, *Scenedesmus almeriensis*, *Haematococcus pluvialis*, and *Nannochloropsis sp.* freeze dried biomass. The extracts were characterized in term of carotenoids and PUFAs concentration following official methods. The characteristics of extracts were compared with the properties of authorized nutraceutical products. A cost analysis evaluation was finally carried out by a market analysis on the price of authorized products.

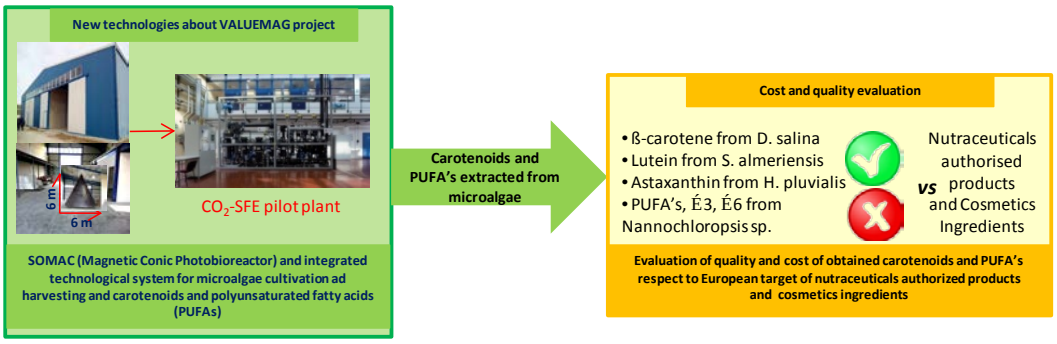

Figure 1. Methodological approach.

3. Results and discussion

Preliminary results have shown that beta-carotene, and astaxanthin can be extracted by CO_2-SFE as the major compounds among carotenoids respectively from *D. salina* and *Haematococcus pluvialis.* The obtained extracts from CO_2-SFE contained also an interesting fatty acids composition regarding compounds as methyl linoleate and palmitate in species such as *D. salina*, *Haematococcus pluvialis* for application as ingredients in cosmetics. In particular, palmitate constituted more than 50% of fatty acids methyl esters extracted from *D. salina* in different conditions.

The extraction was also tested on EPA content by CO_2-SFE from *Nannochloropsis sp.* searching the best operative conditions to improve extraction yield given that EPA content higher than ≥ 10 % is required for nutraceutical EPA rich-oil from *Ulkenia sp.* and and *Schizochytrium sp*. microalgae.

4. Conclusions

Fatty acids and carotenoids composition of extracts obtained from microalgae using CO_2-SFE demonstrated that are promising source for cosmetics and nutraceutical industry.

The successful scale up and commercialization of biopharmaceuticals is a challenging task that requires collaboration of professionals from many disciplines. Process simulators can facilitate this task by assisting scientists and engineers to answer the following and other related questions: What is the impact of product titer increase on the capacity load of the downstream section, the overall throughput of a plant, and the cost of goods? What changes are required in an existing multi-product facility to accommodate the process of a new product? What is the range of variability that a process can accommodate if it operates under a tight cycle time? What is the impact of single-use systems on the demand for utilities, the environment and the cost of goods? Our experience in addressing the above questions will be presented using industrial examples in which we evaluated alternative technologies for producing therapeutic monoclonal antibodies and vaccines.

A microfluidic approach for bioprocess development

Raquel Aires-Barros and Ana Azevedo

iBB – Institute for Bioengineering and Biosciences, Instituto Superior, Lisbon, Portugal
Corresponding author: rabarros@ist.utl.pt

Highlights

- Microfluidic toolbox to expedite the development of downstream processes
- Miniaturization of Aqueous Two-Phase Systems (ATPS
- Chip Chromatography for screening of adsorption/elution conditions

1. Introduction

The number of biotechnology-based pharmaceuticals in the late-stage pipeline has been increasing more than ever in particular monoclonal antibodies (mAbs) representing a quarter of all biopharmaceuticals in clinical trials. As a result, there is an enhanced demand for more efficient and cost-effective processes. Here, the potential of miniaturization as a high-throughput screening tool to speed up process development is explored, considering optimization of antibody extraction conditions with aqueous two-phase systems and chromatographic conditions optimization regarding the capture of an antibody, using a multimodal ligand.

2. Methods

The ATPS-microfluidic setup allowed the screening of a wide range of concentrations inside the microchannel by varying the flow rates of the solutions while using sub-mL volumes for each ATPS-forming system. The partition of molecules between two co-flowing liquid streams confined within a microchannel was demonstrated by the on-line extraction of a fluorescein isothiocyanate (FITC) labeled immunoglobulin G (IgG) from a salt rich flow to a PEG rich flow.

The setup for screening adsorption and elution conditions- Micro- columns on a chip-contains 30 micro-columns in a 15 x 40 mm chip (Resin Volume ~ 35 nL). Fluorescence emission of the packed beads was continuously monitored to obtain the adsorption and elution kinetic profiles.

3. Results and discussion

The ATPS-microfluidic developed setup (Figure 1a) allowed the screening of up to 8 extraction conditions simultaneously, while a second microfluidic structure allows the integration of multi-step extraction steps. The chip chromatography(Figure 1b) microfluidic developed platform allowed the effective screen of multiple adsorption and elution conditions within a few minutes for early stage multimodal chromatography optimization. Both techniques can be used with any target molecule or resin assuming a previous labeling procedure with a proper fluorophore.

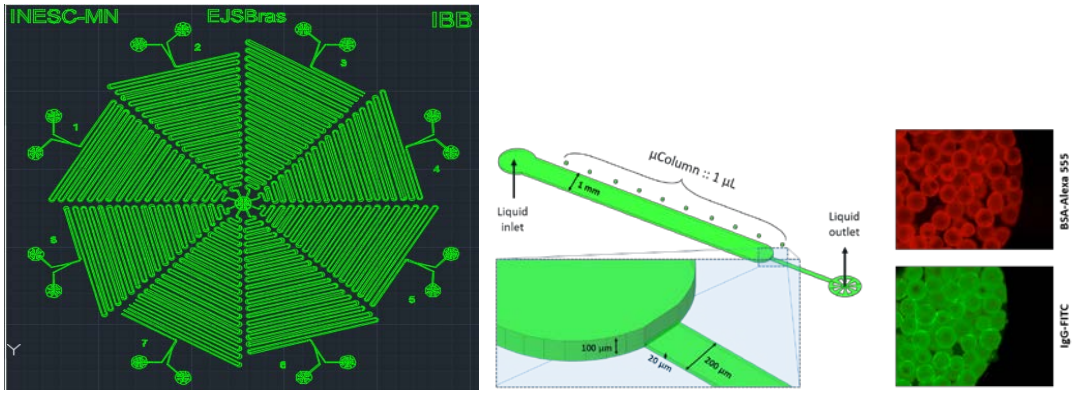

Figure 1. a) Microfluidic-ATPS toolbox; b) Chip chromatography

4. Conclusions

A microfluidic approch was sucessfuly stablished to expedite the development of dsp of biopharmaceuticals using reduced volumes of reagents and shorter experimental times

*sho@xanum.uam.mx

Highlights

- We evaluated naringenin bioconversion by whole cells of *Yarrowia lipolytica 2.2ab*
- Some polyhydroxylated flavonoids are first reported by whole cells
- This study allowed selection and operation of the proper bioreactor.

1. Introduction

The flavonoids are plants secondary metabolites that exhibits important antivirals, anti-inflammatory, vasodilators and antioxidant biological activities [1]. Naringenin is classified on the subclass of flavonones and is naturally present in grapes, tomatoes and citric fruits. Due to its positive effects on health, their study has attracted the attention of several research groups [2, 3]. It has been reported that the increase in antioxidant activity in flavonoids is highly related to the degree of hydroxylation and/or methoxylation [4]. *Yarrowia lipolytica* may express the CYP450 enzyme system, which is indispensable to increase the hydroxylation of hydrophobic compounds such as naringenin [5]. Chang et al. [6] reported the bioconversion of naringenin to 8-hydroxynaringenin by *A. oryzae* cells. The hydroxylation of naringenin to eriodictiol by means of the cytochrome P450 monooxygenase enzyme expressed by *P. chrysosporium* was reported by Kasai et al. [7]. The objective of this study was the identification of the compounds obtained from the bioconversion of naringenin by the enzymatic system produced by *Y. lipolytica* 2.2ab (Yl2.2ab).

2. Methods

Bioconversion experiments were prepared in 250 mL Erlenmeyer flasks with 100 mL of Sabouraud culture broth inoculated with $1x10^6$ cells mL^{-1} of Yl2.2ab and 100 mg L^{-1} of naringenin were added. Concentration and identification of residual naringenin and formed products was performed by HPLC, the use of external standard was required [8].

3. Results and discussion

Figure 1 shows the kinetic profile from the bioconversion of naringenin by Yl2.2ab to the polyhydroxylated compounds identified as apigenin, ampelopsin, myricetin, aromadendrin and luoteolin. All the molecules were produced simultaneously throughout the reaction time.

The obtained molecules exhibit higher antioxidant activity related to molecule used as precursor. It has been reported that the increase in antioxidant activity in flavonoids molecules is directly related to the degree of hydroxylation and/or methylation formed in the new formed molecule [4]. The compounds identified in here are of great interest for the pharmaceutic and food industries.

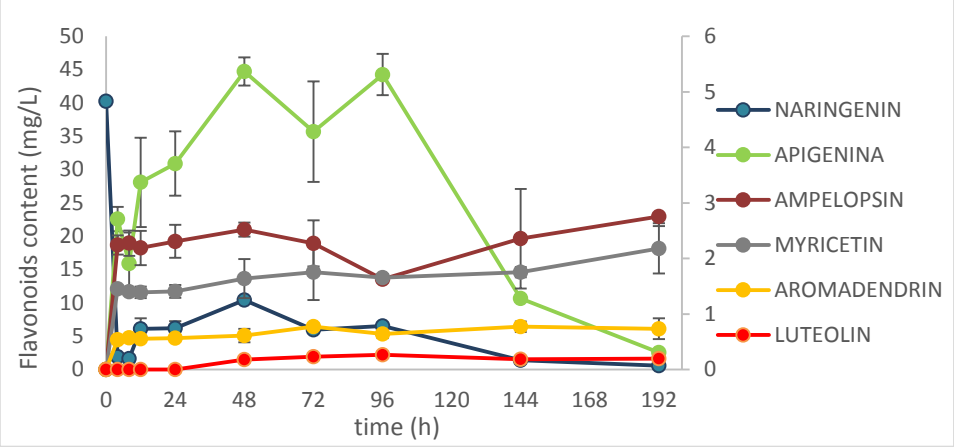

Figure 1. Profile of concentrations during the bioconversion.

4. Conclusions

Five compounds with high valued were obtained during the bioconversion naringenin by Yl2.2ab. The molecules obtained showed higher antioxidant activity than the initial precursor.

Effect of flow behavior in extra-column volumes on the retention pattern of proteins in small columns

Krystian Baran, Wojciech K. Marek*, Izabela Poplewska, Wojciech Piątkowski, Dorota Antos

Department of Chemical and Process Engineering, Powstańców Warszawy Ave. 6, 35-959 Rzeszów, Poland; *wojciech.piatkowski@prz.edu.pl*

Highlights

- Deformation of protein peaks in extra-column volume (ECV) was indicated
- ECV effect stems from radial velocity distribution and slow protein diffusivity
- ECV effect influences on the protein retention on a small column
- Mathematical model was used to predict the extra-column volume effect

1. Introduction

Columns with very small volumes, i.e., maximum 1 mL, are often used in the development stage of protein chromatography to estimate operating parameters for large stale operations at minimal material consumption. Small columns are exploited in high throughput experiments to acquire a huge number of chromatographic elution data that are subjected to statistical analysis to determine the bounds for the process operating window as well as characterize the process dynamics and provide optimum of operating conditions with respect to the process performance. However, reduction in the column size causes an increase in the ratio of the extra-column volume (ECV) in the workstation to the column volume. Therefore, band broadening in ECV can significantly affect the separation efficiency. In this study, the experimental and theoretical analysis of deformation of band profiles in ECV was performed, and its influence on the retention pattern of proteins in a small chromatographic column was quantified [1].

2. Methods

A few model proteins were used for the elution experiments: lysozyme, LYZ; bovine serum albumin, BSA; monoclonal immunoglobulin, IgG4; fibroblast growth factor, FGF2. Additionally, blue dextran as a representative of large macromolecules, and acetone as a representative of small-molecule compounds, were used. The column was packed with a cation exchange resin UNOsphere S (Bio-Rad Laboratories, Hercules, CA, USA, particle diameter 80 μm). The mobile phase was a phosphate buffer pH = 7 free of salt or with 1M NaCl in the solution. Two injection systems were used: a superloop and an injection loop capillary.

3. Results and discussion

The effect of the presence of ECV on shape of band profiles resulted from non-uniform velocity distribution in the radial direction and slow diffusivity of proteins. The phenomenon vanished for a small molecule compound, and it was enhanced with increasing molecular weight of the model compound. The difference in flow behavior of the macromolecule and small-molecule compounds caused them to migrate with different velocities in ECV, which resulted in partial separation of their bands. To describe the elution profiles in ECV and in the column, a mathematical model was used, which accounted for nonideality of the flow pattern. The model reproduced accurately band profiles of macromolecules within a range of relatively low velocities, typical however for protein chromatography.

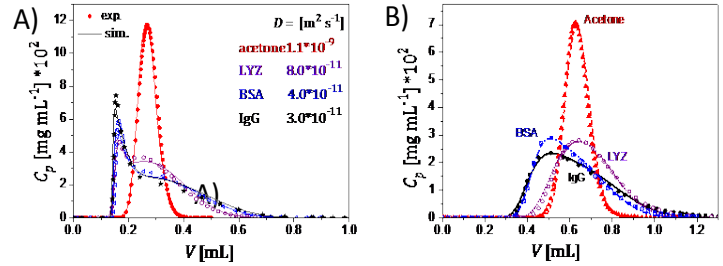

Fig. 1. Experimental band profiles and the corresponding model simulations for small-volume injections for proteins and acetone.
A) in ECV; B) in the column.

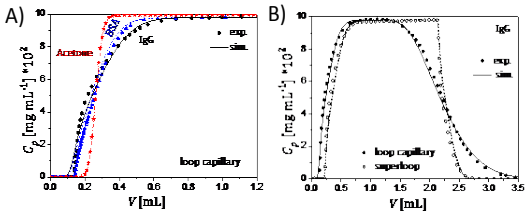

Fig. 2. Band profiles in ECV

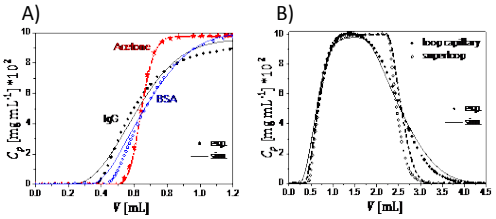

Fig. 3. Band profiles at the column outlet

Experimental band profiles and the corresponding model simulations for large-volume injections. A) Fronts of breakthrough curves for the proteins and acetone injected through the loop capillary; B) comparison of the IgG bands for the injections through the loop capillary and the superloop.

Typical experimental data and the model simulations for small pulse injections recorded in the chromatographic system with and without presence of the column are shown in Figures 1A and 1B respectively. The protein peaks are characterized by deformations which enhance with increase in molecular weight of the protein. Band profiles obtained for large injections are shown in Figs 2 and 3. They exhibit strong asymmetry of the fronts with a slow concentration transition in their upper part. The courses of the concentration decay in the desorption parts of the band profiles obtained by injections using the loop capillary and the superloop differ markedly. In case of the superloop injections, peak tailing is markedly reduced compared to the loop capillary injections. This stems from the differences in the elution pattern of proteins in both injections systems.

4. Conclusions

The ECV effect contributed strongly to the elution behavior of macromolecules in the small column. Peak deformation was observed for small-volume injections and asymmetry of breakthrough curve fronts for large-volume injections. In the latter case, the system performance was higher for the superloop injections compared to the loop capillary injections. Neglecting the EVC effect may result in wrong interpretation of the protein retention mechanism.

Doubling humanized L-asparaginase expression by *Pichia pastoris* through DO-stat controlling induction strategy in bench-bioreactor

Leticia Parizotto[1], Adalberto Pessoa Jr[2], Aldo Tonso[1]

1 University of Sao Paulo, Polytechnic School, Dep. of Chem. Eng.
2 University of Sao Paulo, School of Pharmaceutical Sciences, Dep. Bioch. - Pharm. Technology
**Corresponding author: leticia.parizotto@usp.br*

Highlights

- The engineered *Pichia pastoris* expressed humanized L-asparaginase (ASNase)
- Three induction strategies were studied
- DO-stat strategy resulted in, approximately, two-fold more maximum ASNase activity

1. Introduction

During the last ten years, the yeast *Pichia pastoris (Komagataella phaffi)* has been consolidated as a platform for biopharmaceutical production. Moreover, the development of engineered strains capable to perform 'humanized' glycosylation increased the chances to reach the requirements of the regulatory agencies (Jacobs et al, 2009). Facing this potential, a strain of *P. pastoris* Glycoswitch® (Biogrammatics Inc.) was transformed to express the enzyme L-asparaginase (ASNase), which is applied in acute lymphoblastic leukaemia treatment, with 'humanized' glycosylation. The objective of this work is to obtain the highest ASNase activity through studying different induction strategies aiming the scaling up production of this innovative biopharmaceutical.

2. Methods

2.1 Cell strain and expression vector

Pichia pastoris GS115 Glycoswitch® SuperMan$_5$ his$^+$ (Biogrammatics Inc.) transformed by electroporation with the plasmid pJAG_s1 (Biogrammatics Inc.) containing the gene asn*B* (GenScript) of the bacteria *Erwinia chrysanthemi (Dickeya chrysanthemi)* for ASNase expression, the factor αMF for extracellular expression and the gene for G418 resistance for selection (Effer et al, 2019). The plasmid was linearized and integrated to the promoter AOX1.

2.2 Cell storage and reactivation

Cells storage and seeding were performed according to Invitrogen's protocol (Invitrogen, 2002). The pre-inoculum was prepared to inoculate the bioreactor with 1 $g_{drycell}$/L.

2.3 Bioreactor cultures

Bioreactor cultures began with 1 litre of BSM (Basal Salt Medium) and 4.35mL of PTM1 (metal trace *Pichia* solution) formulated according to Invitrogen (2002) in a 2L-BIOSTAT B (Sartorius, Germany). The glycerol batch phase was performed according to the same protocol and equal in the three experiments with dissolved oxygen (DO) kept over 20% air saturation with control cascade of the agitation between 700 and 1000 rpm and aeration kept at 1 litre per minute. Following, there was a period of starving for, approximately, 2 hours and then induction was started. In the experiment

A, the induction was performed with the addition of 10mL-pulses at every 24 hours; in experiment B, methanol was linearly fed with constant rate of approximately 18mL/h and DO was controlled over 20% with pure oxygen feeding; and, in C, methanol was fed to keep DO at 20% in a control mesh (DO-stat).

2.4 Analytic Methods

The dry mass concentration was related to optical density at 600nm measured in a spectrophotometer (Spectra Max®, Molecular Devices); glycerol was evaluated using a colorimetric kit (Triglicerides Liquiform®, Labtest); ASNase activity, modified protocol of Drainas, Kinghorn and Pateman (1977) and protein concentration, BCA method (Bicinchoninic Acid Kit, Sigma®).

3. Results and discussion

The three cultures provided similar performances during the growth phase on glycerol, with a specific maximum growth rate of 0.18±0.02 h^{-1} and cell productivity of 1.1±0.1 $g_{drycell}$/L/h after 24 hours of cultivation. However, during the expression phase, the ASNase production was different according to the induction strategy. The maximum activities were 1674 U/L (100h), 1501 U/L (76h) and 3068 U/L (97h) in A, B and C, respectively. Moreover, the population grew and produced protein significantly only in culture C. Therefore, the induction strategy based on controlling methanol-feeding by O_2 concentration (C) was the most suitable, since the metabolism was permanently stimulated to produce ASNase and consume methanol differently from pulses strategy (A), that was intermittent, and did not achieve toxic levels as in the constant feeding (B). This result agrees with previously reported by Lim et al. (2003) that achieved 40% higher rGuamerin secretion using DO-stat strategy than manual control of methanol-feeding. This strategy avoids methanol accumulation and lack of oxygen, improving cell growth and heterologous protein production (Lim et al, 2003).

4. Conclusions

As described in the literature (Liu et al, 2019), the induction strategy influenced significantly the heterologous protein production. The maximum ASNase activity approximately doubled with methanol-feeding controlled by DO-stat. This strategy kept methanol constant in a range that stimulated ASNase production, but at a level that was not toxic for the cells during the culture. Therefore, the induction strategy that considered aspects of cell metabolism was the most suitable for humanized ASNase production.

Antibody variant ion-exchange separation and recovery at varying ligand densities

Greta Jasulaityte[1], Hans Johansson[2], Daniel Bracewell[1*]

1 Department of Biochemical Engineering, University College London, Bernard Katz Building, Gower Street, London WC1E 6BT, United Kingdom; 2 Purolite, Unit D, Llantrisant Business Park, Llantrisant, South Wales CF72 8LF, United Kingdom

**Corresponding author: d.bracewell@ucl.ac.uk*

Highlights

- Ratio between charged variants and main antibody changed with ligand density and pH.
- mAb recovery decreased with increasing ligand density and decreasing pH.
- Analytical studies revealed conformational changes to the mAb.

1. Introduction

Charge variant separation from the main monoclonal antibody is often challenging due to their similarities in charge and size [1]. Numerous separation techniques have been suggested including pH as well as salt gradients, a combination of both, or using different resin types [2,3]. In some cases, these conditions have been linked to a reversible or irreversible two-peak elution profile induced by protein unfolding, aggregation, or presence of specific charge-dependant amino acids [4-6]. In order to understand whether the presence of charge variants can affect the two-peak behaviour, we performed the separation using varying ligand density resins and buffer pH.

2. Methods

Antibody containing high levels of charge variants was run on columns packed with five cation exchange resins containing different ligand densities. The separation was carried out under an increasing salt gradient at three pH conditions. Analytical techniques such as size exclusion chromatography, circular dichroism, isoelectric focusing electrophoresis, and mass spectrometry were used to examine elution peaks.

3. Results and discussion

We found that the two-peak ratio and total protein recovery changed with buffer pH and ligand density. Protein recovery decreased by up to 27% with increasing ligand density, and by up to 51% with decreasing pH. No aggregation or reversible protein association was detected. However, circular dichroism data revealed conformational changes to the antibody structure, whereas isoelectric focusing electrophoresis showed the presence of different charge variants in the two peaks. Further analysis using mass spectrometry was undertaken to understand what caused reduction in protein yield and changes to the two-peak behaviour.

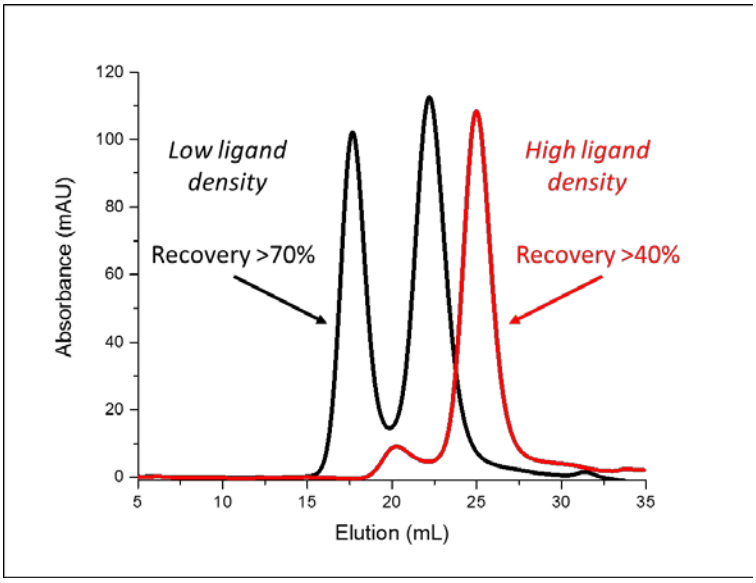

Figure 1. Antibody elution profile and recovery using low and high ligand density resins.

4. Conclusions

The results indicate that ligand density and buffer pH can affect the elution profile and protein recovery. We hypothesize that charge variants become unstable as a result of induced conformational changes.

Highlights

- ABAD Bioenergy© process, developed by Aqualia, for the transformation of biogas into biomethane
- In order to maximize the production of biogas, the pre-treatment of secondary sludge with nitrite and co-digestion have been studied
- Avoiding H_2S contaminant in biogas with micro-aerobic process

1. Introduction

Wastewater treatment plants (WWTPs) use energy intensive processes that consume large amounts of non-renewable energy. In the current context of resources scarcity and environmental protection standards, novel renewable energy sources have become an important issue for the sustainable management of WWTPs. Different approaches have been proposed to enhance sewage sludge digestion, biogas production and exploitation to maximize its value. Aqualia has exerted effort to reduce WWTPs energy dependence and develop new biogas technologies. The present study shows a possible scenario for integrating different technologies in a conventional WWTP (Figure 1). Proposed technologies are focused on i) waste activated sludge (WAS) pre-treatment, ii) low cost biogas up-grading ABAD Bioenergy© and iii) co-digestion with glycerin waters controlling the concentration of hydrogen sulfide with micro-oxygenation technics developed at industrial level.

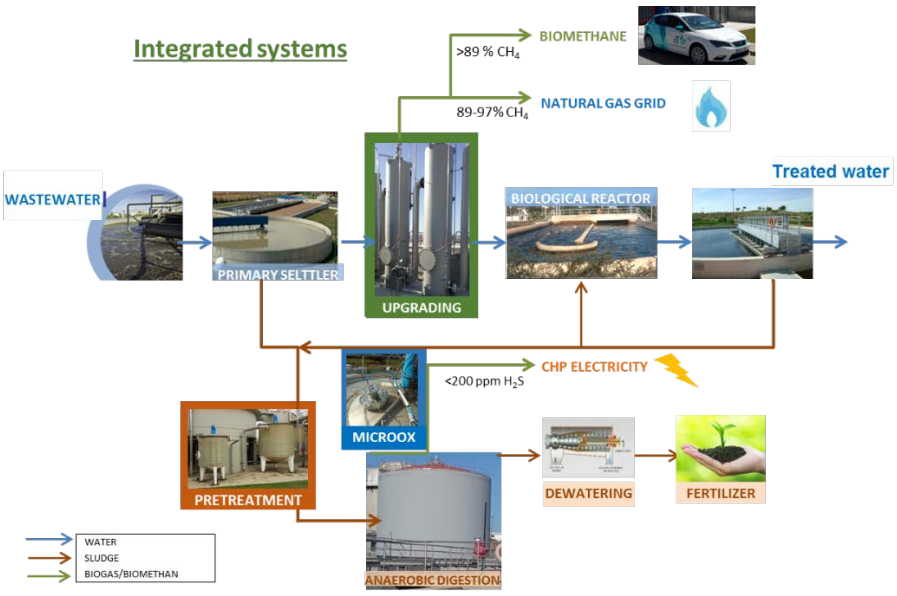

Figure 1. Proposed improvements integrated in a wastewater existing plant

2. Methods

Low cost biogas up-grading. A new up-grading technology (ABAD Bioenergy ©) has been developed by FCC Aqualia (European patent EP 3061515B1, EEUU patent 9901864). This technology is based on a water scrubbing system. Biomethane obtained is H_2S free and contains > 89 % of methane. In contrast with other up-grading technologies, ABAD process presents low energy demand, no need for regeneration of CO_2 absorbent, full integration in the WWTP process, flexibility (operation conditions can be set according to the WWTP regime) and low capital investment.

Pre-treatment. Previous reports have demonstrated that WAS pre-treatment with nitrite (NO_2^-) enhance hydrolysis and acidification processes, stimulating the activities of key enzymes responsible for hydrolysis and acidification [1]. The pre-treatment is achieved through NO_2^- addition (174 mg N-NO_2^-/L) to WAS with a mixing time of 4-5 hours [2]. Batch assays of WAS pre-treatment with NO_2^- have shown that methane production could be enhanced to a range from 12 to 28 % in lab experiments. Also a study was conducted to investigate the influence of nitrite pre-treatments in full-scale continuous anaerobic digesters. Results show the positive effect of nitrite pre-treatments on methane production. An economical assessment was also conducted, showing that pre-treatment benefits, on a full-scale implementation, would be limited to the use of biomethane for electricity generation.

Micro-aerobic process is applied to improve the biogas quality. The supply of O_2 (93 % purity from an O_2 generator) to the headspace of a full-scale digester (2400 m^3) of sewage sludge was studied. The average H_2S concentration in the digester dropped once the microaerobic conditions were applied, the average concentration of H2S in the biogas reach values above 200 ppmv with a removal efficiency of 90-95%. Residual O_2 in the biogas remained below 0.5-1 % during the whole micro-aerobic period and biogas dilution with N_2 was avoided. The energetic content of the biogas was not altered by the oxygen supply, and the CH_4 concentration was 62 % both in anaerobic and micro-aerobic conditions. According to the electric consumption of the generator, operating costs are incredible low compared with iron salts application. Therefore, it is feasible to remove H_2S at full-scale while maintaining the biogas quality and avoiding dilution with N_2 by employing an O_2 generator.

3. Results and discussion

The pilot plant in Guadalete WWTP, located in Jerez de la Frontera (Cádiz, Spain), treats up to 7 Nm3/h biogas. The plant consists on a three stage scrubbing system followed by a polishing process where H_2S, siloxanes and water traces are removed from biomethane. Then, the gas is compressed to 240 bar and stored to refuel car tanks. Two SEAT León have been tested and refueled with the produced biomethane to check its quality.

After 30,000 Km travelling with 100 % autochthonous biomethane produced from wastewater, SEAT will check car components and engines in order to validate this biofuel with all company guaranties.

Biomethane quality. Since November 2016, after the start-up of the pilot plant, biomethane has been produced and stored as compressed natural gas (CNG), used to refuel periodically the two test cars, which were driven intensely. Average gas compositions are shown in Table 1.

	Biogas	Biomethane
CH_4 [%-vol]	65.9 ±2.3	89.2 ±1.1
CO_2 [%-vol]	33.8 ±1.4	4.2 ±1.4
N_2 [%-vol]	2.4 ±1.5	6.6 ±1.1
O_2 [%-vol]	0.5 ±0.5	0.0
H_2S [ppm]	915 ±449	<5
Siloxanes [mg/Nm_3]	10	<1
Water (ppm)	-	<15

Table 1. Gas composition

Biomethane quality meets the legal requirements established by the European Standards [6] with a Wobbe Index close to 45 MJ/Nm^3 and Methane Number of 102.

The pre-treatment system allows to treat 10-20 m^3 of WAS per day, which is the 5-20 % of the total WAS produced and the 10-40% of the WAS feeding the digester. Taking this into account, it could not be possible to observe the effects of nitrite pre-treatment of WAS in full scale implementation. Even so, samples of treated and non-treated WAS were take periodically in order to be characterized by BMP test, solubility (CODs/VS), pH, nitrite (initial / end) and microscopic analysis.

4. Conclusions

A new up-grading technique has been developed by Aqualia to produce biomethane for automotive use from biogas in WWTPs. Its design is focused to be fully integrated in WWTPs with low capital and operating costs. The pilot plant in Guadalete WWTP, as first scale-up, supposes the unique up-grading plant in Spain that produces renewable biofuel from wastewater with a Spanish patent. Biomethane quality meets the legal requirements and real tests in two CNG cars are running.

Operational costs indicate that the patented process ABAD Bioenergy © is competitive with other technics and the investment is the most competitive for a biomethane production from 30 to above 100 m^3/h [3].

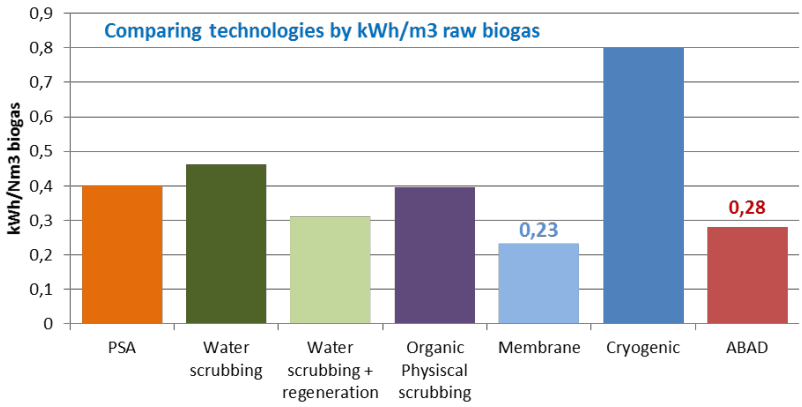

Figure 2. Energy consumption comparison with other upgrading systems

WAS pre-treatment with nitrite was assess in full scale WWTP. Results shows that pre-treatment is highly influenced by temperature, nitrite and VS ratio and WAS evolution in time. Economical assessment shows that nitrite pretreatment presents the highest benefits but those could be seen as limited to engage full-scale implementation when methane is used for electricity generation. Alternative scenario with the use of extra biogas as vehicular fuel could present a better profit.

The micro-oxygenation implanted in various facilities at an industrial level improves the quality of the biogas produced, this being very important for its subsequent valorization as biomethane. It also avoids corrosion problems in the electric cogeneration motors, reducing both preventive and corrective maintenance costs, all of it with a low cost investment and operation.

Determination of maximum specific growth rate of photosynthetic organisms based on steady-state measures in CSTR

Elena Barbera[1], Eleonora Sforza[1], Alessia Grandi[1], Alberto Bertucco[1]

1 Department of Industrial Engineering, University of Padova, via Marzolo 9, 35131 Padova, Italy

**Elena Barbera: elena.barbera@unipd.it*

Highlights

- Diazotrophic cyanobacterium *Anabaena* PCC7122 was cultivated in continuous photobioreactors
- Respirometric tests used to measure kinetic parameters of N, temperature and light
- Maximum specific growth rate was determined from continuous experiments
- Kinetic model was developed and implemented in Aspen Plus process simulator

1. Introduction

Modeling the growth of photosynthetic organisms is challenging, mostly due to the complex role of light, which can be limiting because of self-shading, or photoinhibiting in the case of high intensities. The determination of the maximum specific growth rate is often affected by many variables that, in batch growth systems, may change significantly. On the other hand, in a continuous system, once steady-state is reached, all the process variables remain constant, including the biomass concentration and the specific light supply rate. This allows a quantitative assessment of the effect of this operating variable on the culture performances.

A case of particular interest is represented by nitrogen-fixing cyanobacteria (Anabaena PCC 7122), whose growth is controlled not only by the light intensity, but also by the availability of atmospheric nitrogen, which is related to its liquid solubility. In this work, a new approach, that combines the use of the cultivation in continuous systems and respirometric tests was presented.

2. Methods

Continuous experiments were carried out in vertical flat-panel PBRs with working volume (V_R) of 350 mL and 4 cm thickness, at a temperature T = 24°C. CO_2-enriched air (5% v/v) was sparged from the bottom. Mixing was checked by means of tracer experiments, that allowed to consider the reactor as a completely stirred tank one (CSTR) [1]. Fresh inlet BG11 or $BG11_0$ (with no nitrogen) was continuously fed by means of a tunable peristaltic pump. Continuous artificial white light was provided by a LED lamp.

The equation describing the autotrophic growth rate can be written as a function of biomass concentration (c_x), the maximum specific growth rate (μ_{max}), temperature ($f(T)$), specific light

$(f(I_{sp}))$ and the most limiting nutrient, i.e. nitrogen $(f(N))$. Moreover, the kinetic model takes into account the specific maintenance rate (μ_e) that is a negative term, thus reducing the biomass growth rate (r_x).

$$r_x = c_x \cdot \mu_{max} \cdot f(T) \cdot f(N) \cdot f(I_{sp}) - \mu_e \cdot c_x \quad \text{(Eq. 1)}$$

The kinetic parameters for temperature, nitrogen and light were measured by respirometric tests [2]. The specific maintenance rate (μ_e) was evaluated by elaborating experimental data of continuous cultivation according to the model proposed by Gons and Mur [3]. Finally, the maximum specific growth rate μ_{max} could hence be determined by applying the kinetic model in the material balances of the continuous PBR.

3. Results and discussion

The cyanobacterium was cultivated in continuous photobioreactors with and without supply of nitrates, showing that no nitrogen limitation occurred, and similar productivities were obtained in the two cases. This suggests that the half-saturation constant of the nitrogen is lower than its solubility in water. This was confirmed by the respirometric tests, that resulted in a half-saturation of about 3 mg L^{-1}. In addition, the kinetic parameters for temperature and light were measured by respirometric tests. Afterwards, the experimental results obtained under different incident light intensities were used to evaluate the specific maintenance rate, which was found dependent from the light intensity, ranging between 0.5 and 0.8 d^{-1}. The experimental data were finally elaborated to derive the value of μ_{max} ($8.22 \pm 0.69\ d^{-1}$).

4. Conclusions

In this work, the diazotrophic cyanobacterium *Anabaena* PCC7122 was cultivated in continuous photobioreactors with and without supply of nitrates, to investigate the role of nitrogen, light and residence time on growth kinetics. Based on the results of continuous experiments, the specific maintenance and maximum growth rates were evaluated.

Highlights

- Immobilized phospholipase A_1 was successfully prepared.
- Reaction rate increased by glutaraldehyde treatment.
- Repeated use of immobilized phospholipase A_1 was successfully appeared.

1. Introduction

Immobilized enzyme has been expected to industrial applications. Immobilized enzyme effectively enables to separate the enzyme from products, thus facilitating its recovery and repeated use. A hydrophobic material is most favorable to easy diffusion of substrate in inner pore of carrier in order to quick initiation of hydrophobic enzymatic reaction. Recently, hydrophobic materials, primarily a polypropylene porous commercial carrier called Accurel, has been proposed for lipid [1]. In this study, we focused on hydrophobic porous carrier on reactivity of immobilized phospholipase A_1 progressing toward higher reaction rate and high yield in repeated use.

2. Methods

2.1 Phospholipase A_1 immobilization method

Accurel MP 100 (Membrana GmbH, Germany) (Figure 1 and 2) was immersed in ethanol (99.5 v/v%) for 60min. And then, the Accurel carrier was placed into the PLA1 solution and then shaken to adsorbed PLA1 for 24h at 298K.

Next, the dried Accurel carrier with the adsorbed PLA1 was shaken in Glutaraldehyde (GA) solution (1.5~6 v/v%) for 60 min at 298 K. The desorbed amount of PLA1 in the GA solution was the measured. The immobilized PLA1 carrier was briefly washed in distilled water.

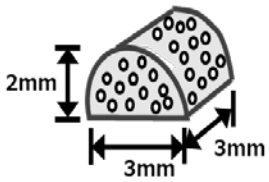

Figure 1. Schematic illustration of Accurel MP100.

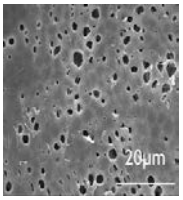

Figure 2. SEM image of Accurel surface.

2.2 Hydrolysis of phospholipid using immobilized PLA1 in Accurel carrier

Phospholipid (from soybean) was dissolved into the organic phase composed of 1-butanol/isooctane. The substrate solution (50mL) was placed in a glass vessel. And then, the substrate solution containing acetate buffer solution (pH5.0) were stirred magnetically for 10min in a water bath (313K). The reaction was initiated when the immobilized PLA1 on Accurel carrier was added to the W/O microemulsion phase. After the reaction was initiated, 0.2 mL of the sample was taken at the desired time in the reaction period. The concentration of produced fatty acid (palmitic acid) was determined by the Lowry-Tinsley colorimetric method [2].

3. Results and discussion

Figure 3 shows the effect of GA treatment on the initial reaction rate (V_i). The V_i increased with increasing GA concentration. Cross-linking of PLA1 by GA was very beneficial for attaining a higher reaction rate.

Figure 4 shows the time course of production of palmitic acid for the repeated use of immobilized PLA1. Repeated use of immobilized PLA1 was successfully appeared without lag time and preserved sufficiently high reaction yield until 2nd run. The activity site of immobilized PLA1 was not damaged after repeated processing.

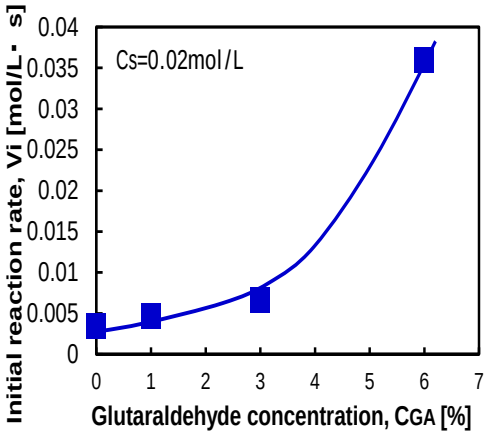

Figure 3. Effect of GA concentration on the V_i.

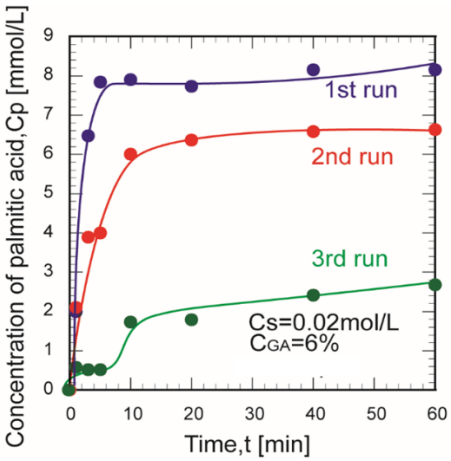

Figure 4. Time course of production for the repeated use of immobilized PLA1.

4. Conclusions

High yield immobilization of phospholipase A_1 and quick initiation of hydrolysis of phospholipid. Immobilized PLA1 was prepared using porous polypropylene carrier (Accurel MP100). Repeated used of immobilized PLA1 was attractively performed and stable. Accurel is expected to hydrophobic friendly phospholipase carrier progressing toward higher reaction rete and high yield in repeated use.

Economic optimization of ethanol production from corn stover

Victor Grisales[1], Mark J. Willis[2]

1 Universidad Libre Seccional Pereira, Facultad Ciencias de la Salud. Grupo de investigación en Microbiología y Biotecnología MICROBIOTEC, Belmonte Avenida Las Américas; 2 School of Engineering, Newcastle University, NE1 7RU, Newcastle upon Tyne, United Kingdom

**Corresponding author: victorh.grisalesd@unilibre.edu.co*

Highlights

- A kinetic model for ethanol production including acetic acid inhibition is proposed.
- The kinetic model is used to study the economic potential of ethanol production.
- Energy needs in the purification are reduced by 17-23% using de-acetylation.
- The minimum ethanol selling price achieved was 1.83-2.25 USD/gal.

1. Introduction

Ethanol production using corn stover requires physical and/or chemical pretreatment before fermentation. The pretreatment methods that achieve the highest final ethanol concentration (65-90 g/l) have been reported by [1] where, as a precursor to physical pretreatment (mechanical refining), de-acetylation is proposed. As acetic acid is a known inhibitor, its effective removal can increase fermentation performance. After pretreatment, cellulose is partially converted to glucose by enzymatic hydrolysis. Unfortunately, the inhibition of soluble sugars during enzymatic hydrolysis reduces the conversion rate of cellulose to glucose. In addition, it is known that secondary carbon sources (e.g. xylose) are not effectively utilised during fermentation.

The aim of this work is to study the economic potential (EP) of ethanol production from corn stover using a conventional fed-batch reactor with a partial enzymatic hydrolysis step followed by simultaneous fermentation and co-saccharification (SFCS). SFCS offers an interesting means to reduce glucose and xylose inhibition during enzymatic hydrolysis. Two pretreatment strategies are considered; mechanical refining and a de-acetylation step followed by mechanical refining. As ethanol purification is energy intensive, a highly-energy efficient distillation system is also proposed: extractive distillation with vapor compression (ED-VC), as the purification method, as this is known to reduce the energy requirements when compared to a conventional purification system by 55% [2].

2. Methods

A kinetic model describing ethanol production using enzymatic hydrolysis and fermentation under atmospheric conditions is developed. This is based upon previously reported work that considered butanol production [3]. The model is validated using experimental data obtained from batch and continuous fermentations reported by [4,5,6]. The kinetic model includes acetic acid inhibition, preferential consumption of glucose over xylose and xylitol inhibition.

The model is used as the basis for the assessment of the EP of the process where hydrolysis and fermentation operating conditions are optimized in order to achieve the maximum EP. The EP cost

function incudes the capital and expenditure costs of pre-treatment, hydrolysis, fermentation and the distillation systems. A number of optimization scenarios are considered to include all possible ranges of concentrations of non-soluble solids, insoluble solids, glucan, xylan, acetyls, and lignin reported for corn stover by [7]. It is assumed that the corn-stover capacity is 2000 ton/day on a dry basis. The distillation costs and energy requirements are calculated using Aspen Plus V9®.

3. Results and discussion

The proposed kinetic model achieves an average correlation coefficient of 0.995. A typical result is shown in Figure 1a where it may be observed that the model accurately follows the measured experimental data. Through optimisation of the process operating conditions, using the kinetic model as a basis, we have found that the de-acetylation step reduces the energy requirements of ED-VC by 17 - 22.6% (see Figure 1b) which, in turn, reduces the minimum ethanol selling price (MESP) by 10 - 13%.

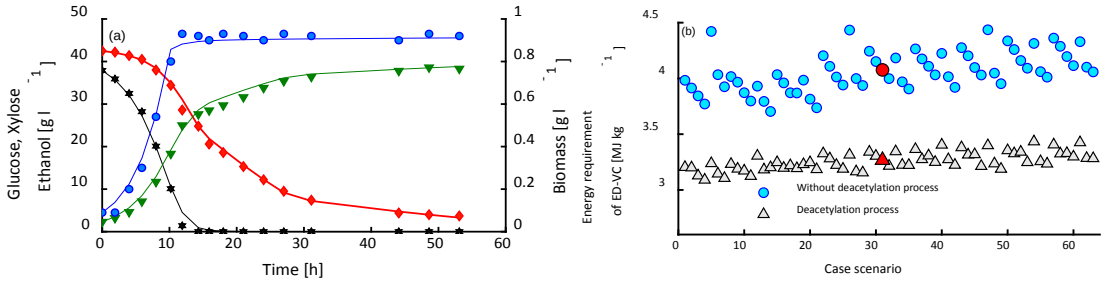

Figure 1. Profiles of the fermentation (initial concentration of acetate of 8 g/l) and energy requirements of ED-VC under optimal conditions. To the left (Figure 1 a) Data points are experimental data: glucose (stars), xylose (diamonds), ethanol (triangle) and biomass (circle). Experimental data was reported by [5]. Continuous lines represent the simulation predictions. To the right (Figure 1b) Fuel requirements of ED-VC. In Figure 1 b the red points represent the base case scenario reported by [7]

4. Conclusions

We have developed a kinetic model that describes ethanol production from corn-stover. The full paper will provide a more detailed account of the kinetic model, however, our results indicate that the inclusion of acetic acid (and the modelling of acetic acid inhibition during fermentation) is required as this significantly affects the EP of the process. Further details of the EP cost function and assumptions made to perform the optimisation will also be provided. In summary, our analysis indicates that the energy needs for ED-VC recovery are between 3.1 and 3.4 MJ fuel/kg ethanol (a reduction of 17 - 22.6% when de-acetylation is not considered) resulting in a minimum ethanol selling price of 1.83-2.25 USD/gal (a reduction of 10 - 13%).

Highlights

- There are a number of isolated communities in sparsely populated Botswana with no access to electricity; their connection to main grid deemed very uneconomical.
- Only explored alternative has been solar, meanwhile there is a large resource of waste encroacher biomass which can be used.
- Exploring pyrolysis alternative where the bulky thorny bushes are pyrolysed on site to increase energy density before being transported to a slightly modified sterling engine that can be a stand alone power generator or part of a hybrid system
- Thermochemical characterization for acacia undertaken.

1. Introduction

The case of access to electricity for remote areas has always been topical, especially for developing nations where the energy poverty translates to retarded development for such communities. Botswana is one such nation that has scattered, isolated and sparsely populated settlements where the extension of the main grid is uneconomical. Close to about 43% of rural and 25% of urban households in Botswana have no access to electricity {Formatting Citation}. Most attention has been directed at powering remote off-grid communities using renewable sources like solar, which are accessible everywhere; however, not much attention has been paid on emerging renewable sources like 2nd generation biofuels from lignocellulosic waste. Coincidentally, Botswana is home to notorious woody encroacher species that are costing the government and communities millions of dollars annually through depleting pastures and subsequently livestock productivity [1]–[3]. Some of the money is spent in debushing exercises to restore the aesthetic appeal in cities, towns and villages, since these drought resistant coppices spring up everywhere. Meanwhile nations like Namibia have turned the woody encroacher nuisance into value through very profitable renewable energy ventures like charcoal [4]. This feasibility analysis which is focused on alleviating energy poverty in remote settlements explores all the possible power generation alternatives that could use the encroacher biomass, especially after converting it into a crude biofuel (bio-oil). Relatively simple technologies that can be run within such contexts are explored. Carbonization techniques for raw biomass, pyrolysis and simple upgrading of oil, various power generation alternatives and

hybrid options with prevalent renewable energy initiatives are examined and compared. A preliminary economic feasibility check is done.

2. Methods

Since this is mostly a feasibility analysis, the major avenues of ascertaining facts is being done through desktop studies, interviews of remote community leaders and relevant civil society stakeholders. Economic feasibility is being done by comparing with similar plants and checking prices of equipment from vendors. Thermochemical characterization was done using equipment for elemental analysis, thermogravimetry and calorimetry.

3. Results and discussion

The results so far obtained pertain the properties of the biomass encroacher species, *Acacia Tortillis*, which is one of the major encroacher bushes. These characterization results help to map the conditions and resulting products for thermochemical conversion processes.

Table 1. Results from thermochemical characterization

	Ultimate analysis- average of 2 (Thermo scientific flash 2000 CHNS-O analyser)				Proximate analysis (Dry basis)- averages (Thermogravimetric analyser- Leco TGA 701)				**HHV** (MJ/kg) Bomb CAL2K-2
%	C	H	N	O[a]	Ash	FC	VM	MC	
ACACIA	41.47	5.15	1.23	52.15	3.90	19.59	76.51	3.72	17.267
PINEDUST	45.76	5.54	0.039	48.66	0.83	20.00	79.16	65.41	17.568

The moisture and ash contents are within acceptable limits; while the high volatile matter typical for lignocellulosics shows a high potential for bio-oil generation. The relatively higher ash (compared to Pine) in the feedstock will report to the bio-oil affecting its stability although the margin of effect would still need to be determined.

4. Conclusions

The thin stems of most of the shrub encroachers from debushing exercises are not eligible for charcoal production, the method largely used by Namibia to valorize its large waste encroacher inventory. The larger trees from rangelands can be converted into charcoal; however construction of even mini power plants to use solid fuel for combined heat and power generation will not be very cost effective for smaller populations. An autothermal pyrolysis plant, possibly integrated with solar, can be a quick alternative requiring less sophisticated technology and expertise. A modified sterling engine can be used to generate power from the pyrolysis oil.

Highlights

- Two-stage kinetic model constrained by the metabolic network of solventogenic *Clostridia*.
- The model accurately represents the acidogenic phase of the fermentation.
- CO_2 and H_2 predicted with consistent material balance without experimental analysis

1. Introduction

The Acetone-Butanol (AB) fermentation can be characterized as a two-phase process via solventogenic *Clostridia.* In the first phase, growth and acidogenesis occur with the production of acetic and butyric acids. In the second phase, a morphological change is observed. Growth ceases and solventogenesis occurs where the acids are re-assimilated by the organism to form solvents. Throughout the fermentation, hydrogen and carbon dioxide gases are released. Previous kinetic and stoichiometric models for the AB fermentation were relatively simple or were not always consistent in terms of the material balance. Further, several models do not account for the biphasic nature of the *Clostridial* biocatalyst. These models are sufficiently accurate for the modeling of batch fermentations without integrated separation. However, when integrated separation is considered in batch, fed-batch or continuous systems, the previous models do not accurately account for the accumulation of intermediary products and productivities are often inaccurately represented. In this work, we introduce a kinetic two-phase model that is constrained by the metabolic network of the *Clostridial* biocatalyst. This model incorporates the morphological change of the biocatalyst and ensures consistency of the material balance.

2. Methods

C. saccharobutylicum P262 was used in this study. A spore suspension of the organism was maintained in deionized water at 4 °C. The seed inoculum was prepared in reinforced clostridial medium (Merck) and the main culture fermented in tryptone-yeast extract-acetate (TYA) medium [1] with 60 g L^{-1} starting glucose concentration. Anaerobic batch cultures were carried out with stirring at 100 rpm at 34 °C in 120 mL serum bottles with an 80 mL working volume. Samples were periodically withdrawn, and fermentations were performed in triplicate.

The metabolic flux analysis (MFA) was based on the metabolic network for *C. acetobutylicum* [2]. The kinetic model was developed using the assumptions listed by [3] except for temperature at 34

°C and pH being uncontrolled. Calculations were carried out on Scilab v. 6.0.1. using the Nelder-Mead simplex method for non-linear regression and the Runge-Kutta method of numerical integration for solving differential equations.

3. Results and discussion

To test the modeling approach without the complexity of the two-phase model, the MFA was coupled to the kinetics of a butyric acid fermentation with *C.* tyrobutyricum ATCC 25755. This is metabolically identical to the acidogenic phase of AB fermentations. Data taken from Song et al [4] were regressed and the results are graphically displayed in Figure 1.

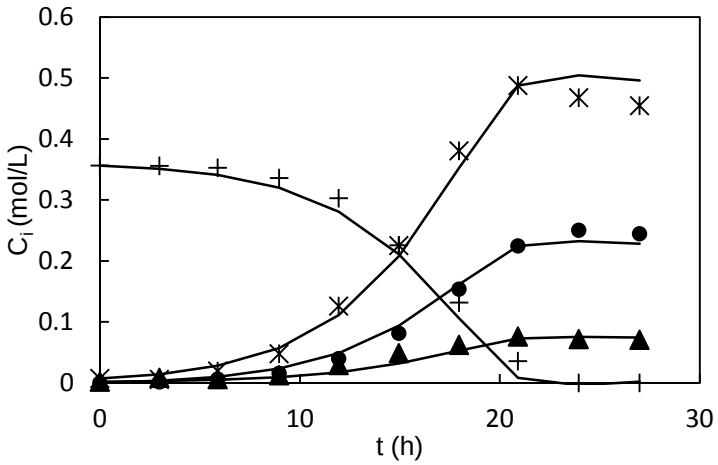

Figure 1. Butyric acid fermentation profile. Raw data taken from Song et al [4]. ✳- biomass (exp), + - glucose (exp), • - butyric acid (exp), ▲- acetic acid (exp). Solids lines indicate predicted concentrations.

By inspection, there is a good fit of the kinetic model to the experimental results. Using MFA, the yields of hydrogen and carbon dioxide were predicted to be 0.02 g $g_{glucose}^{-1}$ and 0.40 g $g_{glucose}^{-1}$ respectively. These results allow for a fundamentally more accurate representation of the fermentation kinetics and material balance.

4. Conclusions

The integration of a kinetic model with the constraint of the metabolic network of solventogenic *Clostridia* has been demonstrated for the acidogenic phase. This allows for a fundamentally more accurate representation of the fermentation profile and ensures consistency for the material balance. Future work will demonstrate the effectiveness of the model including the solventogenic phase.

Highlights

- Phage-free ssDNA production
- Custom ssDNA sequence for DNA-origami
- Mass production of ssDNA becomes scalable

1. Introduction

Scaffolded-DNA-Origami is a nanotechnology where, upon hybridization of ssDNA strands, predefined nanostructures can fold in a one-pot self-assembling reaction. For every so produced nano-object one long ssDNA-strand (scaffold) and multiple short ssDNA-strands (staples) are needed. Up to now the staples are chemically synthesized oligonucleotides and the scaffold is a variant of the single-stranded DNA-genome of the M13-phage. [1]

M13-phages can be produced in high cell density cultivations in stirred-tank bioreactors by infecting *E. coli* cells during cultivation [2]. The phages can be obtained from the culture-supernatant and their ssDNA genome can be prepared in a few simple steps. However most of the sequence is set to be the genome of the M13-phage and synthesis of the staples is very costly. Thus it would be interesting to be able to biotechnologically produce a custom ssDNA where most of the sequence is free to choose.

This can actually be done using a phagemid, a phage-plasmid-hybrid, which by default contains only the packaging sequence and the ori of the phage. All additional bases in the phagemid can be chosen freely. Phagemid-ssDNA can be produced by infecting *E. coli* cells carrying one phagemid with a helperphage or by double-transformation of *E. coli* with a phagemid together with a helperplasmid [3, 4] The first technique however will yield a mixture of helperphages and phagemid-particles which then leads to a mixture of ssDNA-species. On top helperphages are virions which might remain in the bioreactor even after sterilization, which makes production by contract manufactures impossible. The second technique gives only very poor yields and cells transferred to fresh medium don't produce at all which makes storing of those cells and scale-up even to the liter-scale more or less impossible.

2. Methods

M13 genome was purchased from New England Biolabs and phagemid vectors (pBluescript) where received from Addgene. For construction of plasmids PCR amplicons (from Plasmid and M13 genome) where assembled using Gibson assembly [5]. For all experiments *E. coli* NEB turbo (New England Biolabs) have been used. All cultivations have been performed in minimal medium [6].

Cultivation in shake flasks was held at 37°C and 250 rpm in a wise cube shaker (Witeg). High-cell density cultivations were performed in a 2.5 liter stirred tank bioreactor KLF2000 (Bioengineering) using a fed-batch operating mode. Execution was adopted from Kick et. al. 2015 [2].

3. Results and discussion

As production of artificial ssDNA using a helperplasmid gives very low yields, decoupling of biomass formation and production had to be achieved. For this purpose *E. coli* carrying a helperplasmid were grown to an optical density OD_{600} of 0.4 and afterwards infected with phagemid-particles. This however yielded no measurable new ssDNA product. The result is most likely to be attributed to the presence of M13 protein pIII which as described before [7, 8] mediates a kind of infection resistance.

To prove the assumption in an experiment, pIII was put under the expression control of a repressible promoter. *E. coli* carrying a plasmid with this gene-III-cassette could be infected with M13 phages when gene-III-expression was not induced but could not be infected, when gene-III-expression was induced. Upon this result we moved gene III from the helperplasmid to the phagemid enabling the infection of *E. coli* cells carrying a helperplasmid without gene III by phagemid-particles.

Using this system biomass formation could be separated from ssDNA production where cells only carrying the helperplasmid could also be stored at -80°C without loss of production capability. Also with this system the yield could be increased two-fold in shake flask cultivations. More importantly though, as production with the conventional method is not scalable, this new method makes biomass production at any scale possible. Using a stirred- tank bioreactor at the liter scale in a fed-batch operation mode, we were able to increase volumetric yields about 30-fold compared to the conventional method.

4. Conclusions

By moving M13 gene III from the helperplasmid to the phagemid a system could be established, where *E. coli* cells carrying only a helperplasmid could be grown without producing any phage-like-particles. Upon infection with phagemid-particles these cells started producing new phagemid-particles. Through this temporal decoupling of biomass formation and phagemid-particle production, *E. coli* cells could (i) be transferred to a bioreactor without losing their ability to produce phage-like-partikles and (ii) *E. coli* cells started producing phagemid-particles upon infection with the latter. This resulted in a 20-fold increase of volumetric ssDNA yield.

Use of Genome Scale Models to get New Insights into the Marine Actinomycete genus Salinispora: Metabolic Engineering and its Application in Secondary Metabolite Production

C.A. Contador, V.D. Saucedo, J.A. Asenjo, and B.A. Andrews

Centre for Biotechnology and Bioengineering, CeBiB, University of Chile
Beauchef 851, Santiago, Chile,

**Corresponding author: bandrews@ing.uchile.cl*

Highlights

- Bacteria within the genus *Salinispora* are a well-known source of natural products.
- *Salinispora tropica* is a marine actinomycete that produces diverse secondary metabolites
- The first manually curated genome-scale metabolic model for *Salinispora tropica* was constructed.
- GSMs were constructed for fully sequenced type strains of *S. arenicola*, and *S. pacifica.*

1. Introduction

Bacteria within the order Actinomycetales are a well-known source of natural products such as antibiotics and anticancer agents, and the genus *Salinispora* is no exception. *Salinispora tropica* is a marine actinomycete that produces diverse secondary metabolites, including many that possess pharmaceutical properties such as Salinosporamide A (NPI-0052), a potent anticancer agent, and sporolides, candidates for antiviral compounds. Few manually curated actinomycete reconstructions are currently available despite their important role in drug discovery. Recently, the first manually curated genome-scale metabolic model for *Salinispora tropica* strain CNB-440T was constructed [1]. This model provides a starting point to produce Genome Scale Models (GSMs) of closely related organisms such as other *Salinispora* species. This study is focused on new insights into the metabolism of the three-identified species using constraints-based modeling. GSMs were constructed for fully sequenced type strains of *S. arenicola*, and *S. pacifica*, strains CNH643T and CNR-114T, respectively. We also constructed a Salinispora core model that contains the genes shared by 93 sequenced strains. Functional differences between the developed metabolic networks were identified to have a glimpse into the unique metabolic differences attributable to each *Salinispora* species.

2. Methodology

To create metabolic reconstructions to represent each Salinispora species, the gene sequence from the metabolic model for *Salinispora tropica* CNB-440T was used to identify orthologs. We studied 89 genomes of *Salinispora* strains with high quality draft genomes together with the type

strains. Phylogenetic estimation was carried out using the amino acid sequences of the proteins encoded by the core genes.

3. Results and discussion

The genome-scale metabolic model, *i*CC908 was used to study strain-specific capabilities in defined minimal media and to analize growth capabilities in 41 different minimal growth-supporting environments. These nutrient sources were evaluated experimentally to assess the acuracy of in-silico growth simulations. Here, we update, and expand the scope of the model of *Salinispora tropica* CNB-440T, and GSMs were constructed for two sequenced type strains covering the three-identified species. We also constructed a *Salinispora* core model that contains the genes shared by 93 sequenced strains and a few non-conserved genes associated with essential reactions. The models predicted no auxotrophies for essential amino acids, which was corroborated experimentally using a defined minimal medium (DMM). The Core metabolic content shows that the biosynthesis of specialised metabolites is the less conserved subsystem. Sets of reactions were analyzed to explore the differences between the reconstructions. Unique reactions associated to each GSM were mainly due to genome sequence data except for the ST-CNB440 reconstruction. In this case, additional reactions were added from experimental evidence. This reveals that by reaction content the ST-CNB440 model is different from the other species models. The differences identified in reaction content between models gave rise to different functional predictions of essential nutrient usage by each species in DMM. Furthermore, models were used to evaluate in silico single gene knockouts under DMM and complex medium. Cluster analysis of these results shows that ST-CNB440, and SP-CNR114 models are more similar when considering predicted essential genes.

Also, the GSM of *Salinispora tropica* has been used to define a production medium to improve Salinosporamide A production in a recombinant strain with increases compared to the wild type.

4. Conclusions

This study shows that strain-specific models of *Salinispora* can help to better understand the metabolism of *Salinispora* strains, and gain more knowledge about the physiology of the different species. *Salinispora* models would help researchers to establish links between genetic data and metabolic phenotypes. Additionally, the models developed can be used to systematically analyze the essential growth capabilities of Salinispora metabolism that delineate the adaptation process and enhance the production of specialised metabolites.

Highlights

- Viability of SMC was higher in polyurethanes that have greater PCL content.
- Presence of PCL increased the contact angle of polyurethanes.
- Polyurethanes surfaces showed a hydrophilic behavior.

1. Introduction

Cardiovascular diseases represent the first cause of death worldwide, due to some vascular pathologies such as atherosclerosis, hypertension, thrombosis, angioplasty and restenosis that occur in blood vessels [1]. It is known that those pathologies are related with some disorders in the wall vessel structure like abnormal proliferation of smooth muscle cells (SMC) due to a phenotype change from contractile to synthetic [1,2], that lead a migration and accumulation from the media into the intima [3].

The use of polyurethanes as synthetic materials has gained a lot of attention on the field of tissue engineering, for their production process, versatility and biocompatibility [4], owned by the presence of a segmented chemistry that allow to adjust the mechanical, physical and biological properties by the adjustment of the raw materials [5].

Once the material is immersed in the cellular environment, the processes of adsorption of proteins on the surface of the material allows cell adhesion [6]. The properties of the material surface such as hydrophobicity and chemical composition are important for the biocompatibility of the material and can allow a better performance of the grafts. Thus, the aim of the investigation was to relate the effect of the composition, in terms of the contact angle of polyurethanes and the biocompatibility of smooth muscle cells.

2. Methods

Polyurethanes were synthetized via a two-step polymerization. Polycaprolactone, polyethylene glycol, isophorone diisocyanate and pentaerythritol (crosslinker) were used. Each polyol sample was diluted in 10 mL of DMF at 110 °C, and then IPDI was added at an NCO/OH ratio of 1 and allowed to react for 15 min at 70 °C. PE was added to the prepolymer [7]. Thin films of 150 µm were prepared and cured at 110 °C for 12 h.

Sessile drop method was used to measure contact angle in a MobileDrop (KRÜSS GmbH, Hamburg, Germany) with distilled water at room temperature.

Aortic smooth muscle cells (AoSMCs, Walkersville, Maryland) were cultured and used at passage 6-7. Cell suspension with a density of $1x10^6$ cell/mL were cultured for 12 h. Polyurethane samples

were placed with cells for 24 h (5% CO2 at 37 °C). After, samples were removed and 100 µL of resazurin solution (44 µM) was added and incubated for 4 h. The fluorescent product resorufin was measured with at a wavelength of 590 nm using an excitation wavelength of 560 nm.

3. Results and discussion

Figure 1A shows the results for viability test of SMC in polyurethanes. As it can be seen the viability was higher in polyurethanes that have greater PCL content. PCL is a widely used polymer for biomedical applications as their high biocompatibility [8].

The contact angle values of the surface of PUs are presented in Figure 1B. Contact angels over 90° represent a hydrophobic surface, thereby polyurethanes surfaces showed a hydrophilic behavior, that can be explain by the hydrophilic nature of PEG. The presence of PCL increased the contact angel due to its hydrophobic character [7].

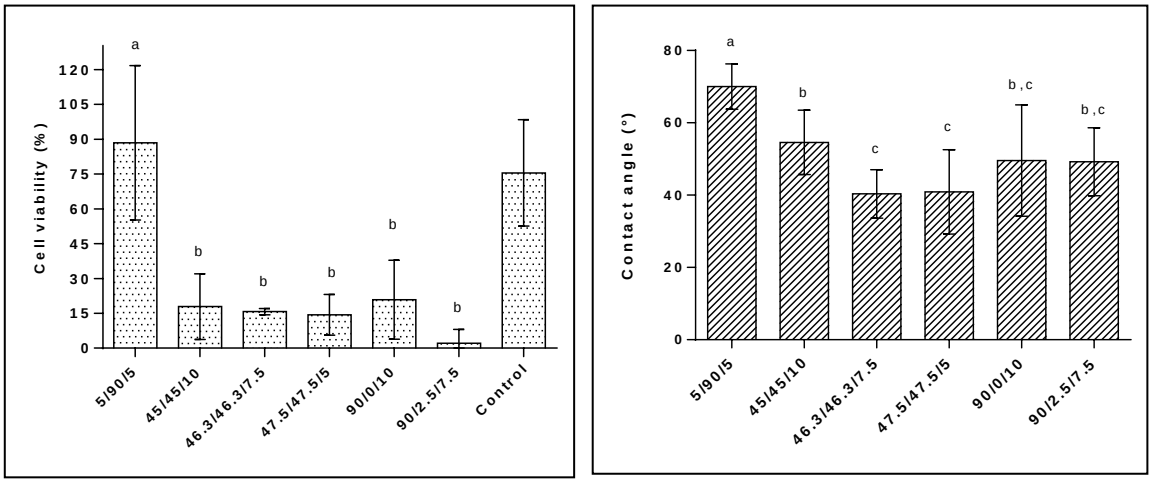

Figure 1. Aortic Smooth Muscle cell viability on polyurethanes (a); Contact angle of polyurethanes surface (b). Polyurethane composition is express as PEG/PCL/PE. Mean (n = 3) ± standard deviation; According to the analyses of variances and Tukey Pairwise Comparisons, means that do not share a letter are significantly different ($p < 0.05$).

4. Conclusions

For AoSMC hydrophobic surfaces allow a better environment for cells. The composition of the material is important for hydrophilicity possibly due to the nature of the polyols (PEG and PCL, hydrophilic and hydrophobic polyols, respectively), which will determine the behavior of the material and subsequently its biocompatibility with smooth muscle cells.

Transfer of the TAPPIR®-Technology to a Packed Bed for Separation of Biomolecules

Fabian Görzgen[1], Gerhard Schembecker[1]

1 Laboratory of Plant and Process Design, TU Dortmund University, 44227 Dortmund, Germany

**Corresponding author: gerhard.schembecker@tu-dortmund.de*

Highlights

- Semi continuous aqueous two-phase extraction
- Packed bed application of the TAPPIR®-Technology in a column
- Impregnation stability of porous particles in incident flow

1. Introduction

Since gentle and cost efficient separation techniques for biochemical products are of major interest for the biotech-industry, Aqueous Two-Phase Extraction (ATPE) has been shown to be a promising approach in this regard [1]. This is mainly based on the high biocompatibility of ATPE resulting from the water content of up to 70-90 wt.-%. However, long phase separation times in “conventional” ATPE design (Mixer-Settler-Approach) are the major drawback of this technique, requiring additional equipment and energy to enable faster phase separation [2]. To circumvent this bottleneck, the Tunable Aqueous Polymer Phase Impregnated Resins (TAPPIR®)-Technology is applied. As one phase of the Aqueous Two-Phase System (ATPS) is immobilized in porous particles enabling extraction through dispersion of these particles in the other aqueous phase, a subsequent liquid-liquid separation is no longer necessary. The impregnation stability [3] and competitive mass transfer kinetics of biomolecules within the TAPPIR®-Technology compared to “conventional” ATPE were already proven in batch experiments. In order to implement this technique in an industrial process, in this work the TAPPIR®-Technology is transferred to a column enabling a semi continuous flow-through separation of biomolecules in a packed bed. Consequently, one aqueous phase is used as the mobile phase, whereas the other aqueous phase is stationary impregnated in the particles providing an easy and cost efficient separation process. Within this work, we focused on the impregnation stability of the stationary phase in porous particles in flow through operation as well as the extraction performance in the packed bed.

2. Methods

A polyethylene glycol - tri-sodium citrate (polymer-salt) ATPS was used in this work. If applicable, sodium chloride was utilized as displacement agent. After preparation, the ATPS is equilibrated and transferred to a dropping funnel for settling. Immunoglobulin G serves as a model biomolecule within this work and is introduced into the system using the salt-rich phase of the APTS. Polymer-rich phase impregnated micro porous ceramic particles are packed in a semi-preparative YMC ECOPlus glass column. An ÄKTApurifier from GE Healthcare is used as utility to ensure stable process conditions. The impregnation status can either be determined by adding a dye to the stationary

phase or the retention time of Bovine serum albumin, introduced as a tracer that partitions selectively to the salt-rich phase. An UV detector is used for the analysis of the biomolecule concentrations.

3. Results and discussion

In order to transfer the TAPPIR®-Technology to a semi continuous operation mode in a packed bed column, several factors need to be evaluated: (1) impregnation stability of the stationary phase, (2) uniform flow within the packed bed, (3) extraction performance comprising the kinetics in continuous flow. The impregnation stability in batch experiments of the polymer-rich phase in porous ceramic particles showed negligible leaching as soon as the three-phase contact angle (measured from the polymer-rich phase on solid material in salt-rich phase) showed values < 90 °. However, upon transfer to a column, in which the impregnated particles have to withstand a steady incident flow, several factors influence stability not encountered in batch mode. It is shown that a uniform packing induces slower leaching rates. Also, packed beds formed by larger particles have a higher impregnation stability than those with smaller particles of the same material. Moderate flowrates (e.g. 1 ml/min in a column with a diameter of 1 cm) additionally lower the leaching of the impregnated phase out of the pores. Changing the ATPS composition itself (e.g. using polyethylene glycol with a higher molecular weight), a stable impregnation in steady flow could be achieved for more than 48 hours. This now allows for further characterization of the new setup towards process parameters that enable an optimal extraction efficiency.

4. Conclusions

Within this work, it was shown that the transfer of the TAPPIR®-Technology to a packed bed in a column was possible enabling a semi continuous two-phase extraction. Thereby, additional downstream treatment of the emulsion compared to classical ATPE was avoided. In the packed bed application, factors influencing the impregnation stability of the polymer-rich phase in the porous particles were identified allowing to apply optimal process conditions in semi continuous mode. The extraction performance was competitive to conventional ATPE and can be optimized further by adjusting design and process parameters. It was shown that the TAPPIR®-Technology in a column offers an improved approach for the implementation of ATPE as a separation technique for biomolecules.

1. Introduction

In order to remove excess acetic acid (HAc) from the reaction product between Nile Tilapia skin and said reagent, a laboratory scale distillation process was carried out by means of a rotary evaporator. Due to the stability of the collagen at low pressures, only the H2O / HAc mixture was evaluated in the distillation process. Given this premise, the Antoine equation was used to know in which pressure the Water and the Acetic Acid would present the vapor state and the operating pressure of the process.

$$\ln P^{sat}(kPa) = A - \frac{B}{T(°C) + C}$$

Where A, B and C are the Antoine parameters which are tabulated and, T the temperature operating in degrees Celsius (ºC).
For plotting the H2O / HAc equilibrium curve, the fundamental equation of Raoult's Law (equation 2.2) was used. For the fractions of the substance and the total pressure of the system (eq. 2.3)

$$y_i P = x_i P^{sat} \quad \text{(eq. 2.2)}$$

$$P = \sum_i x_i P_i^{sat} \quad \text{(eq. 2.3)}$$

Onde:
y_i: vapor fraction of substance *i*;
x_i: Fraction of liquid from the substance*i*;
P: Operating pressure;
P^{sat}: Saturation pressure of substance i

2. Methods

2.2. Collagen Extraction by Acid-Base Method

The extraction were used 100g fish skin, where the methodology was developed from the technique described by Monteiro and Gómez-Guillén. Skin samples were treated using three different solutions, NaCl solution (0.8M) to remove excess water in the skin, and some surface proteins, a solution of NaOH (0.1M) for partial removal of fat in the skin and other impurities, and

finally, a solution of acetic acid (0.05M) for the process of decoupling or breaking of the tissue chain which is also composed of collagen resulting in the hydrolyzed extract.

3. Results and discussion

To determine the operating pressure was used eq. 2.1 for both Water and Acetic Acid (Table 1).

Antoine Parameters				
Acetic Acid		water		Temperature (°C)
A	15,0717	**A**	16,3872	25
B	3580,8	**B**	3885,7	
C	224,65	**C**	230,17	
	kPa	**atm**	**mbar**	
P^{sat}_{H2O}	3,187741617	0,031460564	31,877416175	
P^{sat}_{HAc}	2,071803341	0,020447109	20,718033408	

Table 1: Antoine parameters the HAc e H_2O to determine the saturation pressure in 25ºC
Source: Van Ness, 2007

For better understanding the system pressure, equations 2.2 and 2.3 were used in the range of the molar fractions and the saturation pressures of the substances analyzed in order to plot the liquid vapor equilibrium curves of said reagents (Figure 1).

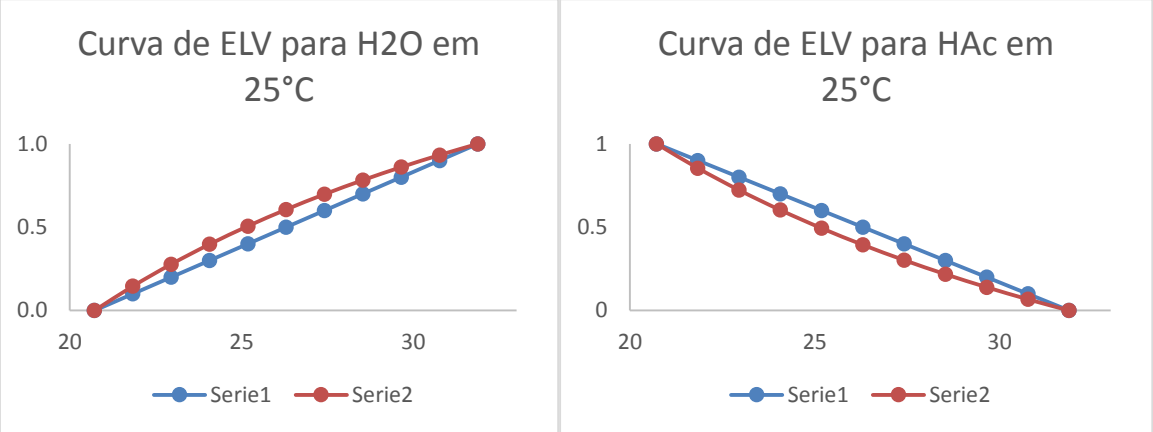

Figure 1: (a) Liquid-Steam Balance for Water at 25ºC (b) Liquid-Steam Balance for Acetic Acid at 25ºC

The region below the blue curve is the region where the water is in the superheated vapor state, while in the region above the orange curve it indicates the state of the subcooling liquid. The region below the blue curve is the region where the Acetic Acid is in the superheated vapor state, while in the region above the orange curve indicates the state of the subcooling liquid.

4. Conclusions

Since the reaction is in equilibrium, the displacement has formed for the reactants, thus generating more associated acetic acid, thus facilitating distillation the hydrolyzate without excess acid.

Hydrogen peroxide (H_2O_2) production is estimated at 4.7 Mton annually by 2017. It is used in various applications such as paper and pulp bleaching, textile bleaching, production of chemicals and environmental applications. Currently, it is industrially produced via the anthraquinone autoxidation process. However, we have shown that with our electrolyser approach (see Figure 1) ~10% H_2O_2 can be produced. This is sufficient for most applications (~75%), except for the production of chemicals which typically requires much higher H_2O_2 concentrations. Electrochemical production of H_2O_2 does not require any chemicals, and allows decentralized in-situ production, which reduces the need for its handling, transport and storage. Our latest research focused on reducing the production costs by increasing space-time yield of hydrogen peroxide and decreasing the electricity usage. Using more concentrated electrolytes, alternative anion exchange membranes, and a better electrolyser design, we were able to decrease the cell voltage considerably (see Figure 2). The electricity consumption could be reduced below 7 kWh/kg H_2O_2 at the industrial relevant current density of 4 kA/m^2.

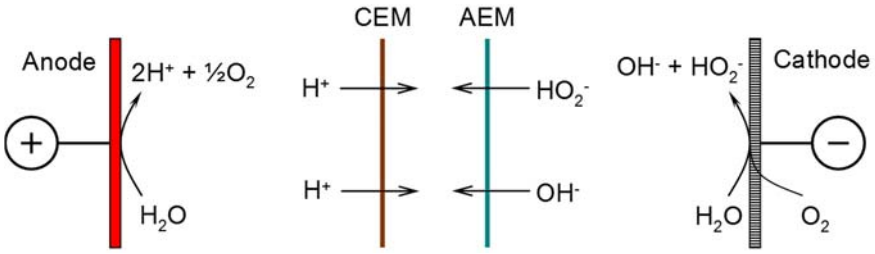

Figure 1: Schematic representation of the H_2O_2 electrolyser configuration.

Highlights

- Electro-Fenton is a facile, low cost, environmentally-friendly route to crosslink PVP
- Semi-dilute PVP, 0.5-1.0 mmol dm^{-3} Fe^{2+}, low j and short t: R_h < 10 nm (intramolecular crosslinking)
- Longer t and higher PVP and Fe^{2+} contents: M_w increases (intermolecular crosslinking)

1. Introduction

In recent years, increasing attention has been paid to the development of nanogels as nanocarriers for biomedical and bioengineering applications [1], being very useful in key tasks such as anti-cancer treatments [2]. Methods like gamma-ray irradiation or pulse radiolysis, which are based on the generation of free radicals that favour the formation of active centers on the polymer, have been previously investigated to promote the inter and/or intramolecular recombination that causes crosslinking. In a recent investigation, we have reported a certainly promising, innovative and simple electrochemical methodology to generate hydroxyl radicals that trigger the formation of chemically crosslinked nanogels [3]. Poly(vinylpirrolidone) (PVP) is a polymer with high versatility since non-charged PVP shows a high hydrophilicity and biocompatibility, absence of toxicity and adequacy to form interpolymer complexes [4]. In the present work, we have focused the attention on the homogeneous electrogeneration of hydroxyl radicals by electro-Fenton (EF) process in order to modify poly(vinylpyrrolidone) (PVP) in aqueous solutions [3,5].

2. Methods

PVP k-60 (M_r = 1.60×10^5 g mol^{-1}, M_w = 3.95×10^5 g mol^{-1}, 45 wt.% solution) was purchased from Aldrich and used as received. Oxygen (99.999% purity) and nitrogen (99.998% purity) were supplied by Air Liquide. All other chemicals used were from Sigma-Aldrich or Fluka and used as received.

Before each experiment, fresh PVP aqueous solutions were prepared using double-distilled water and stirred overnight, filtered with 0.22 µm nylon filters under vacuum. An undivided thermostated glass cell equipped with a water jacket was used for the electrosynthesis of nanogels. The cell contained 50 cm^3 of PVP solution at a given concentration with 0.05 M Na_2SO_4 in the presence of $FeSO_4$ as catalyst at pH 2.8 under continuous stirring. A carbon-polytetrafluorethylene (PTFE) air-diffusion electrode was used as the cathode to electrogenerate H_2O_2, whereas a Ti/IrO_2–Ta_2O_5 (DSA®) plate was used as anode. The geometric surface area of all electrodes in contact with PVP solution was 3 cm^2. The cathode was fed with pressurized O_2 for H_2O_2 generation. An Amel 2053 potentiostat/galvanostat was employed to operate at constant current.

3. Results and discussion

The main operation parameters such as polymer concentration, reaction time, catalyst (Fe^{2+}) concentration and charge passed (Q) were investigated. The dimensions of the nanogel formed, in terms of hydrodynamic radius (R_h) and weight-average molecular weight (M_w), have been evaluated via dynamic and static light scattering and gel permeation chromatography (GPC) analyses. In all cases, an important reduction of the size of PVP particles was achieved, along with narrower GPC peaks. Chain scission and intra-molecular recombination events were promoted at lower PVP concentration (< 0.50 wt.%) and for the low electrolysis times, leading to a reduction of R_h from 28 to 8-9 nm at catalyst concentration of 0.5-1.0 mM, while intermolecular crosslinking also concurred at longer times. Beside the electrolysis time, catalyst concentration and current density, j, are two other tunable parameters that can shift the balance between chain scission and crosslinking reactions. FT-IR analyses confirmed the functionalization of PVP nanogels, which become suitable for further conjugation reactions with biologically relevant molecules.

4. Conclusions

We found that EF can be adopted to crosslink PVP thus offering a cheap, eco-friendly, simple and fast alternative to current technologies. The adoption of proper balance of operation conditions is crucial for tuning up the main features of the resulting PVP nanogel in terms of particle size, mass and functionalization, which are modulated by the rate of generation of $^{\bullet}OH$ obtained from in situ electrogenerated H_2O_2.

Electrochemical microfluidic reactors combined with nanofiltration for wastewater treatment – kinetics and modeling studies

Emmanuel Mousset[1*], M. Faidzul Hakim M. Adnan[1], Marta Puce[1], Marie-Noëlle Pons[1]

1 Laboratoire Réactions et Génie des Procédés, Université de Lorraine, CNRS, LRGP, F-54000 Nancy, France

**Corresponding author: emmanuel.mousset@univ-lorraine.fr*

Highlights

- Firs time combination between nanofiltration and micro-reactors for MWWTPs
- Optimal interelectrode gap related to maximal mass transfer
- Non-linear increase of decay rate constants with electrolyte concentration
- Increase of faradic yield with the number of nanofiltration cycles

1. Introduction

The continuous increase of water demand along with the raise of water scarcity due to climate change make water a very precious resource all over the world. To face this issue, it is considered to reuse treated wastewater within the same process or for a secondary purpose such as irrigation and even drinking water. In the aim at succeeding in the water reuse perspective, there are several scientific and technological obstacles to overcome. Numerous studies highlighted the presence of hazardous organic micropollutants (pesticides, pharmaceuticals residues, personal care products,…) in the water bodies at trace levels (from pg/L to µg/L), at the outlet of municipal wastewater treatment plants (MWWTPs). In this context, advanced physico-chemical treatments have been developed. Advanced oxidation technologies produce reactive radicals (e.g. hydroxyl radicals) [1]. Compared to chemical technologies that require the addition of chemicals, emerging electrochemical advanced oxidation processes (EAOPs) implement a clean reagent (e.g. electron) that allows producing *in situ* and continuously the oxidizing species, leading to higher removal yields [2]. Furthermore, the application of microfluidic reactor within the framework of EAOPs has spurred the capability of wastewater treatment. The average ionic conductivity of effluent of MWWTPs (~1 mS cm^{-1}) is apparently too low for conventional macroreactor of EAOPs in–which the distance between electrodes is in the range of 1-4 cm [3]. Hence, supporting electrolyte reagent is very often added to compensate the low value of conductivity as to avoid huge ohmic drop in-between electrodes. In parallel, membrane filtration has been widely applied to produce clean water. It does not require the addition of chemicals and its efficiency has been well established. However, membrane is technically a filter. It is prone to fouling and concentrated effluent containing organics and very likely toxic compounds are separated in the retentate stream that need to be disposed then.

Thus, in this research work, synergy between nanofiltration and EAOPs is investigated. To date, the application of EAOPs to treat the concentrate of membrane separation techniques has already been reported in literature. However, no report has been found on the coupling of nanofiltration with microfluidic reactor moreover to treat the effluent of MWWTPs. As prevalently acknowledged, the

efficiency of degradation of organics by EAOPs depends on various parameters and they behave differently in microfluidic reactors relatively to the macros. Therefore, throughout this study, the influence of different initial concentration of pollutant, inorganic matrix, applied current density, interelectrode distance and flow rate is particularly investigated. Experimental results of degradation and mineralization of representative pharmaceutics are accompanied with mathematical modelling taking into consideration the enhancement of mass transfer of organics, of kinetic of the redox reactions at electrodes and of flow behavior with microfluidic reactor.

2. Methods

A flow-by cell was used in a batch recirculated mode. The cathode was a piece of graphite felt or stainless steel while the anode was in stainless steel or a BDD coated on Niobium. The cathodes and anodes had the same geometric surface area of 50 cm^2. The interelectrode gap was varied using polytetrafluoroethylene (PTFE) spacers of different thicknesses. The current intensity was applied using a power supply. When synthetic solution was used, representative inorganic salts (Ca^{2+}, Mg^{2+}, Na^+, K^+, NH_4^+, NO_3^-, PO_4^{3-}) where added at concentrations similar to those found at outlet of MWWTPs. Real MWWTPs effluent were also used for comparison. The nanofiltration cell was a stainless steel cross-flow filtration unit using polyamide thin film (6.0 × 7.5 cm^2) NF 90 membrane. The applied transmembrane pressure was varied from 3 to 15 bars.

3. Results and discussion

Varying the inter-electrode distance from 50 to 1000 µm highlight the existence of an optimal mass transfer coefficient at 500 µm (Figure 1a). At too short gap, the gas bubbles increase the mass transfer limitation. Interestingly, increasing the electrolyte concentration make increase non-linearly the acetaminophen decay rate constants (Figure 1b).

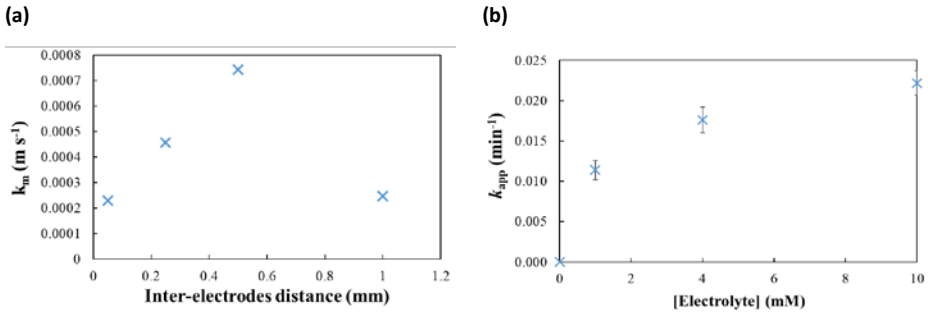

Figure 1. influence of inter-electrode distance on mass transfer (a) and electrolyte concentration on paracetamol decay rate constant (b).

4. Conclusions

The possibility of performing electrolysis at 1 mS cm^{-1} – the average conductivity in municipal WWTP outlets – could be considered in microfluidic reactors. Further results will be presented on the synergy between nanofiltration and electrochemical micro-reactor, i.e. relation between faradic yield and concentration factors.

Highlights

- 2,4-D can be removed by indirect electrochemical oxidation using persulfate.
- Above 20 °C the decomposition of persulfate occurs during its electrosynthesis.
- The current efficiency decreases from 96 % to 52 % increasing j from 5 to 100 mA cm^{-2}.
- 2,4-D disappearance follows a first-order reaction with a constant rate of 0.22 min^{-1}.

1. Introduction

The use of pesticides and their release into the natural environment constitutes a direct threat for the environment and the living beings especially the human health. Consequently, the development of technics to detoxify the pesticide residues to reduce at least areas and contaminated matrix is needed. Electrochemical oxidation using a boron-doped diamond (BDD) anode allows mineralizing various organics such as pesticides. However, in the case of organochlorides, the reaction with •OH may generate undesired toxic intermediates in the form of organochlorides. Costanza et al. [1] have shown that the reaction of tetrachloroethylene with sodium persulfate at 50°C leads to a complete dechlorination, without production of organochorides.

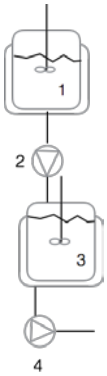
The approach chosen in this study, in view of treating obsolete pesticides solutions with low concentrations of biorefractory organic species, is to combine the following steps:

(i) the electrochemical production of peroxodisulfates using a BDD anode at low temperature and (ii) peroxodisulfate is injected into the preheated solution containing the target organic compound, the 2,4-Dichlorophenoxyacetic acid (2,4-D), for activation and reaction.

2. Methods

(i) Electrochemical reactor for electrosynthesis: The oxidation of sulfuric acid was performed in a two-compartment electrolytic flow cell under galvanostatic conditions [2]. The electrosynthesis was stopped after reaching a conversion rate of sulphate of 25 % corresponding to a persulfate concentration of 0.2 M.

(ii) Reactor for the coupling processes:



The treated solution containing the target compound, the 2,4-D at 0.45 mM, was stored in a thermostated, stirred tank(1) at 60 °C. The solution was pumped into a continuous thermostated, stirred tank reactor of 100 mL (2) at 60 °C, which initially contained the oxidizing solution, electrosynthesized persulfate. Various flow rates of 2,4-D solution were tested in the range of 1.66-50 mL min^{-1}. The corresponding range of residence time for a 100 mL tank reactor is 2-60 min. A pumping device (4) placed at the outlet of the reactor (3) is used to keep the volume constant in the chemical reactor. The system working as a continuously stirred tank reactor (CSTR) at steady state under isothermal condition.

Fig.1 Set-up used for the disappearance of 2,4-D by reaction with the electrogenerated peroxodisulfate**.** (1) Thermostated, stirred tank containing a 2,4-D solution; (2) pump; (3) Thermostated, stirred tank containing the electrosynthesized persulfate; (4) pump

3. Results and discussion

(i) Electrosynthesis of persulfate:

The electrosynthesis of persulfate was performed under various current densities, from 5 to 100 mA cm^{-2}. It appears that after 180 min of electrolysis the current efficiency ranges from 98% to 48.5% for 5 to 100 mA cm^{-2}. To explain this decreasing faradaic efficiency with the increasing current densities, different hypotheses were established. The most likely explanation is the decomposition of persulfate caused by an increasing temperature.

(ii) Degradation of 2,4-D by electrogenerated radical sulfates:

A first series of experiments were performed to study the effect of the residence time of 2,4-D in the chemical reactor on its disappearance. For a residence time of more than 10 min, the 2,4-D disappearance rate reaches more than 70 %. In parallel, the shape of the TOC disappearance correlates well with that of the target molecule 2,4-D. In addition, one can observe that a disappearance of 84% of 2,4-D corresponds to 54% of TOC removal. Unlike the reaction with hydroxyl radicals, this result shows that the reaction of the target molecule with sulfate radicals leads to the formation of intermediates.

4. Conclusions

Throughout this study, it has been shown that the complete disappearance of 2,4-D is possible by indirect electrochemical oxidation. This process uses the electrosynthesis of persulfate from a 2M sulfuric acid solution. The persulfate is then thermally-activated to produce sulfate radicals, which are strong and selective oxidants. These radicals react with the target molecule. The efficiency of this process depends on both of the following operating conditions:

- When the applied current density is too high, 100 mA cm^{-2} for a 2 M of sulfuric acid, secondary reactions occur.
- The complete disappearance of 2,4-D can be reached if the contact time with sulfate radicals is sufficient; the 2,4-D concentration profile follows a first-order reaction with an estimated constant rate of 0.22 min^{-1} under our operating conditions. The feasibility of the process has been demonstrated.

Highlights

- The large scale electrocoagulation unit was operated on site - plant for energetic use of wastes.
- The technology showed solution for industrial effluent (removal of Zn, Pb, Cd).
- Removal of contaminants was successful reaching removal efficiencies above 90 %.

1. Introduction

Electrocoagulation is a water treatment method which can be used for removal of a wide range of contaminants, especially dissolved metallic ions via (co)precipitation processes. The method is an alternative method to standard chemical coagulation, which is one of the most common water and wastewater treatment processes. Whilst chemical coagulation is one of the commonly used procedure in industry, where soluble salts of Al or Fe are used (e.g. $Al_2(SO_4)_3$ and $FeCl_3$), in electrocoagulation (EC) precipitating agent (e.g. Al^{3+}, Fe^{3+}) is generated by corrosion of metallic electrodes made of aluminum or steel. The use of electrodes as a source of Fe or Al ions to solution, effectively replaces chemical dosing stations with more compact electrochemical reactors.

2. Methods

The process was tested in pilot-scale unit placed in movable container and operated in continuous regime on site - plant for energetic use of wastes. Two types of process effluent streams were tested:

- Process water at pH 8.4
- Water focused on Zn reduction

3. Results and discussion

Process water at pH 8.4 was tested with different regimes of pretreatment:

- No pH adjustment
- pH adjustment with addition of $Ca(OH)_2$
- pH adjustment with Na_2S

The EC cell was operated with flow rate 350-400 l/h with current input 60 A, providing 150-180 mg/l Fe according to Faraday's law, established voltage oscillated between 1.2 and 3.5 V depending on electrode surface passivation.

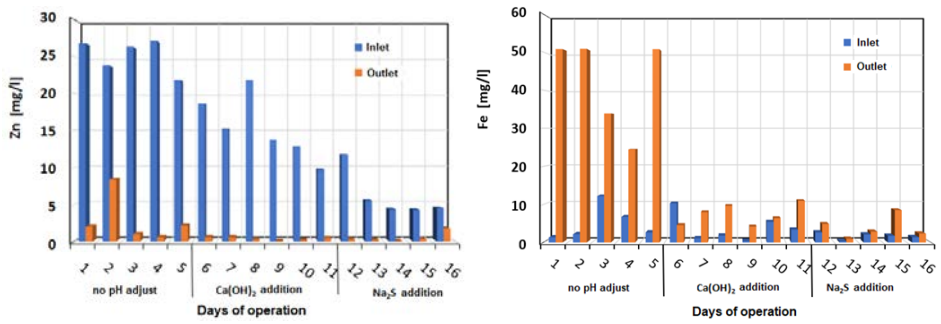

Figure 1. Concentration of Zn (left) and residual Fe (right) during operation with various ways of pretreatment

Figure 1 describes results of Zn concentration before and after treatment by EC with corresponding pretreatment. It is obvious that removal efficiency of Zn in most of the case exceeded 90 % and thus it can be claimed that pH adjustment for Zn removal is not of a significant benefit. Also, other contaminants like Pb or Zn were followed (not plotted). In case of Pb, removal efficiencies were not significantly influenced by pH adjustment while in case of Cd, addition of Na_2S significantly enhanced its removal. That's due to formation of water insoluble CdS. In case of residual Fe, the situation is different. Here, pH adjustment significantly reduces residual concentration of Fe in treated water. The energy consumption during operation was also monitored.

4. Conclusions

The results have shown that the removal efficacies of Zn are satisfactory high and in most of the cases exceeded 90 %. In case of Zn, pH adjustment was not of significant benefit. It is also very reliant on contaminant content in treated effluent. It was verified that electrocoagulation has a great potential in contaminant removal from industrial effluent. The energy consumption was determined to be 0.75-1.1 kWh/m^3 of treated water.

Highlights

- Three miniature microbial fuel cells with 3D anode are proposed
- The cells are characterized for hydrodynamics and mass transfer
- The performances of the cells for bioelectricity generation are assessed
- A versatile mathematical model of the system has been implemented

1. Introduction

Bioelectrochemical systems, such as MFCs exploit the direct transfer of electrons during oxidation of organic compounds by electroactive microorganisms. Very low values of current density are usually obtained with such devices, so that anodes with high specific surface should be used to increase the electricity generation. Carbon felt, and other carbon-based 3D materials with high surface per unit of volume are largely adopted as anodes in MFCs, although may show significant lack in efficiency due to mass transfer limitations, concentration gradients, velocity distribution and resistivity of the material. [1,2]. Several factors should be then considered in a suitable design of the MFCs with 3D anode.

In this work, the effect of aspect ratio and hydrodynamics on the performance of miniature MFCs with carbon felt anodes was studied. The cells were experimentally characterized for hydrodynamics and mass transfer, as well as for bioelectrochemical activity towards oxidation of acetate.

A mathematical model of the cells was then used to quantify the effect of operative parameters on the bioelectrochemical processes under steady state conditions.

2. Methods

Air-cathode single-cell MFCs were used: the anode compartments have a cross section of 5X5 mm and lengths from 30 to 50 mm. The cells operate in flow-through single-pass mode. Hydrodynamics of the anode compartments was characterized with pulse-response experiments with inert tracer, the mass transfer was characterized by limiting current densities with the standard redox ferricyanide/ferrocyanide couple. The enrichment of electroactive biofilm was performed by

feeding the fuel cells with anaerobic sludge, after enrichment the cells were fed with a synthetic waste water [2].

All the electrochemical tests were performed with a potentiostat-galvanostat (Autolab).

A mathematical model was implemented, which combines fluid flow (Navier-Stokes equations for incompressible fluids in free and porous media), kinetics of electrochemical and bioelectrochemical reactions, chemical equilibria and Ohm's law with conservation of current.

3. Results and discussion

Pulse-response curves show that the system is under non-ideal flow conditions and behave as a plug-flow reactor with axial dispersion.

The steady-state current response with different organic load in the feed stream and inlet flow rates was tested: the curves obtained show a Monod-type behavior, substrate inhibition was also observed, depending on length of the anode and organic load.

Polarisation tests show the presence of significant mass transfer limitations, mainly with low concentration of acetate in the feed.

The model solution provided distribution of velocity, current and potential, and concentration of substrate within the anode chamber. The predicted flow is laminar, as it was expected with the low flow rates used. The concentration profiles show the consumption within the porous anode: depending on organic load in the feed stream, low concentrations of substrate were predicted, which can lead to local starvation. The mass transfer limitations observed from the polarisation studies can be related mainly to concentration gradients in axial direction.

4. Conclusions

The effect of design and operative parameters in the performance of flow-through microbial fuel cells with three-dimensional anodes was investigated. A mathematical model was implemented, which was used to understand and predict the effect of flow rate and organic load of the inlet flow on conversion, potential distribution and electricity production of the cell.

Highlights

- Stable alkaline polymer electrolyte developed.
- Design of the laboratory electrolysis stack utilizing polymer electrolyte reported.
- Experimental stack results used to validate mathematical model of the stack.
- Simplified mathematical model of the stack validated.

1. Introduction

Water electrolysis represents a key component of the hydrogen economy concept allowing high capacity and long-term energy storage. It is based on decomposing water molecule into the gaseous hydrogen and oxygen by passing the direct current (DC). Alkaline water electrolysis (AWE) represents most technologically established route of this process. If suitable polymer electrolyte is available (membrane as well as the catalytic layer binder), AWE cell design and operational parameters resembling the PEM water electrolysis can be used. It concerns especially zero gap cell arrangement. At the same time, the advantage of the utilization of the non-PGM catalyst is preserved [1]. This makes alkaline polymer electrolyte water electrolysis (APEWE) highly attractive option. The topic of this study is to report on design of the laboratory APEWE cells stack based on novel alkaline polymer electrolyte developed in our laboratory.

2. Methods

Materials used

Both anodes and cathodes of the stack cells were of identical construction. They were made of nickel foam (INCO Advanced, Technology Materials, (Dalian) Co., Ltd, USA), size 5 × 5 cm^2. Bare, non-activated electrodes were used. Nickel foams served at the same time as a flow field.

Two different anion selective polymer electrolyte membranes were tested as an electrode compartments separator:

- commercial heterogeneous anion selective membrane Ralex® (Mega, Czech Republic)
- experimental polymer electrolyte membrane based on Polystyrene-block-poly(ethylene-ran-butylene)-block-polystyrene (PSEBS) activated by 1,4-diazabicyclo[2.2.2]octane (DABCO) serving as a functional group [2].

Experimental procedures

Stack load curves of the APEWE stack were recorded for the range of current densities up to 390 mA cm^{-2} for operational temperature of 28 °C. Purity of oxygen stream produced during different experiments was determined by means of gas chromatography. Current efficiency was determined in dependence on the concentration of the liquid electrolyte and number of the cells in the stack. It was based on the production of the gases determined using the bubble flow meter.

3. Results and discussion

Distribution of the liquid electrolyte

Sufficient supply of the liquid electrolyte into the electrode compartment represents vital aspect of the alkaline water electrolysis. It was proven, that the proposed geometry of the system ensures homogeneous liquid distribution along the electrodes. This is documented both by load curves, as well as by the flow visualization in the cell.

Influence of the electrolyte feed arrangement

APEWE arrangement allows significant freedom in arrangement of the liquid electrolyte feed into the cell. Both electrode compartments, or just one of them may be supplied by electrolyte [40]. This aspect was found to be of significant importance regarding both, produced gasses purity and cell lifetime. Supplied cathode compartment was found to be preferable regarding the produced gasses purity. But suitable measures have to be introduced to stabilize the electrolyte pH in the range ensuring electrodes stability.

Influence of the electrolyte concentration

Two effects have to be considered in this aspect: (i) due to the improved ionic contact between the electrodes and membrane with increasing KOH concentration current density at given stack voltage increases; (ii) at the same time parasitic current value increases. The second aspect is connected with decreasing resistance of the parasitic current pathways. For the given cell construction KOH concentration of 10 wt.% was chosen as the optimal one.

4. Conclusions

The results obtained within this study prove viability of the water electrolysis stack based on anion selective polymer electrolyte. They allowed to develop necessary cell and system components and to identify bottlenecks in the first version of the cell design. Know how gained allows to continue the development work and to propose new generation of the up scaled alkaline water electrolysis cells stack.

Highlights

- Electrochemical synthesis can be used to make added-value chemicals of fuels
- Real-time methods are needed to determine selectivity at dynamic conditions
- A novel method to determine products at the time they are formed is presented
- The discovery of new interfaces for selective electrosynthesis will be accelerated

1. Introduction

Electrochemical synthesis is the formation of valuable chemical compounds with the direct use of electricity. The field of electrochemical synthesis is currently growing rapidly because renewable electricity can be harvested to produce highly efficient fuels or fine, added-value chemicals. The classical way to characterize the selectivity of electrochemical reactions involves electrolysis at steady state (constant potential or current) and periodic product determination with GC, GC/MS, HPLC, NMR, IC, etc [1-3]. The advantage of this approach is that quantitation is possible in terms of reaction rates, yields, selectivities or faradaic efficiencies. However, two important limitations exist: First, only one material-electrolyte-potential (or current) combination is addressed at a time, thus looking for selective interfaces for new electrocatalytic processes is time-consuming. Second, the temporal resolution is in the order of minutes so transient, dynamic processes that occur within seconds cannot be captured. To address these points, we developed a new method that allows for the real-time detection of gaseous and liquid electrochemical reaction products.

2. Methods

Electrochemical real-time mass spectrometry (EC-RTMS) is based on coupling an electrochemical cell with two mass spectrometry techniques. It allows for the detection of gaseous products as in previously existing methods (e.g. differential electrochemical mass spectrometry [4]) but also the highly sensitive detection (sub-ppm range) of liquid products independent of their vapor pressure. The achieved acquisition frequency is in the order of 1 Hz, which therefore enables investigations under truly dynamic conditions, e.g. during potential sweep or potential step experiments. In the basic EC-RTMS configuration, the electrochemical reactor is an electrochemical scanning flow cell (SFC) [5], where a channel withdraws the electrolyte at the electrode vicinity for analysis. Gases are extracted from the electrolyte outlet with a hydrophobic membrane and analyzed with electron impact quadrupole mass spectrometry (EI-QMS). The degassed electrolyte is nebulized

and the generated mist is transferred for analysis with direct analysis in real time - time-of-flight mass spectrometry (DART-TOF-MS).

3. Results and discussion

The strength of EC-RTMS in characterizing multiple reaction products in real time will be demonstrated by presenting examples from the reduction of carbon dioxide and the oxidation of C_1-C_3 alcohols. Figure 1 shows the product distribution during the electrochemical oxidation of ethanol on platinum. The potential protocol involved a combination of potential steps at 0 V_{RHE} and sweeps from 0 to +1.2 V_{RHE} (black curve in bottom panel - the oxidation current is also shown in red). Simultaneously, the product formation is followed with EC-RTMS. Gaseous products are CO_2 (m/z = 44 and 22) and CH_4 (m/z = 15), the latter formed from the reduction of adsorbed CHx species at low potential. Liquid products are CH_3CHO (m/z = 45), CH_3COOH (m/z = 61) and ethyl acetate (m/z: 89).

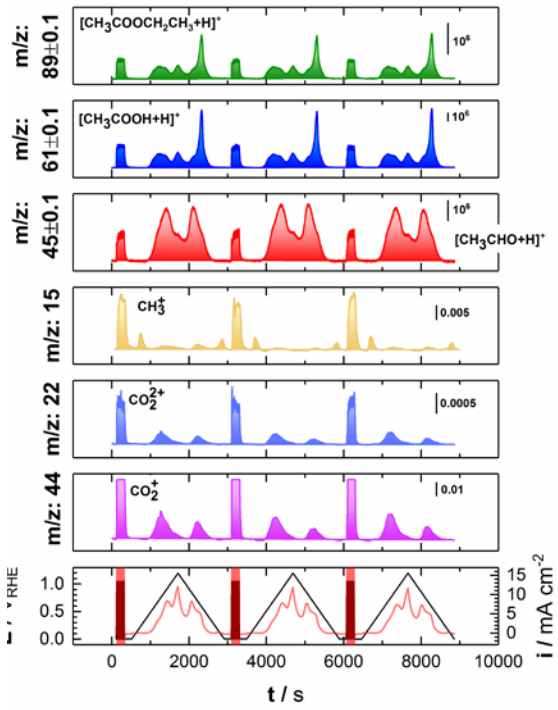

Figure 1. Determination of reaction products with EC-RTMS during the oxidation of 0.2 M ethanol on platinum in 0.1 M $HClO_4$: ethyl acetate (m/z = 89), acetic acid (m/z = 61), acetaldehyde (m/z = 45), methane (m/z = 15), and carbon dioxide (m/z = 22 and 44). The bottom panel shows the electrode potential (black) and the associated current (red).

4. Conclusions

EC-RTMS is a novel method that allows for the simultaneous detection of gaseous and liquid products of electrochemical reactions with excellent temporal and potential resolution. The greatest development is the characterization of liquid products in real time, as it drastically expands the possibilities of complete product determination during an electrochemical reaction independent of analyte vapor pressure or the presence of salts. We anticipate that EC-RTMS will accelerate the design of robust interfaces for highly selective electrochemical processes.

Highlights

- Co-production of two added value products, carbon monoxide and lactic acid.
- Reduction of 35% in energy consumption.
- 7 fold increase in product value.
- Combined faradaic efficiencies up to 160 %.

1. Introduction

The electrochemical conversion of carbon dioxide presents a significant opportunity to create valuable chemicals or fuels[1]. However, the process is not implemented in the industry due to the high energy needed to overcome the high overpotentials of the reaction[2-3]. The electrochemical reduction of CO_2 can be made economically more interesting by pairing to a compatible reaction where a valuable product is formed. With this approach, two valuable product are formed with the same energy usage. This study proves a paired electrochemical process where carbon dioxide is reduced to carbon monoxide and 1,2-propandiol is oxidized to lactic acid. With this strategy, a reduction of 35% in energy consumption during CO_2 reduction, and a 7 fold increase in product value per unit of energy used was achieved.

2. Methods

The electrochemical measurements were performed in a flow cell with a 200 mL reservoir of anolyte and catholyte which were recirculated at 25 l/h. Different currents (15, 30 50 mA/cm^2) were applied by the use of a potentiostat connected to a 10 cm^2 gold plate cathode and a 10 cm^2 carbon felt anode. A 0.5 M $KHCO_3$ solution where pure CO_2 was bubbled through was used as a catholyte, and a 0.5 M $KHCO_3$/ 0.5 M K_2CO_3 solution which contained 20 mM ACT-TEMPO as a mediator and 20 mM 1,2-propanediol (PDO) as a reactant was used as anolyte. The gaseous products were analyzed by gas chromatography and the liquid products were analyzed by high performance liquid chromatography.

3. Results and discussion

During electrochemical reduction of CO_2 paired with 1,2-propanediol oxidation performed at 15 mA/cm^2 a faradaic efficiency of 80% of carbon monoxide and a faradaic efficiency of 80 % to lactic acid was observed, making a combined 160 % total faradaic efficiency. During the paired reaction, a cell voltage of 2.6 V was measured, while during the non-paired reaction (oxygen formation as counter reaction) a cell voltage of 4 V was measured. The decrease of 1.4 V in the cell voltage lead to an reduction in the cost per ton of CO formed when the reaction is performed in a paired manner. In addition, if the counter reaction is based upon oxygen evolution reaction (non-paired) instead of lactic acid production (paired), only one valuable product is formed. The combined value of carbon monoxide and lactic acid makes the paired reaction economically more beneficial per unit of energy used. Figure 1 shows the value of products formed in € per kWh and the cost in € per ton of CO formed for a) the paired reaction and b) the non-paired reaction.

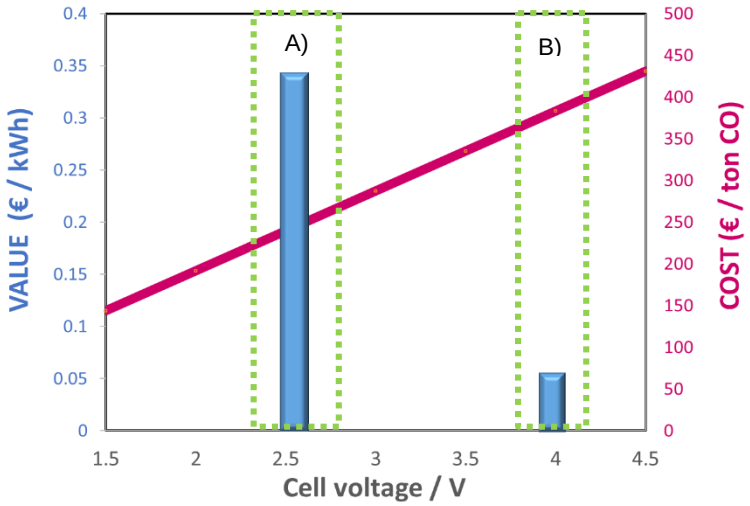

Figure 1. Techno economic comparison of the a) paired and b) non-paired electrolysis in terms of cost per ton of CO formed (pink line) and in terms of the value of the products formed (blue bars). The green boxes indicate the cell potential at which the reactions take place.

4. Conclusions

We have demonstrated that pairing CO_2 reduction to an electrochemical reaction which produce an added value chemical, a significant increase in product value can be achieved. In addition, if the cell potential needed to drive the reactions is reduced, an important decrease in energy usage can be accomplished. This strategy allows to move towards an economically viable electrochemical CO_2 conversion.

Electrocatalytic reduction of CO_2 to solar fuels: Insight into product distribution by varying the current density

Claudio Ampelli[1,*], Chiara Genovese[1], Siglinda Perathoner[1], Gabriele Centi[1]

1 Depts. Of ChiBioFarAm and MIFT (Industrial Chemistry), University of Messina, CASPE/INSTM and ERIC aisbl, Viale F. Stagno d'Alcontres 31, 98166 Messina (Italy)

Highlights

- The influence of current density on CO_2 reduction product distribution is studied.
- 27.4 % carbon Faradaic efficiency is obtained under industrial relevant conditions.
- CO and formic acid are the main products obtained at high current density.
- Current density directly affects the C-C bond formation.

1. Introduction

The (photo-)electrocatalytic reduction of CO_2 to energy-dense chemicals is an emerging route for storing the intermittent renewable energy produced by sunlight and closing the cycle of CO_2 production/consumption [1]. To achieve higher efficiencies towards hydrocarbons and oxygenates, and limit the side-reaction of water electrolysis, many efforts have been made on designing the electrodes and the related cell [2]. The selective distribution of CO_2 products, in fact, depends not only on the catalytic materials used for assembling the electrodes, but it is strongly influenced by the operational conditions (i.e. electrolyte, pressure, current density, cell configuration). Generally, high current densities are often required for industrial application, in which high space-time yields are mandatory, for reasons related to stoichiometry (the specific rate of an electrode reaction is proportional to the current density by Faraday's law) and economics (to support the capital cost of the electrochemical reactors). Thus, the products may be greatly different by changing the current density and this should be taken into account in scale-up industrial operation.

In this context, the main objective of this contribution is to show the influence of current density on product distribution in CO_2 electroreduction, by testing copper-doped carbon nanotubes deposited on a gas diffusion layer, thus opening the route towards a practical implementation of CO_2 electroreduction process with low-cost and earth abundant materials as electrocatalysts.

2. Methods

Copper nanoparticles (Cu NPs) were deposited on pre-functionalized carbon nanotubes (CNTs) by incipient wetness impregnation. The total amount of Cu loaded onto the CNTs was 5 wt.%. The as-prepared Cu NPs-CNTs were then deposited on a carbon gas diffusion layer (GDL) and finally joined to a proton exchange membrane (Nafion) to form a Membrane Electrode Assembly – MEA (in analogy with fuel cells) [3]. The electrodes were fully characterized by different advanced techniques (such as XRD, SEM, HR-TEM) to study their morphological and structural characteristics, as well as by Linear Sweep and Cyclic Voltammetry to evaluate their electrochemical properties.

Finally, Cu NPs-CNTs/GDL electrodes were tested in the process of CO_2 electroreduction using a homemade compact device working in a three-electrode configuration, by processing pure CO_2 in 0.1 M $KHCO_3$ electrolyte.

3. Results and discussion

The tests were carried out at different applied potentials (from -0.5 to -1.7 V vs. Ag/AgCl), corresponding to different current densities (from 0.1 to 2.3 mA cm^{-2}, respectively). A further test was carried out in amperometric mode applying directly 10 mA cm^{-2}, in order to evaluate the catalytic performance under industrial relevant conditions.

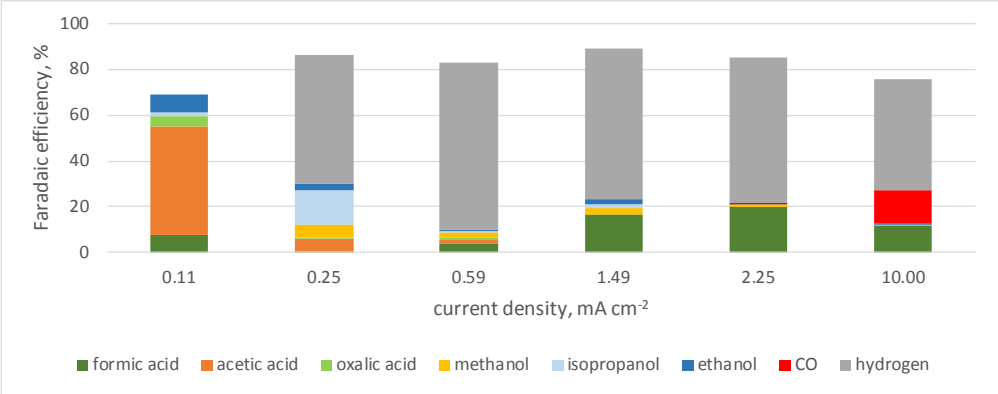

Figure 1. Faradaic efficiency (%) vs. current density.

As shown in Figure 1, the total Faradaic efficiency values are all ranging from 75 to almost 90 %, except when the current density is very low (0.11 mA cm^{-2}). At this current density, no hydrogen was detected, as the applied voltage (-0.5 V vs. Ag/AgCl) was not sufficient to activate water reduction. However, under industrial relevant conditions (10 mA cm^{-2}), the carbon Faradaic selectivity was quite high (27.4 %), indicating Cu NPs-CNTs/GDL as a promising electrocatalyst for CO_2 reduction process. Formic acid was the main carbon product formed, while carbon monoxide started to form at 2.25 mA cm^{-2} and became even higher than formic acid at 10 mA cm^{-2}. At low current density, the product distribution was quite different: methanol, ethanol and isopropanol (especially at 0.25 mA cm^{-2}) were formed, while acetic acid and oxalic acid were produced at -0.5 V vs. Ag/AgCl (0.11 mA cm^{-2}). These are examples of products involving C-C bond formation.

4. Conclusions

These results showed that the current density strongly affects the product distribution. Specifically, acetic acid, ethanol, formic acid, oxalic acid, methanol, and isopropanol are the main products obtained at lower current density, while the production of formic acid, CO and H_2 increased at higher current density, evidencing a direct influence of this parameter on C-C bond formation.

Highlights

- Proton exchange membrane water electrolysis
- Electrochemical compression/purification
- One dimensional modelling

1. Introduction

The global hydrogen consumption is around 50 Mton per year [1]. However, only a small part is used for energy device as an energy carrier. An energy carrier contains energy, facilitates its transport and storage before it is supplied (and converted) to an end user. Hydrogen fulfils the main characteristics to achieve the performance required for efficient energy carrier, but its low volume density remains a weak point. A very high energy-efficient compression is a necessary step. The main advantage of hydrogen production using water electrolysis is the simplicity of the process: only water and electricity are required. Water electrolysis allows to produce pressurized high purity hydrogen in order to facilitate the storage. Nowadays, mechanical compressors are considered to be the most commonly used in the industry. These systems enable to increase gas pressure by decreasing its volume using a mechanical force (energy). For multistage compression from room pressure to a final pressure of 20 MPa (200 bar), about 8% of the higher heating value (HHV) of the transported gas energy content (here hydrogen) is required [2]. Therefore, direct electrochemical compression is mainly advantageous for hydrogen to become a widespread renewable-energy carrier.

2. Methods

This work focuses on Proton Exchange Membrane Water Electrolysis (PEM-WE) which is considered as the most efficient process. In the literature, the analytical models and dimensionless approaches are essentially used for fuel cells. An interesting aspect of dimensionless study is the panel of dimensionless numbers specific to fuel cells including the Wagner number and the number of Damkholer. According to the author's opinion, the analytical modeling and dimensionless methods are currently underutilized in fuel cell (PEMFC) and electrolysis domain (PEM-WE). The developed analytic approach in this work exhibits an innovative approach to quantify electrochemical performances based on dimensionless methodology.

3. Results and discussion

In the present work, the limiting processes are highlighted using the obtained dimensionless numbers. In the case of PEM-WE, the main phenomena are proton diffusion, electrochemical kinetics at catalytic layers, water transport: diffusion, electro-osmotic and osmotic pressure transport in the membrane [3]. Thanks to this mathematical procedure, it is possible to forecast electrochemical behavior and to grant optimal operating conditions. Equivalent Wagner number and Thiele modulus analogy are presented in this paper. Our dimensionless approach is used to scrutinize the mean values as well as the spatial distributions of current densities, over potential, water contents and membrane resistance. Therefore, it allows to frame the usual differential equations into a dimensionless equation set.

4. Conclusions

Direct electrochemical compression of hydrogen during electrolysis process have been successfully modeled using dimensionless approach. According to the resistive energy losses associated with proton diffusion through the electrochemical cell: doubling the current density, doubles the hydrogen flow, but quadruples the dissipated power. The specific resistance of the membrane is main parameter of electrochemical cell. The overall resistance depends on cell materials as well as operating conditions such as pressure gradient, contact resistance, diffusion profiles, and at the selected current density [4].

Highlights

- Electrochemical CO_2 reduction at 300 mA/cm² at Faradaic Efficiencies > 80%
- Stable operation for 7000+ hours
- Reduction of CO_2-crossover by more than 95%

1. Introduction

The electrochemical CO_2 reduction allows to create valuable products from "waste" CO_2 coming from industrial processes, and cheap, renewable energies. Among the different possible electrolysis products, CO is the most promising for industrial application in the near future and thus, has drawn a lot of interest. By now the technology has passed the fundamental catalytical research stage, and different setups have been reported that perform stable, at high faradaic efficiencies for over 1000 hours at industrially relevant current densities [1,2]. In order to keep up with the rapid industrial application plans [3], research is shifting from catalyst design to engineering the electrolysis process and to upscaling of the setups.

2. Methods

The electrochemical experiments were performed in a commercially available flow cell. The different gas streams were quantified, and their composition analyzed via gas chromatography.

3. Results and discussion

Among the stable systems published, the mixed-electrolyte approach detailed in [1] is especially suited for rapid scaling and industrial application, since it does not require expensive ion-selective membranes and is not based on novel, research-level materials. By improving the GDE and the overall system setup, the cell could be operated stably at more than 80% faradaic efficiency for 7000 hours at current densities of 300 mA/cm² (Figure 1).

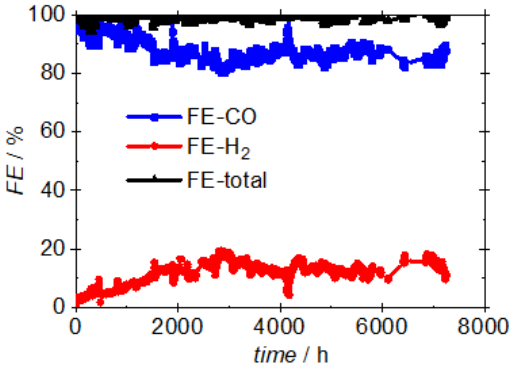

Figure 1. Faradaic efficiencies of a CO_2-electolysis cell operating stably for over 7000 hours

As the technology moves towards industrial application, the transport of CO_2 across the cell becomes an important issue, that has been mostly neglected so far. Due to the formation and neutralization of carbonates, this transport is intrinsic to CO_2 electrolysis and needs to be dealt with [1,2,4]. Here different approaches to minimize the CO_2 transport across the electrolysis cell are introduced, discussed and tested. All methods keep the advantages of a mixed-electrolyte system and work with the previously tested cathodes. By implementing these methods, the CO_2 transport could be reduced by over 95% (Figure 2).

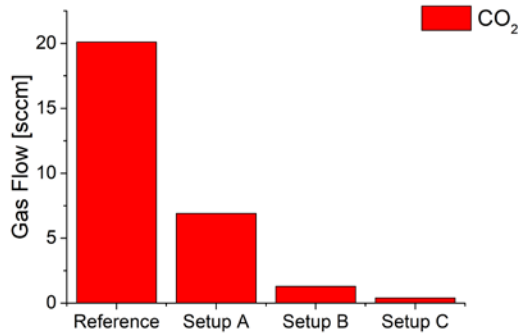

Figure 2. CO_2 content in the anode gas for different setups. Compared to the standard, reference case, the crossover could be reduced by more than 95%.

4. Conclusions

CO_2 electrolysis cells with liquid electrolytes are a viable candidate for near-time industrial application. As in all current approaches, the CO_2 transport across the cell needs to be accounted for and solving this problem is crucial for a successful industrial implementation of this process. The results here show, that an adequate design of the electrolysis setup can achieve this target while maintaining industrially relevant operating conditions without relying on ion-selective membranes.

Highlights

- Aluminium smelter technology
- High-acidic sodium and potassium cryolite melts
- Electrical conductivity
- Tube type cell, electrochemical impedance spectroscopy

1. Introduction

The innovation of aluminium production technology is focused on using the inert electrode materials and low temperature electrolytes. The most significant benefits are energetic, environmental, and economic aspects. The consumable carbon anodes will be replaced by inert, oxygen evolving anodes. Low-melting electrolytes (working temperature 660 °C – 900 °C) are essential due to the oxidation rate of inert electrode materials. The corrosion rate decreases strongly with decreasing temperature. Cryolite-based melts are still the best choice as electrolytes for electrolytic aluminium production, because of its unique capacities as a solvent for electrochemically active compound (alumina). The possibilities for the decreasing of TPC in cryolite-based melts are three: electrolytes based on sodium cryolite with the high excess of AlF_3 (up to 45 mol %), electrolytes based on potassium cryolite, mixture electrolytes with various ratios of sodium and potassium cryolite.

The high addition of AlF_3 into the sodium cryolite systems reduces markedly TPC (up to 700 °C) but also decreases the alumina solubility. The potassium system is more low melting than the sodium system (temperature less than 660 °C). The interest in potassium cryolite melts causes the fact that alumina solubility is higher than in the sodium system at the same conditions. Other properties are less favorable, for instance, the electrical conductivity is considerably lower in the potassium system. The essential physicochemical properties of these low temperature electrolytes, such as solubility of Al_2O_3, density, vapor pressure, viscosity or electrical conductivity were investigated only in less extent. The electrical conductivity is of great importance in the energetic aspects and it also helps with the characterisation of the melts structure. The interest in low temperature electrolytes is growing with the development of inert electrode materials.

2. Methods

Electrochemical impedance spectroscopy is a suitable measurement method for the investigation of electrical conductivity of new types of aluminium electrolytes. Electrical conductivity was measured using a tube-type cell with stationary electrodes applying AC-techniques with a sine wave signal in the high frequency range up to 100 kHz. Electrolytes used in this study contained

high content of aluminium fluoride, up to 45 mol %. Basic binary NaF-AlF_3 melt was studied at different molar ratios MR = (2.0-1.2) in the temperature range from the temperature of primary crystallization to 100 °C overheat. Basic melts KF-AlF_3 and NaF-KF-AlF_3 were studied at molar cryolite ratios MR = (1.5-1.2) in the temperature range defined in the same way as for previous system. The influence of the additions of Al_2O_3, CaF_2, MgF_2 and/or LiF was also investigated.

3. Results and discussion

The electrical conductivity of the NaF AlF3 system as a function of a temperature and composition.

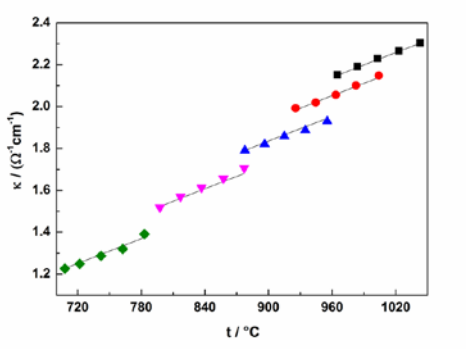

Figure 1. The electrical conductivity of the NaF AlF_3 system as a function of a temperature for compositions: MR = 2.0; ● MR = 1.8; ² MR = 1.6; ¼ MR = 1.4; f MR = 1.2. Symbols represent the experimental data; full lines non-linear regression analysis data.

4. Conclusions

Concentration and temperature dependences of the electrical conductivity for all the studied low-temperature multi-component systems were described by the regression equation. The mutual effect of various combinations of additives on electrical conductivity was similar than the sum of individual allowances. The decrease of electrical conductivity in multicomponent systems for melts with the lowest MR = 1.2 was up to about 13 % when compared to the binary melts. Although LiF improves the value of electrical conductivity, the addition of about 1 wt % of LiF increased the electrical conductivity only by about 1.88 % on average. Temperature and concentration dependencies of the electrical conductivity in studied multicomponent systems were described by regression equations. The summary equation precisely describes the temperature and concentration dependence of electrical conductivity in the whole studied area and can be used for practical purposes.

Highlights

- Furfural oxidation
- Electrochemical maleic acid
- Electro-organic synthesis
- Scale-up

1. Introduction

Lignocellulosic biomass is abundant, cheap, and many platform chemicals can be derived from it. An example of such chemical, furfural is a C5 compound, which is already industrially produced from biomass. Many of value added chemicals can be produced from furfural, for instance, maleic acid. Latter is used in variety processes, such as in production of lubricants, plasticizers, pharmaceuticals [1]. Importantly, maleic anhydride, which is easily made from maleic acid, is used for production of bio-based aromatics [2]. Industrially, produced maleic acid currently is fossil based and is produced by hydrolysis of maleic anhydride, which on the other hand is produced by gas phase thermocatalytic oxidation of butane by oxygen catalyzed by vanadium-based V-P-O catalysts, however the process yields only 50-65 % maleic anhydride, therefore very inefficient. Alternatively, electrochemical oxidation allows selective and less energy demanding conversion at ambient pressures and temperatures using cheap catalysts, such as Pb/PbO_2 [1, 3].

Our research focused on scaling-up of the production of maleic acid to industrially relevant conditions (>5wt %) utilizing a plate-and-frame type electrolyser.

2. Methods

Electrolysis was performed in a divided cell and plate-and-frame type electrolyser (Nafion® membrane) at RT under acidic conditions with anode Pb/PbO_2 and Pt or Pb cathode with anolyte: 0.5 M H_2SO_4 with/without 0.02 M V_2O_5 or 0.02 M $NaMoO_4$ and catholyte 0.5 M H_2SO_4. Potentiostatic and galvanostatic electrolysis modes were used for production of maleic acid.

3. Results and discussion

The electrolysis was investigated directly on Pb/PbO_2 electrode, and the effect of mediators such as V_2O_5 and $NaMoO_4$ was investigated. Optimal potentiostatic operation was performed at 1.5 V vs SCE, whereas the optimal galvanostatic operation was performed at a current density of ~10

mA/cm^2. With starting concentration of 0.05 M furfural, the yield on maleic acid was ~80% with a main side product an oxidation intermediate, formyl acrylic acid. Almost quantitative yields can be achieved if all formylacrylic acid is converted to furfural. Effect of reactant concentration was investigated (0.05- 0.5M furfural). The reaction was tested at temperatures of 25 and 35 ^{0}C, realizing higher reaction rates and yields of maleic acid at elevated temperatures. Permeation of the reactants, products and mediators through membrane was investigated and process optimized. Additionally, downstream processing possibilities of maleic acid have been investigated. Based on the obtained results techno-economic feasibility study has been performed and showed economically favorable production costs.

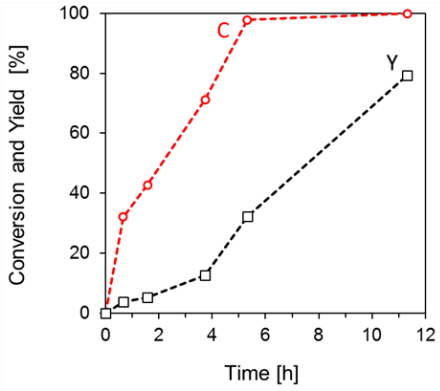

Figure 1. Conversion and yield of electro-oxidation of furfural to maleic acid on PbO_2 electrode in 0.5 M H_2SO_4.

4. Conclusions

Electrochemical production of biobased maleic acid by oxidation of furfural was demonstrated for the first time in a plate-and-frame type electrolyser at industrially relevant conditions. Yields >80% were obtained. Preliminary techno-economic analysis shows that the production process has a high potential to replace fossil based maleic acid production.

Highlights

- New, modular electrochemical microreactor addressing high pressure operation and production scale.
- Application to electroorganic synthesis.
- Asymmetric Kolbe electrolysis and cation pool / flow method.
- Utilization of additive manufacturing for reactor plates realization.

1. Introduction

Organic electrochemistry is considered as future emerging technology for the environment-friendly production of chemical compounds. The search for "green" synthesis routes, the emergence of novel synthesis strategies and also the ambition for a direct utilization of sustainable (excess) electric energy foster the development in this field.[1] Nevertheless, there are still challenges and problems linked to electrosynthesis and there is also a need for flexible reactor concepts.[2] Electrochemical microreactors - characterized by small electrode distances and great surface-to-volume-ratios - contribute to solve these issues.

2. Design and manufacturing of the novel electrochemical microreactor

Taking into account current user requirements, Fraunhofer IMM developed based on its experience in the field of electrochemical microreactors [3] an innovative reactor concept (Fig. 1) following a plate stack design addressing especially the aspects modularity, flexibility, high pressure operation and accessibility of production scale.

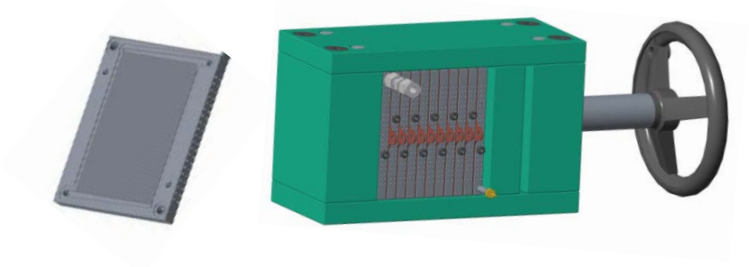

Figure 2.
CAD illustration of single reactor plate with micro-structured electrode and integrated heat exchanger (left). CAD illustration of assembled flexible

electrochemical microreactor with 11 reactor plates (right).

The single reactor plates hosting the structured electrodes typically on both sides and equipped with an integrated heat exchanger have been realized by a sequence of different fabrication steps:

- additive manufacturing to realize the base plates with their complex fluid structures
- surface coating (e.g. with PTFE) of the plates for electric insulation
- milling to create the micro channels on the plates surface
- electroplating to deposit different electrode materials

The basic reactor plates (outer dimension: 100 mm x 118 mm) provide an active electrode surface of 54 cm^2 via 67 micro channels (800 µm x 100 µm x 10 cm) and a channel volume of 0.5 cm^3 per structured plate side. The reactor is designed for operations up to 200 °C and up to 100 bar for electrolyte flow rates up to 200 mL min^{-1}.

3. Results and discussion

The reactor concept allows a multitude of operation possibilities in view of numbers of electrode assembly units in use, functionality (mono or bipolar cell configuration, undivided or divided cell configuration) and operation mode of the stack (parallel, serial or mixed operation). With that also numbering-up and scale-up possibilities are provided. The reactor concept is validated by the use of different reactor assembly configurations for two electroorganic syntheses. Former results regarding the Kolbe electrolysis to produce fuels from fatty acids [4] could be further improved with the new reactor concept. E.g. for the asymmetric continuous Kolbe electrolysis at current densities of 1.7 kA*m^{-2} and residence time of 0.1 s the Faraday efficiency could be increased further to 91% (at quantitative yield and a selectivity towards 97% of n-alkanes). This application example illustrates nicely the precise control over process conditions during the synthesis and the resulting control over product composition (see Figure 2). The Cation Pool / Flow method [5] as modern organic synthesis approach has also been used for the successful reactor concept validation.

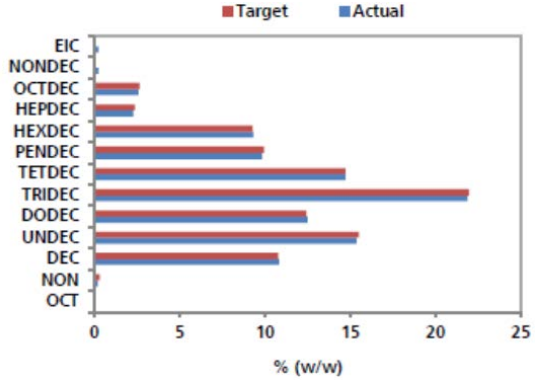

Figure 2. Comparison between target and achieved results of jet oil by Kolbe electroorganic synthesis.

4. Conclusions

Fraunhofer IMM has developed an innovative electrochemical microreactor addressing especially the aspects modularity, flexibility, high pressure operation and accessibility of production scale and validated the reactor concept by applying it in the Kolbe electrolysis and Cation Pool / Flow method.

Highlights

- Photoelectrocatalytic performances of hybrid TiO_2/Au structures are tested
- Different distribution of Au clusters is performed at the TiO2 interface
- The role of Au NP in the working mechanism of the whole structure is investigated

1. Introduction

The paper examines and discusses the behavior of hybrid 3D TiO_2 electrodes, modified with Au nanoparticles (NP), useful as photoanodes for the oxidation of organic compounds from aqueous solution. In such a process H_2 evolution is always the concomitant cathodic reaction, while photogenerated holes are responsible for the oxidation of the organic compound, which may occur either by direct reaction at the active sites of the photoanode, or mediated by OH radicals, generated by the water splitting. In this context, high surface to volume ratios are generally mandatory, being the reactions involved heterogeneous: nano or meso porous structures are commonly used to this aim [1,2]. However, increase of the surface area may not be sufficient to obtain effective catalysts. Actually, the intrinsic characteristics of the semiconductor (SC) cannot be neglected: the structure crystallinity (anatase, rutile or amorphous), as well as the possible presence of defects, which may constitute recombination centers for the photogenerated charges, are of crucial importance to determine the real effectiveness of the SC.

Further considerations are needed when the SC has to be used with solar light. Due to the large band gap, TiO_2 is not suitable in all the wavelength range. In this case, the presence of dopant, or the use of hybrid structures, in combination with another SC with narrow band gap, can allow exploiting the low energetic wavelengths.

Finally, the inclusion of noble metal NPs, such as Ag, Au, Pt, single or alloyed, represents a possible way to enhance the ability of TiO_2 to absorb light in a wider range of wavelength [1, 2] via plasmonic effects, or to favor charge carrier separation to inhibit recombination, directly contributing to the production of long-lived charges, owing to the resulting low Fermi level [3, 4, 5].

In this work the performances of samples of TiO_2 with a hierarchical nanostructure, modified by Au NP, are investigated for the oxidation of bisphenol A, used as model molecule, representative of a class of organic compounds of particular concern for the human health.

2. Methods

Vapor phase Pulsed Laser Deposition (PLD) was used to produce nanostructured TiO_2 photoanode films, while Au NP were produced by PLD or thermal evaporation. By varying the process parameters and exploiting annealing treatments, we tune Au NP size distribution and the hierarchical TiO_2 nanoscale morphology. Optimized Au NPs are coupled with TiO_2, involving deposition of NPs at the bottom or at the top of the TiO_2 as well as co-deposition of integrated TiO_2/Au-NPs assemblies [6]. Photoelectrochemical characterization of the samples was done by direct and alternate current tests: cyclic and linear sweep voltammetry, and photocurrent tests were used in d.c.; electrochemical impedance spectroscopy was used to investigate the response to a.c. signal. A 300 W xenon lamp equipped with air mass (AM) 0 and 1.5 D filters was used to simulate the solar radiation.

3. Results and discussion

The performances of the different samples are investigated, in terms of voltammetric behavior, photocurrent transients, impedance spectroscopy (EIS) responses, in order to understand the working mechanism of the hybrid structures, during electrolysis carried out in supporting electrolyte or in the presence of organic compound, in the dark or under simulated solar light irradiation.

In these conditions the different active centers of the structure play different roles: TiO_2, which always represents the majority component of the hybrid structure, is active for the narrow range of UV light, while Au NP, which constitute the minority component, is fundamental to exploit the Vis range where TiO_2 cannot act. The right combination of the two components is crucial to achieve good performance, in the examined conditions.

4. Conclusions

The results demonstrated that the effectiveness of the samples is connected to both the load and the dispersion of the Au NP with respect to TiO_2. An optimal metal loading has to be individuated in order to guarantee that the Au nanoclusters do not cover all the TiO_2 interface, so that the charge transfer between electrode and electrolyte is not hindered.

A simple model for vanadium precipitation in vanadium redox flow batteries

Killian Poulet-Alligand[1], Florence Druart*[1], Jonathan Deseure[1], Yann Bultel[1]

1 Univ. Grenoble Alpes, Univ. Savoie Mont Blanc, CNRS, Grenoble INP, LEPMI, 38000 Grenoble, France

Highlights

- Optimization of vanadium redox flow battery
- Impact of precipitation on electrochemical performance
- Half-cell modelling

1. Introduction

The future of the energy grid will require an ever-larger capacity of energy storage. Among all the technological solutions available, the redox flow batteries are ones of the most attractive as they deal a large operation scale, a good efficiency and a large design flexibility [1]. The common and most popular redox flow battery is the all-vanadium redox flow battery, which uses the same element in both cell compartments. This system avoids the contamination risk due to crossover, which occurs with the long-run use. This device leads to ideal sustainability and practical unbounded lifetime.

However, the all liquid vanadium redox flow batteries are limited by the solubility of vanadium in water (from 2 to 4 M of $VOSO_4$ in 2M acid sulfuric [2]). The vanadium ions solubility limits the energy density ca. 15 Wh/kg [1]. This energy density is quite low in contrast with the specific energy of Li-ion batteries (close to 100 Wh/kg [3]). Hence, operating points at high vanadium concentrations are essential to obtain higher energy density. Consequently, high concentration of vanadium results in large risk of precipitation of vanadium salts in the cell.

Numerous models have already been introduced to describe the liquid vanadium redox flow batteries [4–8] but without taking into account the precipitation phenomenon. This work exhibits a 2D transient model which takes into account solubility. In addition an experimental study of flow cells is introduced in order to validate the model.

2. Methods

The model solves usual mass, momentum and energy conservation equations. The Butler-Volmer law describes the electrochemical kinetic of the vanadium. The dissolution/precipitation of the vanadium salts is modelled with first order kinetic law and Fick's equation. We have assumed a pseudo-homogeneous system to solve the equation set.

To validate this model, the oxidation of vanadium (IV) to vanadium (V) is studied in a half-flow-cell made of PMMA, with carbon felt electrodes. The inlet solution of $VOSO_4$ and 3M sulfuric acid could be recycled or the cell could be fed by clean solution. Potentiometric measurement have been performed and compared with the model results. At specific time, the solution of vanadium at the outlet of the flow cell is sampled and the vanadium ions are quantified using UV-visible spectrophotometry for the vanadium (IV) and potentiometric titration with Mohr salt for the vanadium (V).

3. Conclusions

This model allows a better understanding of the impact of the vanadium precipitation on the battery operation at high vanadium concentration and could provide strategies for redox flow battery optimization.

Polyaniline/Metal-based Electrodes: Preparation and use as Anodes in Bioelectrochemical Systems

Laura Mais, Michele Mascia*, Simonetta Palmas, Elisabetta Usai, Annalisa Vacca

Dipartimento di Ingegneria Meccanica Chimica e dei Materiali, Università degli Studi di Cagliari, Via Marengo 3, 09123 Cagliari, Italy
**Corresponding author: michele.mascia@unica.it*

Highlights

- A suitable three-step procedure is tested to coat metal electrodes with polyaniline
- Uniform and stable films of polyaniline can be obtained
- High degree of surface coverage is measured
- The obtained electrodes can be used as bioanodes

1. Introduction

Carbon-based anodes have largely used in bio-electrochemical systems, due to their biocompatibility, chemical and microbial stability. However, carbon has a low electric conductivity, which may decrease the cell voltage and the efficiency of the system. Metals may be a suitable alternative, with high values of electrical conductivity, but few metals are stable in the potential window of bio-electrochemical systems and biocompatible.

Although Copper is known to be a natural antimicrobial material, active biofilms have been obtained on this metal [1]. Coating of metals with conductive and biocompatible polymers such as polyaniline (PANI) may prevent release of toxic ions and promote the biofilm growth. PANI have been proposed for different bioelectrochemical applications, such as electrochemical biosensors [2], cell adhesion [3] and tissue engineering [4].

In the present work, copper and gold substrates have been coated with the conductive polymer polyaniline, and tested for biofilm growth. The coating was obtained with a three-step procedure, proposed in a previous work with gold electrodes: the PANI film showed higher stability if compared with that obtained with simple elctropolymerisation of aniline on bare gold [5].

2. Methods

The experiments were carried out in a flow cell with planar electrodes (0.5 cm^2); gold or copper were used as working electrode, platinum was used as counter electrode.

To obtain a stable and uniform coating of polymer, a three-step approach was followed: nitrophenyl group was grafted to the metal (Cu or Au) surface through electroreduction of nitrobenzendiazonium (NBD) salt in acetonitrile medium; the nitrogroup was then electrochemically reduced to amine in ethanol/water electrolyte; aniline was electropolymerized onto the surface of the amino-phenyl-modified electrodes. After each step, cyclic voltammetry and electrochemical impedance spectroscopy were used to characterize the modified surface.

The cells were then fed with anaerobic sludge and acetate, and the trend with time of the bioelectrocatalytic current of the acetate oxidation under potentiostatic conditions was monitored, as a measure of the biofilm growth onto the PANI/metal surface.

3. Results and discussion

Grafting of nitrophenyl groups onto metal surface was obtained in cyclic voltammetry: well-shaped peaks were observed in the first cathodic and attributed to the electroreduction of nitrobenzendiazonium. The reduction peak disappeared in the other scans, as the active sites of the metal surface were blocked by the organic moieties.

The surface coverage of the NBD modified electrodes was evaluated from the charge transfer resistance to electron transfer of the ferri/ferrocyanide redox probe by electrochemical impedance spectroscopy. Values of coating higher than 98% were obtained with gold electrodes, while lower values were observed with copper electrodes.

During the voltammetric reduction of nitro group to amine a cathodic peak was observed, which decreased with the number of cycles and disappeared after about ten cycles, indicating that all the electroactive grafted groups are reduced.

During electropolymerisation of aniline, well defined oxidation and reduction peaks were observed, indicating that the aminophenyl modified electrodes were effective for the self-catalytic head-to-tail polymerization of PANI. The peaks are less evident with copper electrodes. At the end of the process a uniform, well visible coating of PANI was obtained with both electrodes.

During biofilm cultivation under potentiostatic control with activated sludge and acetate, a growth of current can be observed, with an apparent lag phase.

4. Conclusions

Results show the effectiveness of the three-step procedure used for electrochemical coating of copper and gold with polyaniline. A stable and uniform coating of polyaniline was obtained with both metals.

Preliminary results on the use of PANi/metal electrodes as bioanodes are promising: the presence of PANI made possible to obtain an electrochemically active biofilm with copper electrodes.

Highlights

- Ruthenium oxide electrodes have been prepared by spin-coating deposition
- Electrochemical characterization was performed by cyclic voltammetry
- Electrochemical performance was affected mostly by number of cycles and rotation speed

1. Introduction

Metal Oxide electrodes consist of an electrocatalytic thin film of noble metals oxides coating a Platinum or Titanium support. They have been successfully used in the chloro-alkali industry for the last 30 years. In more recent years different compositions (Mixed Metal Oxide MMO), have been extensively used with a view to both fundamental understandings of the processes involved and for treatment of wastewater [1], [2].

Preparation conditions, for instance, the solvent used during preparation, the nature of the oxide precursor and the calcination temperature, affect the physical properties of oxide electrodes [3]. Electrodes were prepared by several techniques: thermal decomposition, sputtering, electrochemical deposition, CVD. The thermal decomposition is the most common technique and the film can be deposited on the substrate by drop-cast, spin-coating, dip coating.

In previous works [4], [5] we have prepared different types of MMO and studied their electrochemical performances. In a standard procedure, the films were obtained by drop-cast. This method is very simple but unfortunately, it is not easy to obtain a uniform and well-controlled film.

In this work, we prepared thin RuOx film by spin-coating, a more accurate and controllable technique. In particular, we studied the influence of different process parameters on the electrochemical performances of electrodes. The investigated parameters were the number of depositions, the speed of spinning, volume, concentration, and aging of precursor solutions.

2. Methods

The cleaning procedure and the precursor solution preparation were described elsewhere [4]. Titanium samples (1.5 cm × 2.0 cm), were coated with the solution containing the precursor by spin coating using Polos SPIN150i / 200i. A variable number of depositions were made and after each of them the sample was dried in an oven at 100°C for 10 min. After the last deposition, a thermal treatment was conducted at 450°C for an hour.

The electrodes obtained were analyzed on the basis of polarization measurements and cyclic voltammetry in aqueous solutions containing Na_2SO_4.The scan rate was fixed at 50 mV/s and the potential range chosen was between -0.2 V and + 1.12 V (*vs* SCE)

3. Results and discussion

The sample prepared are presented in Table 1. As expected and confirmed by a simple visual analysis, a greater number of depositions results in a more uniform and thick film; also a lower rotation speed leads to a more homogeneous film.

Item	Speed [rad/s]	N° deposits	Molarity [mol/L]	Volume [µL]
1	500	3	0.1	10
2	500	3	0.1	20
3	1000	3	0.1	20
4	250	3	0.1	20
5	500	1	0.1	20
6	500	2	0.1	20
7	500	6	0.1	20
8*	500	3	0.1	20
9*	500	3	0.05	20
10*	500	3	0.01	20

Table 1. Prepared samples. * Freshly prepared solution

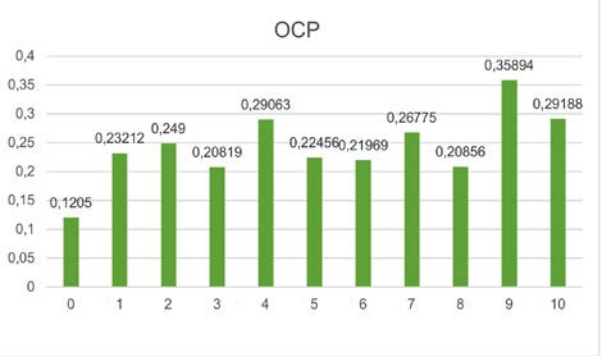

Figure 1. OCP values for the samples

Preliminary results show that all samples have similar and positive values of OCP in the range between 0.2 and 0.35 V. Total charge calculated from voltammograms is reported in Figure 2. The best value is found for sample 7 (greater number of depositions), followed by sample 4 (lower speed of deosition). The worst results are recorded in samples 3 (higher speeds), sample 5 (lower number of depositions) and sample 10 (most diluted solution). The accelerated life tests to evaluate the electrodes durability are still in progress.

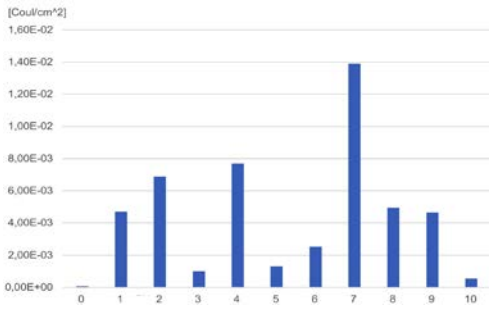

Figure 2. Q* values for the samples

4. Conclusions

We prepared several types of RuOx thin films by spin-coating. Cyclic voltammograms indicate that the total charge (Q*) increases with increasing thickness and homogeneity of the obtained film. Moreover, the electrochemical performances of electrodes obtained from aged solutions are better than the corresponding electrodes obtained with freshly prepared solutions.

Structured multiphase reactors for electrocatalytic conversions

J.Ruud van Ommen[1], John Nijenhuis[1], Johan T. Padding[1]

1 Delft University of Technology, TU Delft Process Technology Institute & e-Refinery, Delft, the Netherlands

**Corresponding author: j.r.vanommen@tudelft.nl*

Highlights

- Millichannel reactors are an attractive choice for CO2 conversion.
- Dimensionless numbers show that millichannels have clear advantages over microchannels.
- The channel walls can act as electrodes; the channel flow prevents stagnant bubbles.

1. Introduction

There is a broad consensus that the chemical industry will have to make a transition to renewable feedstocks. An important route will be to use electrochemical processes, driven by electricity from sustainable sources, to produce hydrogen from water, hydrocarbons from CO_2 and water, and ammonia from nitrogen and water. This will require novel reactor designs, with special attention to the structured design of electrodes. Although there is progress in electrochemical flow reactors, scalable macro- and micro-reaction environments need to be developed involving e.g. gas-liquid electrolyte flow [1].

2. Methods

We examine the use of millichannels in designing multiphase reactors for electrocatalytic applications. We give a general analysis based on dimensionless numbers, followed by an illustration of this approach to catalytic packed-bed reactors. Finally, we discuss how such reactors can play an important role of increasing the number of electrocatalytic processes in the chemical industry.

3. Results and discussion

Although the electrocatalysts required for CO_2 reduction receive substantial research interest, the research efforts devoted to the design of electrocatalytic reactors remains behind. Traditionally electrochemical reactors are designed as semi-2D geometries (one dimension much smaller than the other two) because of the use of plate electrodes. However, when gas bubbles are involved (e.g., due to hydrogen formation), the use of small channels might be attractive. Here we study the influence of channel size (hydraulic diameter d_h and length L), possibly filled with particles of diameter d_p, at porosity ε. We consider flow at superficial velocity U of two types of fluids through these reactors, one gas-like and one liquid-like, for which we will use the physical properties of air and water at 20 ^{0}C temperature and 1 atm pressure.

The differential pressure drop necessary to reach significant convective improvement of mixing and heat and mass transfer (typically Re>100) becomes prohibitive for small channels. For example, for an empty structured channel of hydraulic diameter d_h, the pressure drop associated with wall friction can be described by the Darcy-Weisbach equation [2]. Fig. 1 shows $\Delta p/L$ as a function of d_h for liquid-like (black solid line) and gas-like (black dashed line) fluids at Re = 100, assuming f = 64/Re. At this *fixed* Re, U decreases like $1/d_h$, leading to $1/d_h^3$ scaling of the required pressure drop: for d_h = 0.1 mm, the pressure drop to reach Re=100 is already substantial, approximately 10 bar/m, while for d_h = 1 mm the necessary pressure drop is a more manageable: 0.01 bar/m.

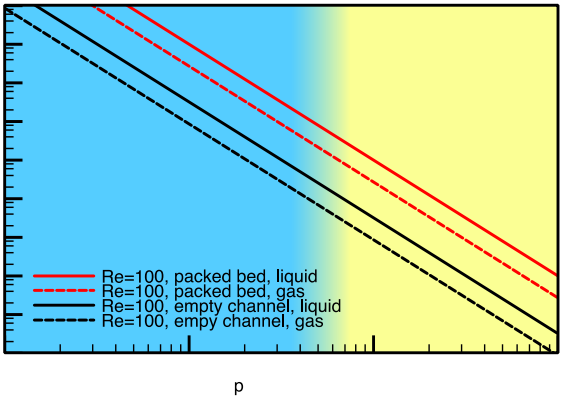

Figure 1. Pressure drop needed to reach Re=100 as a function of hydraulic or particle diameter. Blue: microchannel, yellow: millichannel.

For a channel filled with catalytic particles of diameter d_p, the differential pressure drop can be described by the Ergun equation [3]. Figure 1 shows $\Delta p/L$ as a function of d_p for liquid-like (red solid line) and gas-like (red dashed line) fluids at Re = 100 and ε=0.5. For the Ergun equation, *both* laminar and turbulent terms scale like $1/d_p^3$ at fixed Reynolds number. Under these conditions, for d_p = 0.1 mm, the pressure drop necessary to reach Re=100 is enormous, approximately 1000 bar/m, while for d_p = 1 mm, the necessary pressure drop is much more reasonable, approximately 1 bar/m.

Pressure drop and mass and heat transfer are not the only important consideration. We also need to consider that smaller reactors are also more prone to contaminants and agglomerates getting stuck in corners of the channel or pore space. Moreover, it is important to tune the residence time in the channel to optimize reaction yield or selectivity. The average residence time is $\tau = \varepsilon L/U$. At fixed Re, this leads to $\tau/L = \rho d_h/(\mu \mathrm{Re})$ or $\tau/L = \rho\varepsilon d_p/(\mu \mathrm{Re})$, for the two respective systems. In the regime where inertial flow enhancement becomes relevant (Re>100), reaching sufficiently *long* residence times requires sufficiently wide channels or sufficiently large particles.

4. Conclusions

Millichannels have clear advantages over traditional, non-structured reactors, in electrocatalytic processes. Analysis based on dimensionless numbers shows that the use of millichannels has important advantages over microchannels. The walls can act as electrode, while the channel configuration prevents problems with gas bubbles encountered in other types of electrocatalytic reactors.

Improvements in the treatment of the polluted streams containing non-polar organochlorine pesticides

Alexandra Raschitor, Javier Llanos, Gustavo Santos Acosta, Manuel Andrés Rodrigo, Pablo Cañizares

Department of Chemical Engineering. Faculty of chemical sciences and technologies. University of Castilla-La Mancha. 13071 Ciudad Real. Spain

Highlights

- The efficiency in the degradation of oxyfluorfen increases with concentration strategies.
- The most efficient process is the combination of electrocoagulation and electroFenton.
- The solid produced in electrocoagulation can be efficiently treated as a solid phase.

1. Introduction

The removal of chlorinated organic compounds from wastewater has become a matter of high interest lately due to their high toxicity, persistency and bioaccumulation.

In order to minimize the mass transfer limitations related to the treatment of low-concentrated streams the development of concentration strategies may be the solution. They can be integrated to the main treatment process or coupled as a pre-treatment step. When choosing a treatment technique, the nature of the pollutant must be considered. According to their physical and chemical proprieties, the organochlorine pesticides can be classified as polar or nonpolar, ionic or nonionic. For the ionic polar pollutants such as 2,4-Dichlorophenoxyacetic acid, electrodialysis combined with electro-oxidation offers a good solution to treat high volumes of wastewater, as demonstrated in our previous work [1].

For the nonpolar nonionic pesticides, the concentration by electrocoagulation was successfully developed in a previous work [2] leading to various treatment options that can be further applied. By applying the electrocoagulation as a pre-concentration step, it can be achieved the transfer of the pollutant from the liquid phase into a smaller volume of solid phase. The solid phase can now be dissolved and treated as a liquid waste or, treated as it is, like a solid or pulp.

This work aims to demonstrate that by concentrating the wastewater applying a cheap and noninvasive concentration technique followed by an aggressive degradation step it is possible to increase the removal efficiency and to reduce the energy consumption. Moreover, different alternatives for the treatment of the concentrated stream are presented and compared.

2. Methods

In this work, 2 types of electrochemical cells and 3 technologies were used. The first cell, a homemade cell equipped with a Fe anode and a BDD cathode it was used for

electrectrocoagulation, EC (j = 50 Am^{-2}). The second cell, a commercial Adamant Cell equipped with BDD electrodes, was used for electrooxidation (EO) and electroFenton, EF (j= 254.67, j= 177.33 and j= 63.6 A/m^2 respectively). In order to dissolve the concentrated phase it was added H_2SO_4.
When the concentrated phase is treated as solid, it must be applied another disturbing agent, ultrasound irradiation in this particular case, (75 khZ and 1MhZ) in order to alter the structure to release the pollutant for its further electrochemical removal step.

The concentration of Oxyfuorfen was measured by means of High Performance Liquid Chromatography (HPLC) equipped with an analytical column Phenomenex Gemini 5 µm C18.

3. Results and discussion

By applying EO to a non-concentrated wastewater, it was possible to achieve a removal of Oxyfluorfen from 100 to 79 mg/l in three hours at j= 254.67 A m^{-2}. When electrocoagulation is previously applied and the concentrated phase is treated as a liquid stream (acidified with H_2SO_4), it is possible to achieve a removal of Oxyfluorfen from 1250 to 776 mg/l with EO, giving a specific power consumption almost 10 times lower than that required when treating the raw diluted solution. When applying EF, the concentration can be reduced from 1340 to 69.3 mg/l F in only three hours at the same current density, thus resulting in the best performance when the concentrated solution is treated as a liquid.
The treatment of the concentrated phase as a solid phase (as it is obtained in the EC process) is still in development but the preliminary results obtained so far show that by applying ultrasonic irradiation to the mixture it is possible to release an important amount of the pollutant that is trapped into the flocs, being the best performance obtained when the lowest ultrasound frequency is applied.

4. Conclusions

This work demonstrates that by previously concentrating a wastewater containing non-polar organochlorine pesticides, it can be significantly increased the removal efficiency, being the combination of EC with EF the process with the better performance.

Moreover, the treatment of the concentrate as a solid phase seems to bring promising results opening a new path for the treatment of this type of contaminants.

Energy and Chemical Engineering

Energy efficiency classification method in processing crude oils using data envelopment analysis tools.

D. Narciso[1], F. G. Martins[1*]

1 LEPABE - Laboratory for Process Engineering, Environment, Biotechnology and Energy, Faculty of Engineering, University of Porto, Rua Dr. Roberto Frias, 4200-465 Porto, Portugal

**Corresponding author: fgm@fe.up.pt*

Highlights

- Topping distillation unit simulation model for a variety of crude oil assays.
- Characterization of the energy efficiency in processing crude oils using data envelopment analysis as a tool.

1. Introduction

Crude oil refining is a very energy intensive industry. Modest increases in performance typically translate into considerable energy savings [1], creating a strong drive in this industry to optimize their operations by focusing on various process options and configurations.

One of the key decisions to be made by refineries' management teams is which crude oils should be selected for attaining the energy consumption target performances. A large number of factors may play a strong role in this selection, including price, estimated product distribution, geo-politics, among others. Given the high impact of energy consumption on refineries, an assessment on crude oil energy efficiency correlates closely with process economics and could be an important and complementary tool for crude oil selection.

2. Methods

The focus of this work is on the impact of the crude oil selection on energy efficiency obtained by simulation approach, using a fixed process set-up and operation objectives, thus enabling a quick scan of many different assays.

A simulation model of a topping distillation unit was implemented in Aspen Plus V9. In this set-up, crude oils are pre-heated through a heat transfer network, and further heated in a furnace before being feed to the distillation unit. The furnace heating power (FP) is the main (heating) energy consumption. The distillation column includes four outlet streams enabling the separation of crude oil components according to their boiling points, obtaining naphtha, kerosene, gasoil and residue as main products. The sum of all heat released is defined as the total cooling power (TCP).

A collection of 10 assays was selected from the Aspen Plus data bank. The distillation system model was simulated using a fixed feed rate for each of the 10 assays.

Data Envelopment Analysis (DEA) is an efficiency-modelling framework [2], where efficiency indexes are expressed as a weighted quotient of (valuable) outputs to (cost) inputs and ranging from 0 (inefficient) to 1 (efficient). The efficiency indexes take the general form:

$$\theta = \frac{\sum_i w_i \times output_i}{\sum_j w_j \times input_j} \quad (1)$$

In the context of crude refining, outputs include one or more product flowrates and inputs include at least one energy consumption. Several output/input configurations were used, each providing complementary information on process energy efficiency. The scenarios considered are presented in Table 1:

Table 1. Scenarios used for energy efficiency ranking.

Scenario	Inputs	Outputs
1	FP	GKN
2	FP, TCP	GKN
3	FP	GKNR
4	FP	NAFHTHA, KEROSENE, GASOIL, RESIDUE

Where GKN is the combined flowrate of gasoil, kerosene and naphtha, and GKNR the total outlet flowrate (GKN and Residue flowrates). For all scenarios, a DEA model was created and energy efficiency indexes were calculated. pyDEA [3] was used as the DEA solver.

3. Results and discussion

The energy efficiency scores obtained for each of the identified scenarios are presented in Table 2:

Table 2. Energy efficiency indicators for each crude oil assay using Scenarios 1 - 4.

Scenario	ARABLT1	ARGYLL	ASHTART	BACHAQUE	OSEBERG	SAHARNBL	DANISH	SKUA	WSTTXINT	BELAYIM
1	0.809	0.822	0.757	0.549	0.865	0.896	0.850	1.000	0.878	0.689
2	0.910	0.910	0.921	0.778	0.942	0.897	0.901	1.000	0.895	0.832
3	0.806	0.778	0.868	1.000	0.785	0.701	0.764	0.698	0.715	0.867
4	1.000	0.985	1.000	1.000	1.000	1.000	1.000	1.000	1.000	1.000

In Scenario 1, the special focus was to obtain more valuable product streams, by excluding the residual stream. SKUA crude oil is the most energy efficient crude oil. Scenario 2 is a slight variation of the Scenario 1, where the furnace heating load and the total cooling are considered as independent inputs, with no significant impacts other than generally increasing the efficiency indicators. In Scenario 3, as the target output was the total production (GKNR), BACHAQUE is considered the most efficient. This crude has a high residue flowrate, which typically requires much less energy consumption. In Scenario 4, all of the outlet flowrates were considered independently, resulting that there are no differences in energy efficiency performance. Increasing the number of independent DEA inputs or outputs typically leads to a loss of resolution. As long as a crude oil yields a high content of any of the refinery's products, its efficiency will be high. In this sense, Scenarios 1 and 3 provide more insightful information on product distribution and energy efficiency.

4. Conclusions

Indicators obtained by DEA have proven to be useful to provide useful information on crude oil energy efficiency. Extensions in the number of assays and benchmarks will provide greater generality.

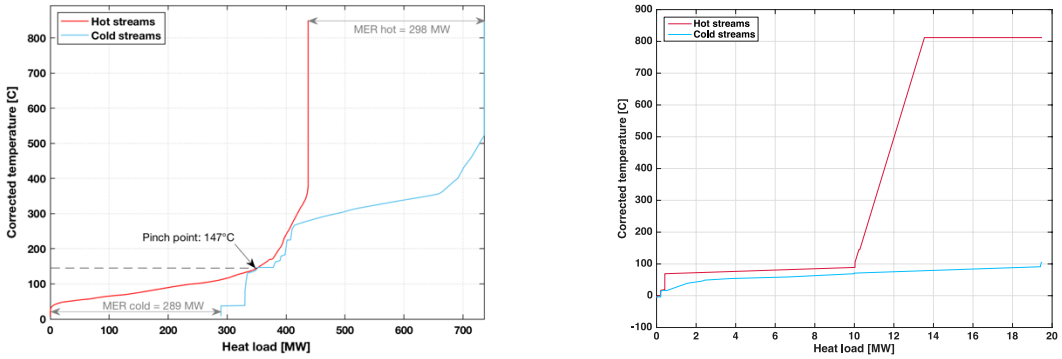
Highlights

- Utilisation of blueprints for the detection of industrial symbiosis opportunities
- Heat integration between a refinery and a District Heating Network

1. Introduction

Industrial Symbiosis (IS) is at the heart of the European Union's (EU) strategy to transition towards a lower carbon and more circular economy. It focuses on the cooperation of large and small enterprises in industrial or district clusters for exchanging materials, energy and waste (co-product) [1] as well as services, technologies or even knowledge and information [2], [3]. However, data confidentiality is still a barrier, preventing the discovery of new IS opportunities. The concept of blueprints [4], developed in the framework of the EPOS project [5], is a solution for sharing information across industry sectors. In this abstract, the blueprints' thermal energy profiles of a refinery and a District Heating Network (DHN) are combined in order to find heat integration opportunities between a petrochemical site and a nearby community.

2. Methods



(a) (b)

Figure 1. Refinery (a) and DHN (b) blueprints' thermal profiles

The blueprint's thermal energy profile includes the hot and cold requirements of a given process [4], represented by Pinch Analysis composite curves [6]. The refinery's blueprint consists of 10 interconnected process units comprising: a crude distillation unit, a gas plant, three hydrotreatment units, a catalytic reformer, an isomerisation unit, a vacuum distillation unit, a

visbreaker and a fluid catalytic cracker with a total capacity rate of is 35'000 t_{crude}/d. The DHN blueprint is available for four different climate locations, obtained using the European heating and cooling indices [7]. In this work, the distribution network is located in the Northern Zone (Zone 5) with a population of 10'000 inhabitants. The refinery and DHN thermal profiles are respectively displayed in figure 1.

3. Results and discussion

Table 1 shows the DHN's thermal power consumption before and after heat integration with the refinery. The DHN's energy consumption is decreased by ~50% (-9.57 MW) after the integration with the refinery. It shows that there is an interesting potential for creating a synergy between a refinery and an urban area. Nevertheless, it should be noted that the distance between the refinery and the DHN is not considered (no heat losses and no pressure drop) as well as the related investment costs.

Table 1. DHN thermal power consumptions before and after integration with the refinery

	Power Business as Usual (kW)	Power after integration (kW)
Refrigeration	200	200
Centralised heating	142.2	0
Electrical heating	47.84	0
Heating District Hot Water	2'031	2'031
Space heating	7'446	7'446
Boiler	9'380	0
TOTAL	19'247	9'677

4. Conclusions

The use of blueprints is a powerful tool for overcoming the burden of industrial data confidentiality. The case of heat integration between a refinery and a DHN demonstrates that blueprints can be used for the identification and evaluation of new IS opportunities. When integrated with the refinery, the DHN's energy consumption is reduced by 50%. This case can also be replicated for other geographic zones, different population sizes and for various capacity rates of the refinery. A complete thermos-economic study should also be carried in order to take into account all the costs.

Optimal Process Design for a Sustainable Methanol Production Using Renewable Energies by Applying the FluxMax Approach.

Dominik Schack[1], Kai Sundmacher[1,2]

1 Max Planck Institute for Dynamics of Complex Technical Systems, Sandtorstr.1, D-39106 Magdeburg, Germany; 2 Otto-von-Guericke-University Magdeburg, Universitätsplatz 2, D-39106 Magdeburg, Germany

**Corresponding author: schack@mpi-magdeburg.mpg.de*

Highlights

- Simultaneous flux optimization and heat integration.
- Decoupling of nonlinearities by discretization of thermodynamic state space.
- Versatility of FluxMax approach demonstrated at different levels of details.
- Powerful tool for identification of novel, non-intuitive, processes.

1. Introduction

In the context of energy transition, one of the major goals of the chemical industry is to replace fossil raw materials with renewable resources by using sustainable process technologies. However, even if in the main focus of interest, not only the substitution of feedstock, but also an increase in energy efficiency will be decisive for a successful transition towards a more sustainable production of chemicals. In order to enhance the overall process efficiency, challenges must be faced at different levels of detail. While at the plant level, more general questions and early stage decisions of chemical production networks are addressed, at the process level and process unit level the detailed optimization of chemical processes and process units is in the focus. We developed the FluxMax approach that enables the simultaneous flux optimization and heat integration by discretization of the thermodynamic state space. As a consequence, process-based nonlinearities are decoupled effectively from the flow optimization problem, which allows the optimization of chemical processes across different length. Heat integration is considered as integrated part of the optimization problem by introducing additional inequality constraints, which results in an outperformance compared to classical, sequential approaches.

2. Methods

The general idea of the FluxMax approach is an effective decoupling of process-based nonlinearities from the subsequent network flux optimization by discretization of the thermodynamic state space. The discretization allows the representation of chemical process across different length scales, which enables the transformation of a nonlinear process optimization problem into a convex flux optimization on a defined network graph. The chemical process is represented as directed graph, where the nodes correspond to thermodynamic substances, elementary processes and heat and work utilities. While each mixture is uniquely determined by thermodynamic coordinates, the elementary processes are uniformly described by stoichiometric equations. The edges, that connect the nodes, correspond to mass- and energy fluxes, and are decision variables of the optimization problem. As a result, the FluxMax approach

can be divided into the three steps: i) discretization of the thermodynamic state space; ii) modeling of elementary processes; and iii) solution of the flux optimization problem.

3. Results and discussion

The methanol synthesis process was selected as example to apply the FluxMax approach to different levels of details. At the plant level [1,2] we systematically analyzed the influence of feedstock and energy sources on the specific methanol production cost and its specific CO_2 emissions. It could be shown that an economically competitive production process can be designed also under the usage of renewable energies (Figure 2 A). As a consequence of the simultaneous consideration of heat integration, the FluxMax approach identified energy-optimal process configurations [3], which outperform configurations identified in a sequential procedure (Figure 2 B). The proof-of-concept for the application at process unit level was provided for the reactor (Figure 2 C) and compressor cascade design of the methanol synthesis [4].

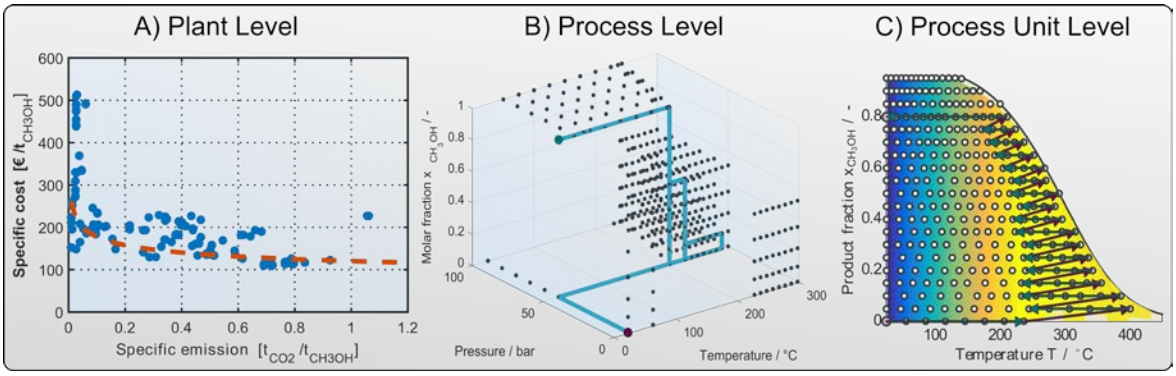

Figure 1. Pareto optimum of competing objectives, specific cost and CO_2 emissions (A), optimal trajectory of methanol synthesis process within discretized thermodynamic state space (B), and kinetic rate optimization of reactor part (C).

4. Conclusions

In this contribution, the FluxMax approach for the optimization of chemical processes across different length scales is presented, which enables the simultaneous flux optimization and heat integration. The introduction of nodes corresponding to mixtures, elementary processes and utilities allows the representation of any chemical process as a directed graph, with the edges corresponding to the mass and energy fluxes to be optimized. As a consequence, the FluxMax approach effectively decouples process based nonlinearities from the optimization problem. The heat integration is considered by additional constraints in the optimization. Using the methanol synthesis process as example, the FluxMax approach was applied to different levels of details. In particular the outperformance compared to classical approaches makes the FluxMax approach a powerful tool for designing chemical processes across different length scales.

Evaluation of Hybrid Electric Steam Generation for a Chemical Plant under Future Energy Market Scenarios

Holger Wiertzema[1], Elin Svensson[2], Simon Harvey[1]

1 Chalmers University of Technology, Division of Energy Technology, 412 96 Göteborg, Sweden;
2 CIT Industriell Energi AB, 412 88 Göteborg, Sweden

**Corresponding author: holgerw@chalmers.se*

Highlights

- Hybrid electric steam generation can be economically feasible already today
- The cost-optimal capacities are very sensitive to future energy market conditions
- Electricity is compared with biomethane as fuel for steam generation

1. Introduction

Industrial processes currently account for 25–35% of the world's total energy demand and related emissions. During recent years, the amount of low-carbon electricity from renewable energy sources (such as wind and solar) has increased continuously while the corresponding electricity generation cost has fallen. This leads to an increasing interest in process electrification to reach long-term goals for reduction of greenhouse gas emissions. One option to reduce CO_2 emissions from the utility system of chemical plants is to implement hybrid electric steam generation concepts in which electric and gas boilers are coupled. It is assumed that the gas boiler can switch freely between natural gas and bio-methane fuels.

The objective of this study was to evaluate hybrid electric steam generation for a specific chemical plant in terms of CO_2 emissions and cost under future energy price and policy conditions.

2. Methods

In the first step, an optimization model was used to identify the optimal boiler capacities to reach the lowest total annualized cost for a hybrid system. The model takes into account the specific characteristics of the steam demand and the steam generation technologies. It was applied to a refence scenario with current Swedish energy market conditions, as well as two sets of future energy market scenarios from the ENPAC model [1]. ENPAC is a tool to generate consistent scenarios for energy prices and marginal CO_2 emissions associated with the use of energy for large-volume industrial customers based on forecasted prices for fossil fuels on the commodity market and costs associated with emitting CO_2. The scenarios used in this work were generated based primarily on output from the "New policies" and "Sustainable development" scenarios from the IEA's World Energy Outlook [2]. For these scenarios, power grid capacity additions are assumed to generate electric power from renewable sources with no CO_2 emissions with wind power as marginal electricity production technology. The scenarios also include data for costs for biomass fuel as well as CO_2 emissions related to increased use of biomass, under the assumption that biomass is a limited resource. In both scenarios, the significant increase over time of the charge for

emitting fossil CO_2 leads to a major increase of the market price of natural gas, but it also leads indirectly to a significant increase of the cost of the biomass feedstock for production of bio-methane.

In this work, steam generation capacities were fixed to values corresponding to the average optimal values resulting from the "New policies" scenarios for the period 2025-2040 in order to simulate an investment decision. The boiler system performance was then evaluated by a what-if analysis in terms of CO_2 emissions and cost for the "New policies" and the "Sustainable Development" scenarios for 2025, 2030 and 2040. Additional runs were performed in which the system was forced to follow an emission reduction path at the lowest cost, allowing the gas boiler to switch from natural gas to biomethane if necessary. The emission reduction was in line with the Swedish target of net zero emission of greenhouse gases by 2045.

3. Results and discussion

Results from the first step show that hybrid steam generation concepts can be economically feasible even under today's energy price conditions. In the "New policies" scenario, the optimal capacity for the electric boiler for the energy market conditions in 2030 and 2040 are only slightly higher than the one in 2025. In contrast, the optimal electric boiler capacity for 2030 and 2040 in the "Sustainable Development" scenario is equal to the maximum steam demand, meaning that there would be no investment in a gas boiler.

The what-if analysis with fixed capacities reveals for the "New policies" scenario that there is only a slight increase in total annualized cost when emission constraints that are in line with the Swedish emission reduction goals need to be respected. Under these conditions, there is a shift of boiler load from the gas to the electric boiler. In 2040, the electric boiler even replaces the gas boiler as baseload technology. For the "Sustainable Development" scenario, there is no change in total annualized cost when adding the emission constraint. This is due to the higher cost associated with natural gas. For both scenarios, the choice of biomethane to reduce CO_2 emissions would be much more expensive than replacing natural gas by electric boiler.

This study takes only yearly values for the electricity price, the natural gas price and cost associated with CO_2 emissions into account. An assessment on an hourly basis would allow a more detailed assessment and would enable a correspondent operational scheduling of the technologies.

4. Conclusions

Electric and hybrid steam generation can reduce emissions of the utility system and can be economically feasible even today. The emission reduction and cost-benefits of the electric steam generation is amplified when taking assumed future energy market conditions into account. From a cost perspective, electricity as fuel to produce steam is more attractive than biomethane.

Simulis Pinch: quick and efficient process energy integration in Microsoft® Excel

Olivier Baudouin[1*], Stéphane Déchelotte[1], Philippe Leurent[1], Benjamin Wincure[2]

1 ProSim SA, Immeuble Stratège A, 51 rue Ampère, F-31670 LABEGE, France

2 ProSim, Inc., 325 Chestnut Street, Suite 800, Philadelphia, PA 19106, USA

Highlights

- Process energy integration;
- Pinch technology;
- Microsoft Excel.

Industrial sectors account for one third of global energy consumption. A common feature of industrial processes is reliance on fossil fuels as the primary source of energy, where a large part of the energy consumption is spent on production of utilities. Due to the huge negative impacts of fossil fuel combustion on the environment, the scientific world makes a significant effort to find alternative sources of energy. However, even by the most optimistic assessments, these alternatives are long-term solutions and many projections show that in the near future, fossil fuels will remain the primary sources of energy, in particular for the process industries.

Pinch analysis [1] is a well-known methodology to optimize process energy consumption. It allows the determination of the minimum required process utilities consumption. Simulis Pinch [2], software used directly in Excel, has been developed to perform energy integration calculations with the pinch method, while also systematically considering real-world engineering constraints. Based on a chosen pinch that is acceptable for the whole process, Simulis Pinch calculates the minimum utility requirements and the maximum heat that can be recovered through energy integration. The software also plots the hot and cold composite curves, as well as the grand composite curve. The energy integration concept is used by the software to reach the optimal synthesis of a heat exchanger network that achieves the maximum energy recovery. In Pinch theory, the synthesis of the optimal heat exchanger network is subject to construction rules (for example, the division of the problem into two sub-problems, one below and the other above the pinch temperature). However, the ideal point may not be simple to reach (due to partial exchanges on streams, stream divisions…), and the number of heat exchangers needed may be significant. While optimisation tools can help to determine the optimal structure of the heat exchanger networks using MINLP-type algorithms, these tools often have calculation times that are very long, and their convergence on an industrial scale is not guaranteed. The approach of Simulis Pinch is more pragmatic: the aim is to quickly propose some good solutions with a limited number of heat exchangers. The method is not an “optimal” method in the mathematical sense of the term, as it systematically aims to exchange the maximum power between two streams. If a hot stream and a cold stream can exchange heat, the algorithm searches for the possible couplings that allow the exchange of the

maximal thermal power under certain limitations or “boundary conditions”. The automatic synthesis of a ‘good’ heat exchanger network takes into account the specific constraints on particular exchanges (fluids incompatibility, different units, distance, difficulties…). Between two streams that can exchange heat, the combination of the possible exchanges is limited to a maximum of 3 possible couplings between these streams.

An application example, from an industrial case of an existing bio-refinery, will be presented to illustrate the use of Simulis Pinch. Two heat exchanger networks are proposed, which take into account the on-site constraints. The heat recovered corresponds to more than 80% of the MER (Maximum Energy Recovery).

Thermochemical energy storage materials for high-temperature concentrated solar energy

Marco Gigantino[1], Aldo Steinfeld[1*]

[1] *Department of Mechanical and Process Engineering, ETH Zurich, 8092 Zurich, Switzerland*

**Corresponding author: aldo.steinfeld@ethz.ch*

Highlights

- High-temperature heat was stored via the $SrCO_3$/SrO and CuO/Cu_2O cycles.
- MgO and YSZ were selected as support framework to diminish thermal sintering.
- Preparation methods affected the cycling performance.
- Stable energy density was achieved over 100 consecutive cycles.

1. Introduction

Thermochemical energy storage (TCS) employs reversible endothermic/exothermic chemical reactions to store/release heat delivered by concentrated solar energy systems, thus overcoming solar radiation intermittency and enabling round-the clock dispatchability of high-temperature process heat. The TCS approach is considered attractive since it can achieve higher energy densities than sensible and latent energy storage [1]. Several metal oxides which undergo gas-solid reactions are suitable materials for high-temperature TCS systems (>600°C), but very often they exhibit a decreasing extent of conversion (directly related to the energy density) over consecutive charging/discharging cycles due to sintering. Of special interest are the $SrCO_3$/SrO and CuO/Cu_2O cycles that store heat at around 1000°C.

2. Methods

To tackle sintering and maintain cycling stability, sintering-resistant materials MgO and YSZ were incorporated into SrO and CuO, respectively, by means of various mixing methods, namely: dry-mixing, wet-mixing, co-precipitation and sol-gel. The resulting SrO-and CuO-based materials were tested over multiple consecutive charging/discharging cycles in a thermogravimetric analyzer.

3. Results and discussion

The specific thermal energy storage capacity and cyclic stability over multiple carbonation-calcination cycles was systematically investigated by thermogravimetry for different precursors, sintering-resistant additive contents, mixing methods, operating and pre-treatment conditions.

4. Conclusions

Full stability over 100 consecutive charging/discharging cycles was achieved for a MgO-stabilized SrO-based material (40 wt% SrO) and a YSZ-stabilized CuO-based material (65 wt% CuO) with values of gravimetric energy densities of 0.81 MJ/kg and 0.56 MJ/kg, respectively.

Synthetic inertia provision by fast responsive reversible hydrogen production processes

Jens Baetens[1], Danny Smet[2], Greet Van Eetvelde[1,2] and Lieven Vandevelde[1]

1 Electrical Energy Laboratory (EELAB), Department of Electrical Energy, Metals, Mechanical Constructions & Systems (EEMMeCS), Ghent University, Tech Lane Ghent Science Park – Campus A, Technologiepark-Zwijnaarde 131, 9052 Ghent, Belgium; 2 INEOS Group

**Corresponding author: j.baetens@ugent.be*

Highlights

- Need for synthetic inertia with increasing RES penetration.
- Potential in electrolysis processes and fuel cells.
- Large overall potential in DSM for provision of ancillary services.

1. Introduction

One of the effects of integrating more RES in the electricity grid is the loss of system inertia. Classical thermal power plants have large rotors, all spinning at speeds so to generate power at 50 Hz, hence the term synchronous generators. The total mass of these rotors inherently created a large system inertia, limiting the Rate of Change of Frequency (RoCoF) in case of a disturbance. The RoCoF is a measure for the robustness of the electrical grid and needs to be maintained within certain limits for safe operation.

2. Inertia in the electricity grid

ENTSO-E, the European Network of Transmission System Operators for Electricity, has launched a guidance document for the implementation of Synthetic Inertia (SI) for countries that already see large penetration of RES in their network [1]. ENTSO-E defines SI as a facility provided by a power park or HVDC system to replace the effect of inertia by synchronous generators. While able to be provided by wind or solar power parks [2], also on the demand side possibilities are identified. Already in 2015 a private company made news with the possibility of providing SI with an electrolysis process. The respective system was able to respond within 800 ms and 140 ms for the "turn on" and "turn off" respectively [3]. Indeed, also in the doctoral dissertation of Rezkalla M., Demand Side Management is identified as one of the suitable technologies for inertia support. It is also stated that the capacity of DSM has been underestimated due to the complexity considering monitoring and aggregation [4]. With recent advances on both levels, DSM could withhold a large potential in providing ancillary services, including SI.

While in some EU countries regulation regarding frequency response from large RES power parks are already in place, no real market for inertial frequency response is set-up. This with the exception of Ireland where with the DS3 program system services like synchronous inertial response and fast frequency response are contracted with market parties [5].

3. Link to chemical industry

Building an electrolyser for the sole purpose of supporting the grid by supplying synthetic inertia or Frequency Containment Reserves (FCR) might not be economically viable. For that reason it should be looked at from a different viewpoint. Let's take hydrogen as an example. The large majority of the used hydrogen in chemical industry today is produced by Steam Methane Reforming (SMR) with natural gas, releasing large amounts of CO_2. A hydrogen demanding process could be fed with own – electrolyser produced – hydrogen. Combining intermediate hydrogen or methanol storage with a hydrogen or methanol fuel cell creates ideal storage potential, with the possibility of feeding electricity back into the electricity grid. With respect to the storage, methanol is to prefer over hydrogen for large scale and longer term storage. Drawbacks of hydrogen storage are the diffusivity, high pressures and lower caloric value compared to methanol. Methanol synthesis can be done with CO_2 captured from an own – preferably high CO_2 concentration - process stream, reducing the direct CO_2 emissions.

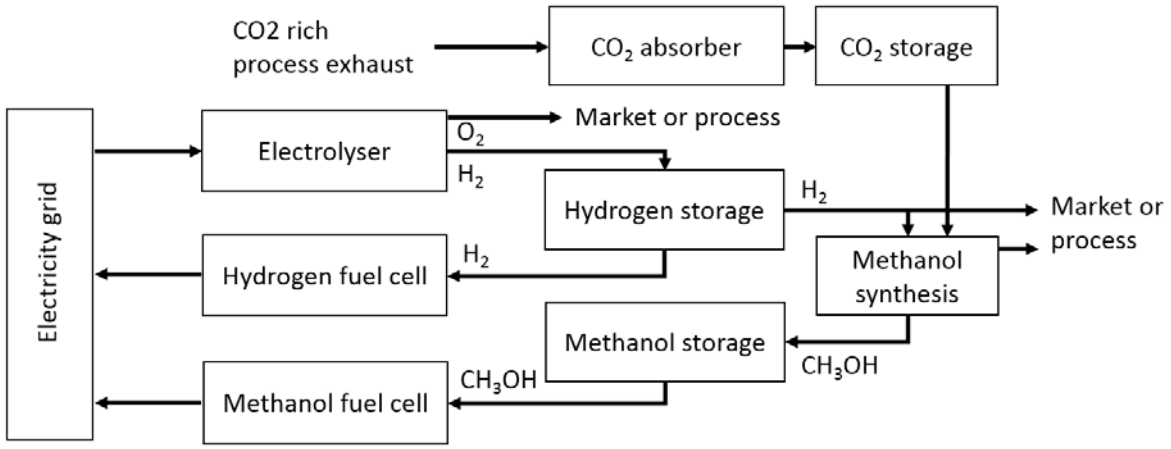

Figure 1: Flow diagram of reversible hydrogen production installation

4. Conclusion

With the increasing penetration of RES in the synchronous grid, caution should be taken to maintain the systems inertia, limiting the ROCOF. In chemical industry, potential is present in the form of electrolysers and fuel cells, which can be controlled to deliver synthetic inertia. The economics of SI provided by dedicated electrolysers might not be viable. Therefore integrated systems could be implemented, in which the provision of SI and ancillary services in general can create extra revenue.

Usage of Future Energy Market Scenarios for Assessing the Benefits of Residual Heat Recovery From a Chemical Cluster in Western Sweden.

Simon Harvey[1,*], Erik Axelsson[2], Thore Berntsson[3], Johan Holm[2]

1 Energy Technology, Chalmers University of Technology, Göteborg, Sweden;
2 Profu AB, Göteborg, Sweden; 3 CIT Industriell Energi AB, Göteborg, Sweden;
**Corresponding author: simon.harvey@chalmers.se*

Highlights

- 140 MW of residual heat are available at a chemical cluster in Western Sweden
- This heat could be delivered to the city of Göteborg, constituting the largest industrial residual heat recovery project in Sweden
- The costs and climate benefits are analyzed using energy market scenarios

1. Introduction

Over 50% of building heating requirements are covered by district heating in Sweden. Approximately 8% of the heat supply to district heating systems comes from residual heat from industrial processes. Many studies indicate that there is a potential to substantially increase this share, and a number of policies promoting energy efficiency and greenhouse gas emissions reduction are providing incentives to do this. Quantifying the medium and long term economic and climate benefits of such investments is difficult because the background energy system against which new investments should be assessed is also expected to undergo significant change as a result of the afore-mentioned policies. Furthermore, in many cases, the district heating system has already invested or is planning to invest in non-fossil heat sources such as biomass fueled boilers or CHP units. This paper illustrates usage of energy market scenarios for assessing the long term benefits of recovering residual heat from a chemical cluster located approximately 50 km from the city of Göteborg on the West Coast of Sweden and delivering the heat to the city's district heating network which aims to be completely fossil-free by 2030.

2. Methods

Availability and costs for residual heat at the chemical cluster site were investigated in previous work [1] using pinch analysis tools. Piping costs for transporting the residual heat from the chemical cluster to the city's district heating system were estimated from previous studies, as summarized in [2]. The impact of delivery of the residual heat on district heating system production costs and greenhouse gas emissions was performed using the method described in [3]. Energy carrier costs and carbon intensity factors were estimated for future energy market conditions using the ENPAC tool described in [4]. The energy market scenarios include energy prices for years 2030 and 2040 for two different scenarios based on the IEA's World Energy Outlook 2017 [5]: New Policy (NewPol) and Sustainable Development (SustDev). The NewPol scenario reflects implementation of global policy announcements and plans, which is expected to lead to moderately increasing energy prices. The SustDev scenario reflects global commitment to sustainable development, resulting in high carbon dioxide prices, which we have extrapolated to also imply high biomass fuel prices.

3. Results and discussion

140 MW of residual heat are available at the chemical cluster. If recovered and transferred to the district heating in Göteborg, this would be the largest residual heat recovery project in Sweden. The total investment cost to collect 140 MW of residual heat and deliver it to the district heating system is approximately 3 billion SEK. Figure 1 shows the total costs for this investment compared with investment in a biomass-fired CHP plant with the same heat output. The direct climate consequences of using the residual heat are negligible for both the chemical cluster and for the district heating system. However, decreased use of biomass and decreased electricity production will affect the climate impact of the surrounding energy system. Assuming fossil-free grid electricity production in the future, the climate consequences of decreased electricity production in the CHP unit are also close to zero. Hence, decreased firing of biomass in the CHP unit is the main cause of climate consequences of residual heat recovery. Assuming that biomass will be a limited resource in the future, the released biomass can be used to further decrease the use of fossil fuels. In this case, the carbon dioxide decrease is approx. 200 ktonnes per year.

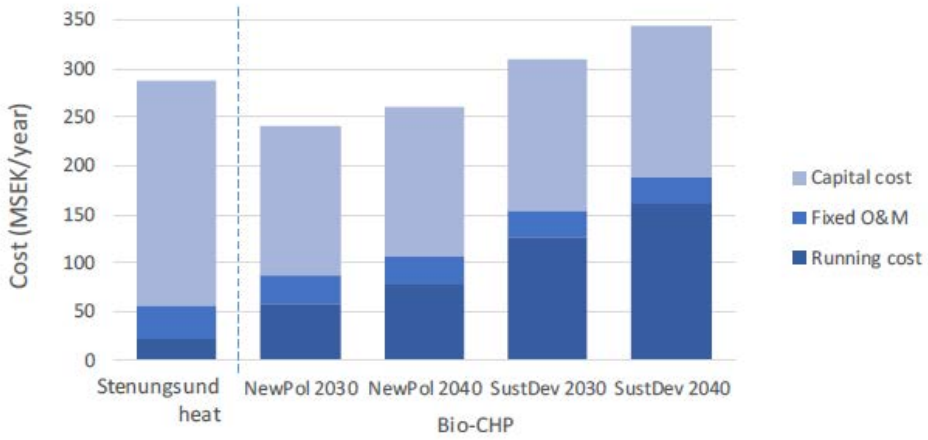

Figure 1. Total cost for residual heat from the Stenungsund chemical cluster and a bio-CHP plant, both delivering 140 MW heat and with about 5000 hours of yearly utilisation time.

4. Conclusions

There are many opportunities to substantially increase recovery of residual heat from industrial processes and clusters. Industry as well as the heating and power sectors are in a period of rapid transition due to ambitious energy efficiency and greenhouse gas emission reduction policy targets. As a result, new methods are necessary to understand the economic and climate consequences of recovering residual heat for use in the heating sector.

Hydrothermal Treatment of Spent Contaminated Ion Exchange Resins in Sub and Supercritical Water.

Antoine Leybros, Jean-Christophe Ruiz, Thibault d'Halluin, Egle Ferreri and Agnès Grandjean

CEA, DEN, Univ. Montpellier, DE2D, SEAD, LPSD, F30207 Bagnols sur Cèze, France;

**Corresponding author: antoine.leybros@cea.fr*

Highlights

- Efficiency of hydrothermal process to degrade Cs; Sr; Co and Eu exchanged IER.
- Leaching yields around 100 % are obtained for Cs; Sr and Eu using batch setup.
- A semi-dynamic process allows an efficient treatment of IERs.

1. Introduction

Some water treatment systems in nuclear industry involve Ion Exchange Resins (IER) to control water chemistry, minimize equipment corrosion and remove radioactive contaminants. Typically, the volume of contaminated IER from a nuclear power plant is around 5-7 m^3 per reactor and per year. The different issues studied for these IER solid waste is either the immobilization in an inert matrix (cement, bitumen, polymer) or the mineralization, so as to obtain inorganic residues before solidification [1]. Among mineralization processes, hydrothermal treatment in sub or supercritical water may be a promising alternative to leach resins and recover radionuclides such as ^{137}Cs, ^{90}Sr, ^{60}Co or transuranic in an aqueous solution. Thus, the secondary waste would be solid waste of lower radioactivity, which may be incinerated or immobilized, and liquid wastewater containing radionuclides, which can be managed simply by the liquid treatment facility. Previous studies carried out using continuous supercritical water oxidation setup allow to reach 99.9% degradation yields on crushed IER [2]. Unfortunately, owing to IER radiolytical and thermal deterioration and high radioactivity, a grinding preprocessing step is not easy to manage. This is the reason why batch and semi-dynamic process have been considered on millimeter size resins. This study deals with the feasibility of leaching IER by hydrolysis and/or oxidation (by H_2O_2) runs carried out with temperature and pressure respectively ranging from 100 and 450°C and from 20 and 300 bar.

2. Methods

Considered IER are strong cationic Amberlite IRN77 and anionic Amberlite IRN78. Contamination of each species of interest (Cs, Sr, Co and Eu) is 10 mg/g IER. The setup used to carry out runs under subcritical and supercritical hydrothermal conditions is described Figure 1. A titanium jacket allows to confine aggressive species and protect reactor outer walls from corrosion. Furthermore, this

jacket is flexible to compensate any difference of pressure with the reactor. During batch experimental runs, {IER/ water or water + H_2O_2 with stoichiometric ratio equal to 1.3} mixture is introduced into the jacket while the reactor is filled with water, with equivalent volume ratios. This ratio has been set to reach targeted autogenous pressure (between 60 and 290 bar) according to operating temperature (300 or 450°C). The duration of runs is about 4h.

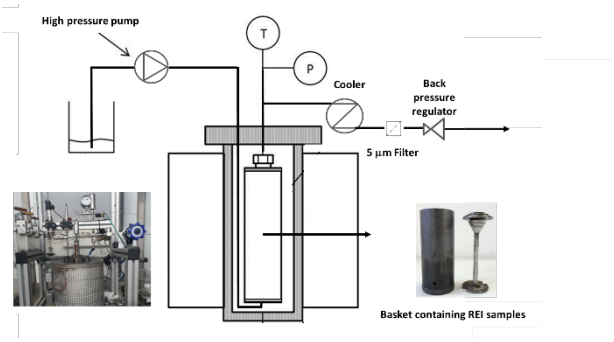

Figure 1. Experimental setup for hydrothermal treatment of IER (semi-dynamic mode)

Then, the experimental setup has been modified to be used in semi-dynamic mode. IER samples are introduced into a basket, inside the reactor, which is then fed continuously with a {water or water + H_2O_2} stream at a 5 mL/min flow rate. The reactor is heated until the working temperature is reached (set between 100 and 290°C). Pressure (from 5 to 50 bar) is controlled by a back pressure regulator. The aqueous effluents are then recovered downstream, in a collector, after cooling and depressurization. The treatment capacity of this setup is 50 g of IER per batch.

Solid residues as well as generated effluents are gravimetrically analyzed. TOC-metry is used to measure carbon degradation yields. ICP-AES and AAS analyzers are used to measure ions release (Sr, Co, Eu and Cs).

3. Results and discussion

Experimental runs in batch mode allow to highlight following trends. Whatever operating conditions, carbon degradation yields higher than 86% are obtained, with especially yield around 99.7% for hydrothermal oxidation of IRN77 IER at 450°C/290 bar. Cs, Sr and Eu leaching yields close to 100% are noticeable not only for supercritical water treatment of IRN77 or {IRN77/IRN78} mixtures but also for subcritical water treatment at 300°C/for 70 bar. On the contrary, Co leaching yield is lower than 10% for each experimental run, because of “CoS type compounds” precipitation. Speciation study in hydrothermal medium is in progress to predict and explain these results.

Semi-dynamic device allows to entirely decontaminate 50g of exchanged IER in 3h with softer operating conditions (200°C/50 bar/oxidation with H_2O_2). Furthermore, significant cobalt extraction capacity, around 460 mg/kg of water, has been obtained. Such results will be considered both for the process scale-up and for the compatibility with the downstream wastewater treatment plant.

The Experiment and Simulation Analysis of the Effect Of CO_2 and Steam On Syngas Composition of Natural Gas Non-Catalyst Partial Oxidation.

Zhenghua Dai*, Guangsuo Yu, Haifeng Lu

Key Laboratory of Coal Gasification and Energy Chemical Engineering of Ministry of Education, East China University of Science and Technology, Shanghai 200237, China

**Corresponding author: chinadai@ecust.edu.cn*

Highlights

- The syngas composition of non-catalyst partial oxidation should be adjusted to satisfy the request of different chemical synthesis.
- CO_2 has bigger adjustment range of H_2/CO ratio than that of steam.
- The multi-reforming by CO_2 or Steam addition is feasible.

1. Introduction

Non-catalyst partial oxidation technology has been widely used to produce syngas by reforming of hydrocarbon, including gas (natural gas, shale gas, refinery gas, coalbed gas, coke oven gas, pyrolysis gas, etc.) and liquid (residual oil, asphalt, deoiled asphalt, biomass oil, etc.). For natural gas non-catalyst partial oxidation, the H_2/CO of syngas is about 1.8, which is agreed well with the request of FT synthesis. But for other process, such as carbonylation and glycol, the H_2/CO should be close to 1 and 2 respectively. So the syngas composition of non-catalyst partial oxidation should be adjusted to satisfy the request of different chemical synthesis. That means a multi-reforming method by CO_2 or Steam addition.

2. Methods

The experimental platform for the non-catalyst partial oxidation of natural gas is shown in Fig.1.

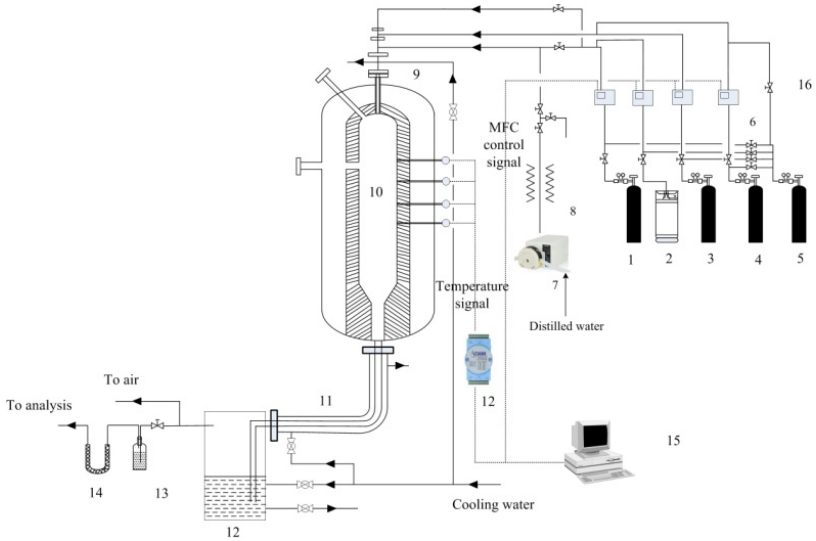

Fig. 1 Diagram of natural gas non-catalyst partial oxidation hot-model experiment platform

The reactor network model of the reformer is shown in Fig. 2.The reactions in the reformer are described by GRI-3.0.

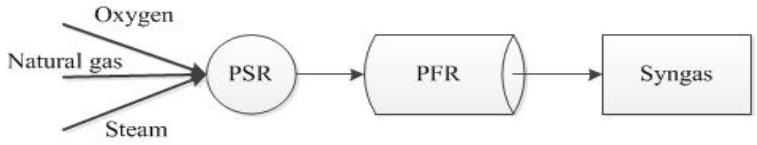

Fig.2 Schematic diagram of reactor network (PSR: 12.758m³; PFR: Length=7.08m, Diameter=1.8m)

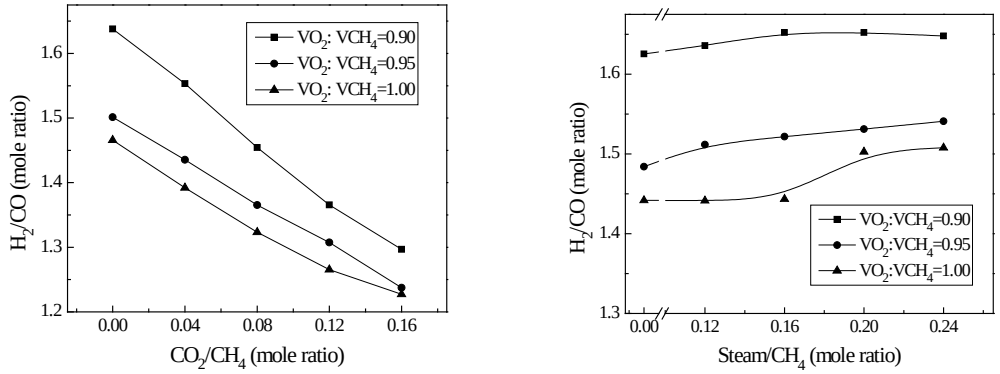
3. Results and discussion



(a) CO2 **(b) Steam**

Fig. 3 Effects of CO2 and Steam addition on the syngas compositions

The experiment results of the Effects of CO_2 and Steam addition on the syngas compositions are shown in Fig.3. For the case of the O_2/CH_4=0.95, the H_2/CO is decreased from 1.5 to 1.24 when the CO_2/CH_4 is increased from 0 to 0.16; However, the H_2/CO ratio is increased slightly from 1.62 to 1.65 When the H_2O/CH_4 ratio is increased from 0 to 0.24.

Table 1 shows the feasibility analysis results of multi-reforming. The greater of required adjustment of H_2/CO ratio, the addition amount of Steam or CO_2 into the reformer is greater. Correspondingly, the oxygen and natural gas consumption per unit effective gas is slightly increased.

Table1 The multi-reforming analysis

	1	2	3	4	5
O_2/NG(v/v)	0.775	0.690	0.657	0.675	0.720
Steam(CO_2)/NG (v/v)	1.80(H2O)	0.48(H2O)	0.107(H2O)	0.15(CO_2)	0.52(CO_2)
H_2(v%)	63.02	63.16	62.83	57.45	45.13
CO(v%)	25.15	31.65	33.87	38.35	44.60
CH(v%)	0.62	0.60	0.76	0.61	0.64
H_2/CO	2.51	2.00	1.86	1.50	1.01
T, K	1522	1562	1578	1570	1533
Oxygen $Nm^3/kNm^3(CO+H_2)$	317	262	247	255	283
Natural gas $Nm^3/kNm^3(CO+H_2)$	409	379	376	378	392

4. Conclusions

CO_2 has bigger adjustment range of H_2/CO than that of steam. This paper presents the feasibility of multi-reforming on the natural gas non-catalyst partial oxidation by CO_2 or H_2O addition.

Synthesis and Modification of Water-Stable CPL-2 MOF for Ethylene/Ethane Separation.

Huan Xiang[1], Yilai Jiao[2], Flor R. Sinperstein[1,*], Xiaolei Fan[1,*]

1 School of Chemical Engineering and Analytical Science, The University of Manchester, Manchester M13 9PL, United Kingdom; 2 Shenyang National Laboratory for Materials Science, Institute of Metal Research, Chinese Academy of Sciences, 72 Wenhua Road, Shenyang 110016, China

**Corresponding authors: Flor.Siperstein@manchester.ac.uk; xiaolei.fan@manchester.ac.uk*

Highlights

- CPL-2 MOF exhibits preferential adsorption of ethylene over ethane.
- CPL-2 MOF is relatively hydrophobic and shows excellent water stability under humid conditions.
- Ethylene/ethane adsorption selectivity was enhanced six-fold by silver ions modification.

1. Introduction

Adsorptive separation of ethylene/ethane mixture has growing interest in petrochemical industries compared to the conventional energy-intensive cryogenic distillation.[1] Metal-organic frameworks (MOFs) have attracted considerable attention in gas adsorption and separation due to their combined properties of large surface area, functionalised and adjustable pore structure and surface.[2] However, the open metal sites in MOFs interact strongly with water molecules, resulting in material decomposition and poor water stability,[3] limiting their potential in practical settings. Therefore, development of water-stable materials with high selectivity is of great importance to accomplish the ethylene/ethane separation.

In this work, pillared-layer CPL-2 MOF was selected as the model MOF and synthesised at room temperature for separating binary ethylene/ethane mixture. The water stability of CPL-2 was evaluated under dynamic humid conditions. Ag(I) ions modification of CPL-2 was also conducted to explore the possibility of improving the selectivity of CPL MOFs in ethylene/ethane separation.

2. Methods

Hydrothermal synthesis was used to prepare CPL-2. Silver ions modified CPL-2 MOFs (denoted as Ag/CPL-2) were prepared using the incipient wetness impregnation method. Dynamic water vapour adsorption analyses at 25 °C and 50 °C with relative humidity values ranging from 0% to 90% (10% per step) were measured using a dynamic vapour sorption (DVS 1) equipment. Prior to the water vapour adsorption, all samples were dried at 0% relative humidity for 3 h. Intelligent gravimetric analyser (IGA-001) based on the static gravimetric technique was applied to determine ethylene and ethane adsorption isotherms on developed CPL-2 and Ag/CPL-2 materials at a constant temperature of 25 °C, 35 °C and 50 °C, respectively. The adsorption selectivity was calculated as a ratio of Henry's constants.

3. Results and discussion

CPL-2 can be easily synthesised at room temperature, which was confirmed by XRD and SEM analysis. Characteristic peaks at 2θ = 6.4°, 8.8°, 10.3° and 12.6°, matching the simulated results, were identified in all the synthesised CPL-2 MOFs, confirming the presence of the pillared-layer structure in the crystalline domain. All SEM images show squared slab-shaped crystals aggregated together with sizes ranging from 0.2 µm to 2.5 µm. The synthesised CPL-2 has excellent water stability confirmed by the dynamic water vapour adsorption analysis under 90% relative humidity, showing no significant framework decomposition, even at 50 °C. The calculated selectivity based on gravimetric single-component gas adsorption experiments shows the significantly improved C_2H_4/C_2H_6 selectivity from 1.2 to 6.6 after loading 10% (theoretical) of sliver ions on CPL-2.

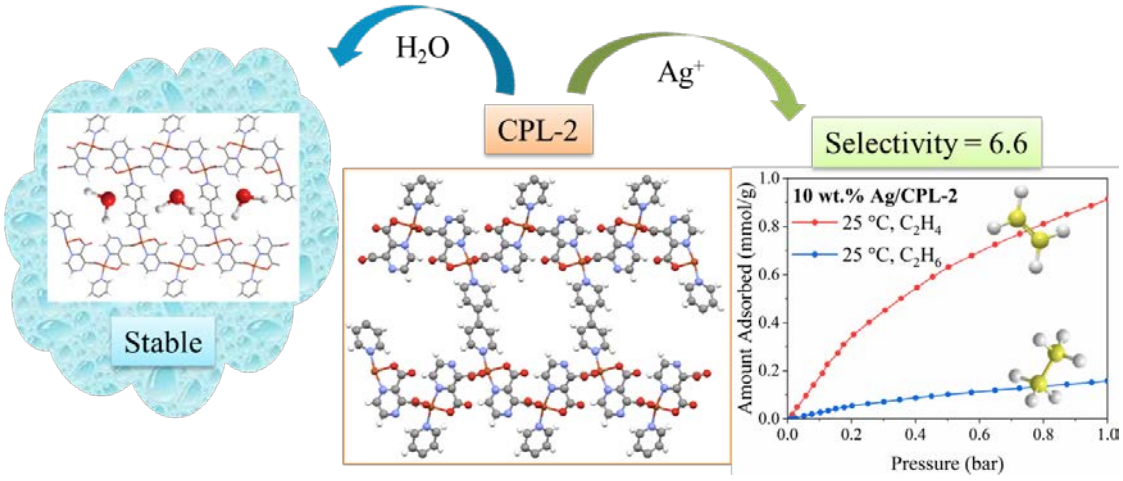

Figure 1. Schematic presentation of CPL-2 framework and its water stability and adsorption performance in C_2H_4/C_2H_6 separation.

4. Conclusions

The synthesis of CPL-2 is facile with fast crystallization, *i.e.* 3 h is sufficient to prepare CPL-2 MOF at room temperature. CPL-2 demonstrated the outstanding water stability under dynamic humid conditions at 25 °C and 50 °C, showing the reversible water vapour adsorption under the conditions used. Gas adsorption study shows that 10 wt.% Ag/CPL-2 by Ag(I) impregnation gave the best adsorption performance considering both capacity and selectivity towards C_2H_4 over C_2H_6. The good selectivity combined with the water stability makes it promising and potentially feasible to use CPL-2 in the separation of ethylene/ethane mixtures, especially under conditions where water vapour exists.

Process Integration for Decentralized Power to Fuel Conversion Based on Fischer-Tropsch Synthesis

Hannah Kirsch, Chenghao Sun, Peter Pfeifer, Roland Dittmeyer

Institute of Micro Process Engineering (IMVT), Karlsruhe Institute of Technology (KIT), Hermann-von-Helmholtz-Platz 1, 76344 Eggenstein-Leopoldshafen

**Corresponding author: hannah.kirsch@kit.edu*

Highlights

- Production of liquid fuels by coupling Fischer-Tropsch synthesis and hydrocracking.
- Integration of Fischer-Tropsch synthesis and hydrocracking in a single-stage microstructured reactor.
- Different integration patterns influence the performance of the coupled process.

1. Introduction

Global warming is to be limited to a maximum of 2 °C by 2050 compared with the pre-industrial level [1]. The transport sector's share of anthropogenic greenhouse gas emissions as a percentage of total emissions is almost 20 %, and global demand for mobility will even rise steadily in the future due to the growing world population and rising living standards. Studies show that liquid fuels will continue to play an important role in the transport sector in the future alongside alternative options such as e-mobility and hydrogen, especially for heavy goods vehicles and air traffic. So-called power-to-fuel technology can contribute to the transition of the transport sector from fossil fuels to CO_2-neutral fuels. Renewable energy and carbon dioxide are converted into alternative liquid fuels. These fuels are characterized by negligible aromatics and high volumetric energy density and the drop-in quality makes it possible to use the existing infrastructure [2]. An attractive process route is via Fischer-Tropsch synthesis (FTS) and hydrocracking (HC). Decentralized, compact plants based on process intensification enable dynamic operation in order to meet the challenges of strongly fluctuating and locally distributed renewable energies.

Related to the Kopernikus project Power-to-X and funded by the Peter-und-Luise-Hager Foundation, the process integration of cobalt-catalyzed low temperature Fischer-Tropsch synthesis with the hydrocracking of FT products in one microreactor is investigated in this contribution.

2. Methods

A Co/Re-Al_2O_3 catalyst was selected for the FTS with 20 wt% cobalt and 0.5 wt% rhenium as promoter. It was prepared by an impregnation method with γ-Al_2O_3 (3 µm, 80-120 m^2/g) as support and an aqueous solution of cobalt nitrate and perrhenic acid. The catalyst was tried overnight at 120 °C and then calcined at 400 °C for 2 h. [3]

A Pt-ZSM5 catalyst was chosen for the HC with 0.5 wt% platinum. It was prepared by impregnating H-ZSM5 with an aqueous solution of tetraamineplatinum(II)hydroxide. The catalyst was dried overnight at 120 °C and then calcined at 550 °C for 6 h. [3] Before testing, both catalysts were pelletized, crushed and sieved to obtain a size fraction of 50-100 µm. Moreover, both catalysts were characterized by common methods.

For the study of the single-stage integration of FTS and HC a micro annular fixed-bed reactor was designed (see figure 1). Both catalysts were reduced online in hydrogen atmosphere at ambient pressure and 350 °C for 15 h. Reaction conditions were: 30 bar, 225-260 °C, WHSV 6-12 h^{-1} and H_2/CO ratio 1.9. All products leaving the reactor system were first separated in a wax fraction, liquid product fraction and residual gas by a hot trap (190 °C) and a cold trap (6 °C). The residual gas was directly analyzed by an online GC, whereas the liquid and the wax fractions were sampled and analyzed by an offline GC.

Figure 1. Micro annular fixed-bed reactor for the integration of FTS and HC.

3. Results and discussion

The integration of Fischer-Tropsch synthesis and hydrocracking in a single-stage microstructured reactor for the production of liquid fuels is feasible. The liquid fuel selectivity of the coupled process is higher than for the FTS at the same conditions, indicating that the long-chain hydrocarbons are selectively cracked. Quantitative statements, however, can only be made after the product analyses have been evaluated, but this has not yet been completed. As expected, the conversion increases with rising temperature and decreasing WHSV. Both catalysts showed a reasonable long-term stability during up to 120 h of experiments.

Two different integration patterns were investigated – the sequential bed and the hybrid bed. As anticipated, the catalytic performance of the coupled process is influenced by the integration pattern. As a liquid phase is involved in the process, dilution or bed configuration might effect the wetting of the catalyst particles as well as the flow through the catalyst bed [4]. The observed trends and the reproducibility needs to be further investigated to validate the importance of several possible parameters observed in the present study.

4. Conclusions

The integration of FTS and HC was investigated in a single-stage micro annular reactor for the production of liquid fuels. The coupling of FTS and HC increases the liquid fuel selectivity by selectively cracking the long-chain hydrocarbons. The integration pattern has an influence on the catalytic performance of the combined process. The experiments show that the operation of compact small-scale power-to-liquid plants seems possible.

The model of crude oil oxidation for in-situ combustion technology.

Ushakova Alexandra, Pu Wan-Fen, Zatcepin Vladislav

The models of crude oil oxidation in terms of chain reaction approach have been developed in the recent years. The set of chemical reactions suggested in our work was simplified and solved under certain conditions.

The formation and accumulation of hydroperoxides is a key stage of the oxidation process. First oxygen molecules penetrate into the oil chains and forms free radicals. Radicals are passed from one molecule to another (chain growth), until they form hydroperoxides. Also some products of the reactions are gases CO and CO_2 water, oxidized components, aldehydes, ketones, acids. This stage is widely investigated in experiments and called low temperature oxidation (LTO). The hydroperoxides can decompose into a pair of radicals - this is a branching chain reaction. New radicals initiate the new chains and start the new processes of oxidation. The figure 1 shows the cyclic character of the oxidation through radical appearance and hydroperoxides accumulation. The more hydroperoxides are accumulated the higher is oxidation rate. This process self-accelerates and causes the ignition in crude oil with oxygen. With the temperature growth above 250 °C one can observe non-radical high temperature oxidation where chain mechanism takes place, but it is not the main one.

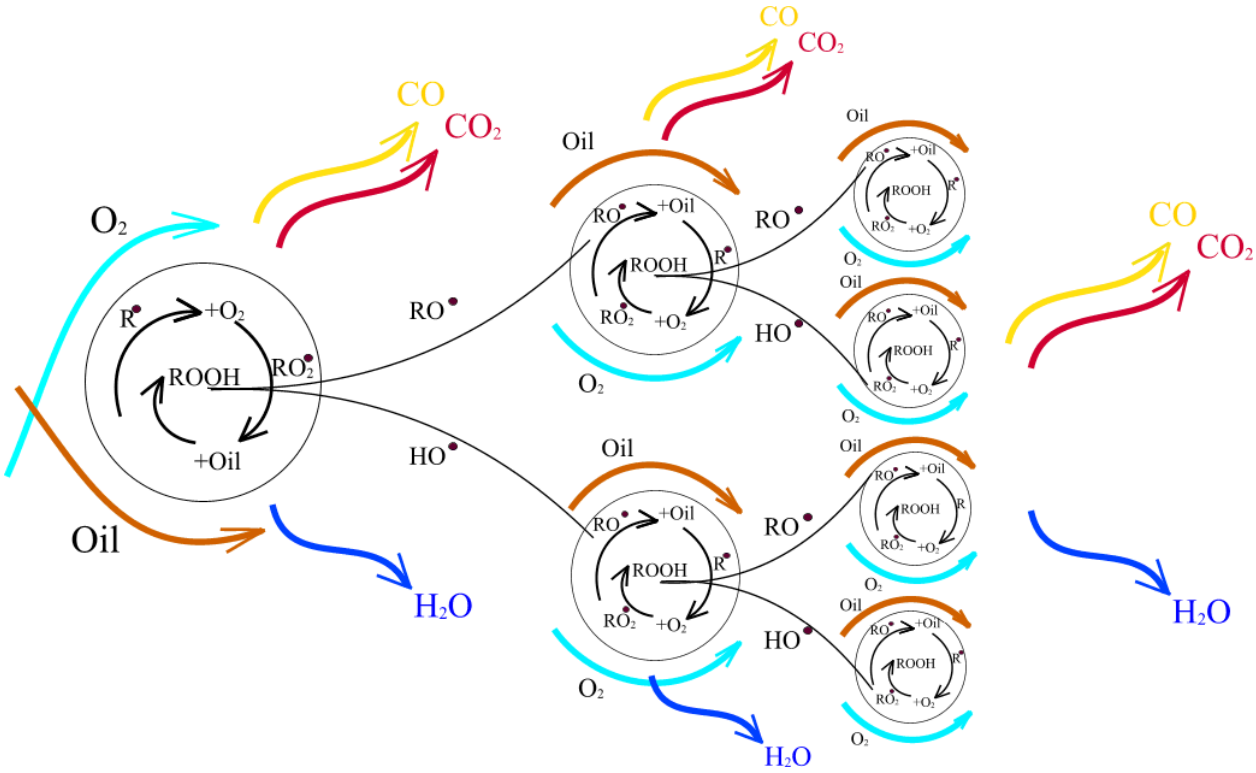

Figure 1. The scheme of chain reaction mechanism of oil oxidation

In the present oxidation scheme we consider active and inactive oil components at the initial oxidation stages. Both of these compounds oxidize simultaneously but they lead to different products. Crude oil separates into the main oxidizing components – alkanes (denoted Sat) and their oxidation inhibitors - aromatic compounds, which then form the fuel (denoted *Inh*). The other components - Resins and Asphaltenes become solid at the early oxidation stages and are out of the investigation here, they just make a gift into the heavy residuals for high temperature combustion.

The time dependence of hydroperoxides concentration strongly depends on the initial reactions rates. We drove out the dependencies for cases of exponential growth of free radical concentration – which lead to self ignition, limited growth – which leads to oxidized compound formation only and intermediate cases which have not been examined before but also exist in experiments of oil oxidation (figure 2).

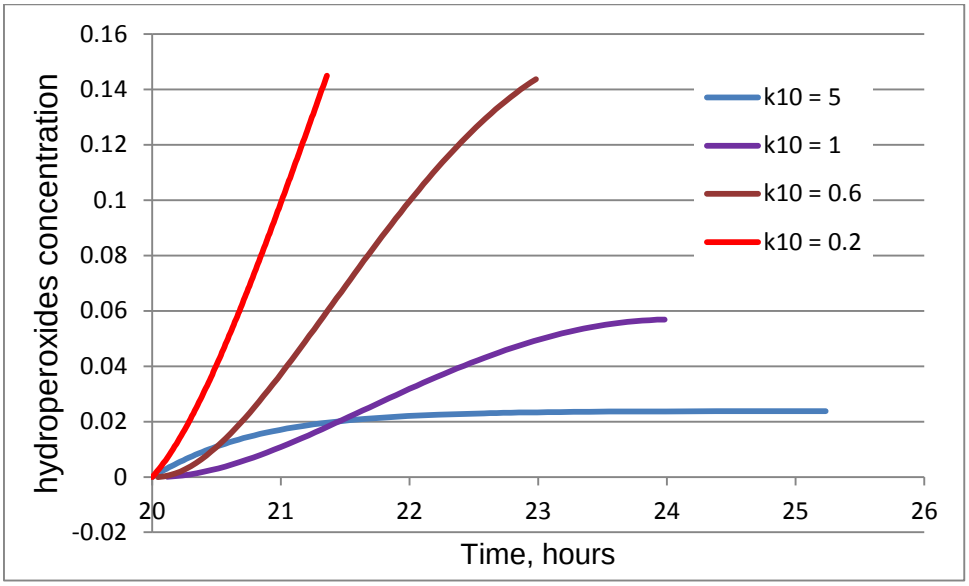

Figure 2. Time dependence of hydroperoxides concentration in oxidation process.

Here we also consider the probability of inhibition on any stage of the reaction scheme – in the chain growth stage, hydroperoxide formation and decomposition stage. In fact different types of inhibitors act at different stages. Here we attempt to solve such system of equation and obtain how the inhibition of different stages governs the whole process. It is needed to mention that oil components are very different and various types of inhibitors exist in crude oils.

We also suppose that catalytic effects of different additives which are explored in many papers cannot be we explained without inhibition scheme consideration. Because lots of catalysts prevent the inhibition reactions, act as inhibitors adsorbents or shift the balance towards slowing down the inhibition processes. All this shows that inhibition consideration is the step preceding any theoretical investigation of catalysts application.

A realistic vapour phase heat transfer model for the weathering of LNG stored in large tanks

Felipe Huerta[1*], Velisa Vesovic[1]

1 Department of Earth Science and Engineering, Imperial College London, London SW7 2AZ, United Kingdom

**Corresponding author:* f.huerta-perez17@imperial.ac.uk

Highlights

- A new model to predict the weathering of LNG in storage tanks is developed
- It dispenses with the assumption of vapour being at the same temperature as LNG
- It demonstrates that the vapour to liquid heat transfer is small
- It shows that the initial amount of LNG has a pronounced effect on weathering

1. Introduction

The global energy sector is changing unprecedently as it transitions from its reliance on fossil fuels to renewables. For the transition, natural gas will play an important role because of its competitive cost and lower emissions when compared to other fossil fuels [1]. Natural gas (NG) is predominantly a hydrocarbon mixture consisting mainly of methane and, in general, lower amounts of other *n*-alkanes and small inorganic molecules. It can be distributed to users directly from the source through pressurized pipelines or it can undergo a liquefaction process and then be distributed as liquefied natural gas (LNG), by marine transportation, to large storage facilities. LNG is becoming the preferred way to transport natural gas and it is finding an use as marine and heavy-vehicle fuel.

LNG is industrially stored in highly insulated tanks at cryogenic temperatures below -160°C, that are subject to heat ingress from the surroundings that leads to preferential evaporation of the most volatile components. The vapour produced is denominated boil-off gas (BOG), and it is typically removed to keep the tank pressure constant. The heat ingress and BOG removal produce weathering of the remaining LNG, as the concentration of the heavier components increases over time. This has major industrial implications, as it can induce safety hazards such as rollover and it limits the NG marketability. In this work, a new non-equilibrium model relevant to LNG weathering in large storage tanks has been developed.

2. Methods

The new model treats the heat influx from the surroundings into the vapour and liquid phases separately and allows for heat transfer between the two phases. The main heat transfer mechanisms in the vapour phase are assumed to be advection, due to upward flow of evaporated LNG, and conduction. The vapour heat ingress is included as a source term and the evaporative flow is approximated by an average vertical velocity. The numerical integration is based on adaptive time-steps to capture the strong transient behaviour at the beginning of weathering.

3. Results and discussion

It was observed that the vapour temperature increases monotonically as a function of the height, in agreement with recent experimental results [2] . For three typical LNG mixtures (Light LNG, Heavy

LNG and N_2-rich LNG), we observed very similar temperature profiles and vapour to liquid heat fluxes as we observed for evaporation of pure methane. In all the simulations performed the vapour to liquid heat transfer was small and is estimated to contribute less than 0.3% to BOG rates. A strong transient dynamic was found at the beginning of weathering, until a pseudo-steady state is achieved when the vapour heat ingress is balanced with the vapour to liquid heat transfer and the advective flow. Figure 1 illustrates the BOG as a function of weathering for the LNG studied. For the light and heavy LNG mixtures the model predicts a decreasing BOG rate. In contrast, for the N_2-rich LNG mixture both models predict a local maximum because of the interplay between the decreasing liquid heat ingress and decreasing enthalpy of vaporization. For all mixtures the BOG rates were between 1 and 4 % lower than in previous work [3] because of lower vapour to liquid heat ingresses.

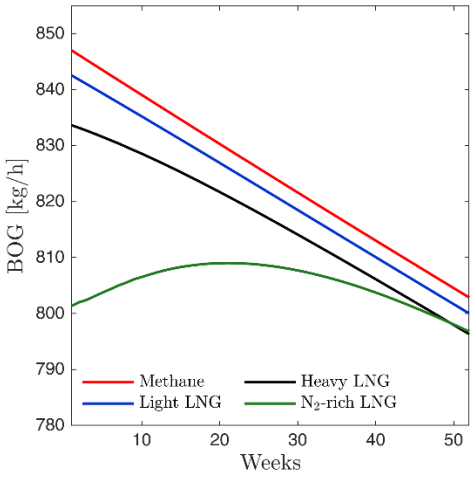

Figure 1. BOG rates as a function of time for three different LNG mixtures

The initial liquid filling has a pronounced effect, leading to a decrease in vapour and boil-off gas temperatures and an increase in boil-off rates. For a storage tank initially filled with 30% of light LNG, using previous non-equilibrium and equilibrium models [3, 4] would overestimate BOG rates by 26% and 100%, respectively. The transient time strongly depends on the initial filling of the LNG tank, with the nearly full tanks taking least time to reach the steady-state.

4. Conclusions

The results of this work indicate that the heat transfer by the advective upward flow dominates the energy transfer within the vapour, while the natural convection, in the body of the vapour, can be neglected. The developed model allows for the optimization of LNG storage tank operations and different scenario planning taking into account the initial liquid filling and nitrogen content.

Ceramic Filter Candle Filled With Catalyst Pellets Inserted in the Freeboard of a Fluidized Bed Gasifier for In-Situ Syngas Conditioning.

Elisa Savuto[1,*], Andrea Di Carlo[2], Katia Gallucci[2], Pier Ugo Foscolo[2], Sergio Rapagnà[1]

1 University of Teramo, Via R. Balzarini 1, 64100 Teramo, Italy; 2 University of L'Aquila, Via Campo di Pile, L'Aquila, Italy

**Corresponding author: elisa.savuto@gmail.com*

Highlights

- A ceramic candle filled with catalyst was inserted in the freeboard of a gasifier
- Two different catalysts (A, B) were tested for tar reforming inside the gasifier
- Catalyst B showed very good performance, reaching 89% of tar conversion
- Catalyst B was more active than catalyst A, even though used at higher GHSV

1. Introduction

Gasification is a very promising conversion process to produce a fuel gas (syngas) from biomass, usable for direct power production or for the synthesis of high quality bio-fuels [1]. However, syngas has to be cleaned before its use, in order to remove main pollutants that may compromise its exploitability: particulate and tar [2]. Fluidized bed gasifiers have several advantages, including the presence of a free space above the bed (freeboard) in which devices for in-situ gas conditioning can be integrated. In this work, a segment of a commercial ceramic filter candle is inserted in the freeboard of a bench scale fluidized bed gasifier for particulate removal, and its internal hollow space is filled with catalyst pellets, in order to perform catalytic reforming of tar in the raw gas. Two different commercial catalysts are tested inside the filter candle and their performance is studied and compared.

2. Methods

Experimental tests were carried out in a bench scale biomass gasification system composed of a cylindrical fluidized bed reactor (ID 0.1 m) heated with an external electric furnace. The bed material is composed by olivine sand and the biomass used is ground almond shells. In the upper part of the reactor a ceramic candle is hosted (L 440 mm, 60 mm OD and 40 mm ID). At the outlet of the gasifier the gas composition (H_2, CO, CO_2, CH_4) is analyzed online and its volume flow is measured; tars are sampled according to the standard CEN/TS 15439 and then analyzed with HPLC. Temperatures and pressures are measured in different points of the reactor. More details on the experimental rig can be found in [3].Tests were carried out with the empty ceramic candle and with the candle filled with two types of Ni based commercial catalysts for steam reforming of methane and naphtha, referred to as A and B, respectively. Catalyst A has the shape of perforated pellets with a high void fraction; catalyst B instead, having the shape of small cylinders, could cause excessive pressure drop. For the tests with catalyst B the cavity of the candle was filled only partially, with an annular bed of catalyst pellets, leaving a cylindrical internal hollow space to reduce the whole pressure drop (see **Figure 1**).

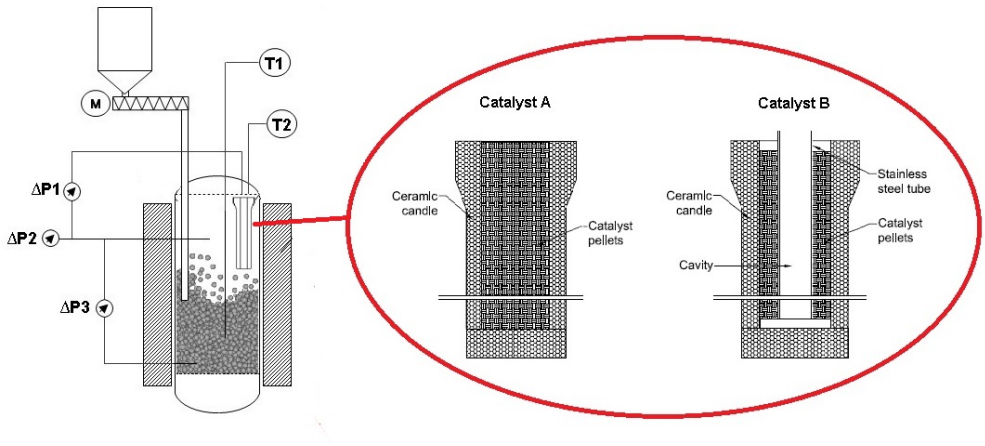

Figure 1. Scheme of gasification reactor and configurations of catalyst filled candle

3. Results and discussion

Table 1. Input conditions and test results

Test	1	2	3
Filter candle	**Empty**	**Catalyst A**	**Catalyst B**
Temperature (°C)	789	770	775
Gas yield (Nm^3 dryN_2free/kg_{bio})	1.13	1.45	1.66
Water conversion (%)	24.25	36.13	53.65
Tar (g/Nm^3 dryN_2free)	3.28	2.75	0.36
GHSV (h^{-1})	-	4211	5729
H_2 (%vol dryN_2free)	40.65	55.34	54.04
CH_4 (%vol dryN_2free)	9.03	2.13	1.20

Results reported in **Table 1** show that both catalysts lead to an upgrading of the gas quality compared to that of the raw syngas. However, catalyst B (even though filling only partially the candle cavity, thus confined in a smaller volume) performed much better than catalyst A, with higher gas yield and water conversion. In fact, with catalyst A, tar is only slightly reduced (16%), while catalyst B brought to almost complete tar conversion (89%) with a final concentration in the gas lower than 0.5 g/Nm^3 dry and N_2 free.

4. Conclusions

The integration of catalyst pellets in the cavity of a ceramic candle placed in the freeboard of a fluidized bed gasifier can be an effective solution for syngas upgrading. In particular catalyst B showed excellent performance in tar reforming, increasing H_2O conversion, gas yield and H_2 content. Even though catalyst B was filling only partially the candle cavity (thus under higher GHSV), better results were obtained compared to those exhibited by catalyst A.

Highlights

- A solar-from-water photocatalytic H_2 production engineering is presented.
- A predictive model using multi-level light-matter processes description is proposed.
- Validation is done on an accurate experimental bench using an innovative photoreactor.

1. Introduction

Considering the exhaustion of fossil resources and CO_2 emission rise due to their combustion, the use of solar renewable energy is an evidence to cope with the energy demand of Humanity in the future. This resource being naturally fluctuating, it is necessary to convert it into storable energetic vectors. Among solar fuels, one of the first accessible is undoubtedly the H_2, whose production can be carried out in slurry photoreactors [1] making use of photocatalytic water splitting [2]. The challenge is huge as the Humanity needs to develop in the same time efficient and cheap semiconductor photocatalysts and optimized solar photo-reactive processes.

2. Methods

Multi-scale model: From a chemical engineering point of view and considering that photo-reactive processes are limited and controlled by photon transport and conversion, the understanding and optimization of the elementary process of light-matter interaction at different scales and description levels is essential to develop predictive knowledge models. We present such rigorous and generic models with the objective to conceive, size and optimize highly efficient processes for solar-to-hydrogen energy conversion (yield > 15%) by geometric inverse design. Their multi-scale structuration requires first the determination of the spectral optical properties for the photocatalysts which can be found in experimental databases and/or using density functional theory with Kramers-Krönig causality relations. The second step is aimed at determining spectral radiative properties (phase function, absorption and scattering coefficients) of the photocatalyst particle by solving Maxwell's equations using Mie theory (for equivalent sphere approximation), with additional information on shape and size distribution that can be experimentally acquired. The last phase consists in solving the photon transport equation (Boltzmann equation) to determine luminance distribution within the system volume for known boundary condition i.e. the spectral incident photon flux density q_{λ} and its angular distribution. As a result, the (spectrally averaged) Local $\mathcal{A}(\mathbf{x})$ and Mean $\langle\mathcal{A}\rangle$ Volumetric Rates of Radiant Energy Absorbed (LVREA and MVREA) are estimated and linked to local H_2 reaction rate $r_{H_2}(\mathbf{x})$ using mechanistic elementary

thermokinetics coupling laws. The mean H_2 reaction rate $\langle r_{H_2} \rangle$ is then obtained by averaging local kinetics over the entire photoreactor volume.

Experimental set up: First, the radiative properties are experimentally validated thanks to transmittance measurements with an integrating sphere. Then, our knowledge model is validated by carrying out a photocatalytic reaction for H_2 production in a lab-scale photoreactor [3]. H_2 is produced in the gas tight photoreactor illuminated by a LED panel (various spectral distributions) or a solar simulator. Its production rate $\langle r_{H_2} \rangle$ is correlated through a detailed mass balance with the pressure increase in the headspace of the reactor measured with a pressure sensor.

3. Results and discussion

Experimental result will be presented for the pressure time course (with decompression steps) during H_2 production under irradiation of the photoreactor (see figure 1a). It enables to determine the mean H_2 volumetric rate $\langle r_{H_2} \rangle$. Several accurately controlled values of incident photon flux densities q_{n} [4] are tested for a given photocatalyst concentration. For each q_{n} value corresponds a $\langle r_{H_2} \rangle$ value which is plotted as shown in figure 1b. The multi-scale predictive model presented in section 2 is then used to fit the results with the identification of only one lumped parameter.

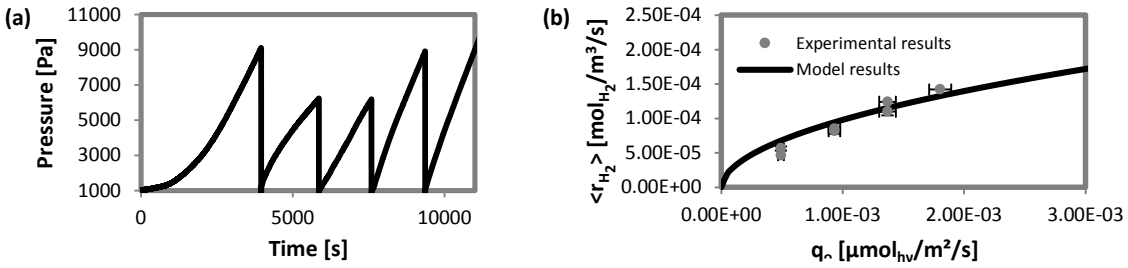

Figure 1. (a) Example of experimental pressure evolution at different photon flux densities q_{n} – (b) Hydrogen mean volumetric rate as a function of incident density photon flux at 0.02 g/L photocatalyst concentration.

New experimental results using costly Pt and cheaper MoS_2 as co-catalysts will be also presented.

4. Conclusions and perspectives

Predictive results obtained by means of our multi scale model accurately fit with our experimental results for $\langle r_{H_2} \rangle$ at different photocatalyst concentrations. The next steps of our study will be: (a) to determine the optical properties of our catalyst by density functional theory; (b) to use other electromagnetic approaches than Mie theory (as T-Matrix and ADDA) to solve Maxwell equations for non-spherical particles of catalysts; (c) to improve the thermokinetics coupling law integrating doping process; and finally (d) test the robustness of our model with natural fluctuating solar light on a new demonstrator under development.

Highlights

- Study of the main parameters for the gasification process.
- Use of a green catalyst for the problematic tar removal.
- Usage of Computational fluids dynamics (CFD) to model reactors hydrodynamics.

1. Introduction

In order to minimize the use of conventional fuels, various renewable technologies and alternative energy sources have been studied during past decades, such the gasification of lignocellulosic biomass. Gasification is a thermochemical process of conversion at high temperature (>700°C) of organic matters into synthesis gas such as monoxide of carbon (CO), dihydrogen (H_2), methane (CH_4) and dioxide of carbon (CO_2).However, predicting the behavior of biomass and its products under this particular thermochemical process, especially in a fluidized bed reactor, is not a simple task. Fluidized bed reactors represent a notable advantage for this process because of the fact that the biomass particles interact with inert materials inside the reactor and remain in a fluidized or suspended region, which provides better results in terms of mass and heat transfer. The composition of these products may vary due to the effect of numerous parameters in the gasification process including reactor temperature, residence time of gases, particle size of solids, type of oxidant, oxidant/feed ratio, nature of biomass and type of catalyst used. The latest one is a critical parameter due to the presence of undesirable products in the gasification process known as tar. Tar removal is an important problematic in biomass gasification. Different catalyst such as nickel-based, calcined rocks, alkali metals and others have been tested in order to reduce tar from final products. The use of a green catalyst like biomass biochar is an alternative solution to this problematic, being very effective in tar removal (up to 99% conversion) and considered a sustainable option (El-rub, 2008). Highly accurate techniques to model hydrodynamics, such as Computational Fluid Dynamics (CFD), are used to study gas-solid interactions, reaction kinetics like homogeneous and heterogeneous reactions and reactor hydrodynamics as the parameters used for the latter have proven to influence the final products obtained.

2. Methods

The experimental setup is a fluidized bed reactor in quartz (Fig.1). The biomass is feed at the center of the reactor by a stainless steel tube connected from the top of the reactor. Gases get out from the top to a cyclone in order to collect solids particles trained by the gases. The reactor temperature

varies from 500-1000 °C. Nitrogen (N_2), air and dioxide of carbon (CO_2) were used as carrier gas for gasification reaction. Tar produced was condensed at -13°C temperature and then analyzed in a GC/FID and GC/MS. Product gases are collected in a sample bag and then analyzed in a micro GC/TCD and a GC/FID-TCD according to the system configuration (discontinuous or continuous). For hydrodynamics modelling, a CFD Euler-Lagrange code is used to study the behavior of reactor taking in account the hydrodynamics phenomena.

Figure 1. Fluidized bed reactor dimensions.

3. Results and discussion

The variation of the each operation parameter influence the results of the final composition gases and tar. Gasification oxidant have a strong influence in the results because it favors the main gasification and tar reactions (dry reforming, water gas-shift, etc.). Temperature influencing the thermal cracking and production of light tar and gases. In the case of hydrodynamics parameters, the fluidization velocity strongly influences the behavior of gas and solids inside the reactor. The use of biochar as bed material for gasification reaction showed a high conversion of tars.

4. Conclusions

This work presents an experimental study of the influence of different reactor parameters such as biomass particle size, vapor residence time, reactor temperature, oxidant/biomass ratio, product composition. Tar removal is study using a green and sustainable catalyst (biochar) to show the strong performance of biochar against commercials catalyst. In order to optimize the hydrodynamic of the fluidized bed of biochar, a numerical model has been developed. Additionally, this would help study the shrinkage effects of biomass particles in the process, a phenomenon often neglected in literature.

Highlights

- High pressure and high temperature photocatalysis explored
- Productivity boosted by unconventional reaction conditions
- Tunable selectivity to different fuels from renewable or waste materials

1. Introduction

Photocatalysis can be seen as a route for the storage of solar energy by producing "solar fuels", i.e. with artificial photosynthesis. In this work, we dealt with two challenging applications: i) the production of hydrogen through photoreforming of aqueous solutions of organic compounds and ii) the photoreduction of CO_2.

Different carbohydrates (glucose, xylose and arabinose, as well as levulinic and formic acid) were used as renewable substrates for photoreforming, since they may be rather easily obtained from the hydrolysis of biomass. On the other hand, the transformation of CO_2 into regenerated organic compounds, to be used as fuels or chemicals (CH_4, HCOOH, HCHO, CH_3OH) was also studied. Our attention was predominantly focused on the development of innovative photoreactors, operating under unconventional conditions, with the fine tuning of the operation parameters. In particular, we have set up and optimized a new photoreactor operating at pressure up to 20 bar and relatively high temperature (up to 90°C) which allowed to overcome one of the main limitations for the photoreduction of CO_2 in liquid phase, *i.e.* the low CO_2 solubility. The possibility to increase the operating pressure also allowed to explore unconventional reaction conditions, evidencing an unexpected boost of hydrogen productivity when increasing temperature in the case of the photoreforming of carbohydrates.

2. Methods

The selected photocatalysts were based on TiO_2, since the main focus was reactor optimization. The materials were prepared by flame spray pyrolysis as dense nanoparticles, or in mesoporous form through a soft template synthesis, and compared with commercial samples of nanostructured TiO_2 P25 by Evonik. Different metals, such as Cu and Au, Pt, Pd, Ag, Ni, with loading ranging from 0.1 to 1 mol% were added as co-catalysts (mono or bimetallic formulations). The role of the metals was that of electron sinks, to inhibit the electron-hole recombination and they were also selected due to the formation of a plasmon resonance band which improves visible light absorption. The

photocatalytic activity tests have been carried out in batch mode using a high pressure photoreactor (up to 20 bar, 95°C), using a UVA immersion lamp, coaxial with the photoreactor (λ_{max} = 365 nm, ca. 77 W/m^2).

3. Results and discussion

As for the photoproduction of H_2 we have investigated extensively the effect of pressure, temperature, carbohydrate and catalyst concentration, selecting 80°C, 4 bar, 5 g/L of carbohydrate, 0.5 g/L of catalyst and neutral pH as the best operating conditions. The highest productivity was achieved with 0.1 mol%Pt/TiO_2 or 1 mol% Au_6Pt_2/TiO_2, leading to ca. 14 mol/h kg_{cat} of hydrogen.

As for the photoreduction of CO_2, operation at high pressure allowed to boost the conversion to partially reduced compounds (HCOOH, HCHO and CH_3OH), with much more limited conversion to CO and CH_4. The present high pressure photoreactor also showed extremely versatile to drive the reaction towards the desired product among those listed by tuning pressure, temperature, reaction time and pH. The highest productivities reached up to now were obtained with 0.2% Au/TiO_2: 40 mol/h kg_{cat} of HCOOH (7 bar, 80°C, pH=14, 24 h reaction time), 17 mol/h kg_{cat} of HCHO (7 bar, 80°C, pH=14, 6 h reaction time) and 1.7 mol/h kg_{cat} of CH_3OH (7 bar, 80°C, pH=7, 24 h reaction time, 0.2% CuO/TiO_2 as catalyst).

The increase of pressure from 7 to 19 bar almost doubled the amount of HCOOH obtained and, also in this case, the increase of temperature allowed to increase the productivity. This was unexpected, since the increase of temperature is often discussed as negative for photocatalysis due to an increased recombination rate of the photogenerated charges.

The apparent quantum yield (AQY) has been here calculated as follows:

$$AQY\ (\%) = \frac{\text{moles of product(i)}\ per\ second\ \times\ \nu(i)}{Incident\ photons\ per\ second}$$

where ν(i) is the number of electrons consumed to reduce CO_2 to the desired product and is directly calculated from the productivity data here reported. The incident photons flow has been calculated based on the measured intensity of radiation. Considering the productivities here reported we have calculated an AQY much higher than 10% in the best cases.

4. Conclusions

In this work we have investigated the effect of unconventional reaction conditions, i.e high pressure and relatively high temperature, on two of the most challenging photocatalytic processes, such as the photoreduction of CO_2 and the production of H_2 from carbohydrates. The increase of temperature to 80-90°C revealed beneficial for both reactions. The increase of pressure boosted the productivity for CO_2 photoreduction to results presently unrivalled in the literature. For this latter application, the use of this photoreactor also allowed to tune the selectivity towards different compounds by simply changing the reaction conditions.
The main achievement, besides the interesting products yields, is the development of a new concept of photoreactor, which can open new unexplored routes in photocatalysis.

Highlights

- Design of an innovative, efficient and scalable process of synthesis with yields of the useful product higher than those of literature
- Definition and optimization of the unitary operations of extraction by determination of the various solid-liquid-liquid ternary phase diagrams involved
- Characterization of the energetic properties of the propellant of interest
- Very promising substitute for the replacement of highly toxic hydrazines

1. Introduction

Propellants, which are part of the space hydrazines family, are mainly used in the aerospace and defense industries, in storable propellant engines for launchers, in satellite apogee motors as bipropellants, associated with nitrogen peroxide, and as mono-propellants in trajectory correction thrusters. In this paper, we describe the development of a new storable, reducing liquid propellant with prospective use in space launchers. Tetramethyl-2-tetrazene and its derivatives was identified by the French Space Agency (CNES) as interesting candidates[1] to replace highly toxic hydrazines such as monomethylhydrazine (MMH), which is considered a substance of high concern (SHC) and is prone to be banned by the REACH European Union regulation. The molecule of interest in this study is the cyclic tetramethyl-2-tetrazene (1,4,5,6 tetrahydro-1,2,3,4 tetrazine $C_4H_{10}N_4$), which should provide optimum propulsive performances and should not have a significant impact on human health and the environment. The objective of the first stage will be to develop a green synthesis process that is competitive on the international level, in line with sustainable development and which can adapt to market fluctuations.

2. Methods

Cyclic tetramethyltetrazene (c-TMTZ) is obtained by two successive reactions: the first step is the synthesis of the bishydrazine by nitrosation of the amine followed by a reduction[2]. The second reaction is the oxidation of this bishydrazine leading to the formation of c-TMTZ by intramolecular cyclization[3,4]. Due to the low yields described in the literature, a study was carried out in the laboratory to optimize the oxidation conditions of bishydrazine and obtain the highest yields of c-TMTZ. The reaction kinetics were deduced from the in-situ concentrations of c-TMTZ obtained by RMN ^{1}H spectroscopy. The second part of the work focused on the design of the extraction and isolation process of c-TMTZ. In the actual process, the extraction of the bishydrazine (BH) from the complex reaction media is the key and tedious step of the global process, implying numerous

unitary operations of distillation (at various pressures) and filtration, leading to a low yield of extraction. In our new concept, the basic idea would be to benefit from a gap of miscibility at the liquid state in the ternary system BH-H_2O-NaOH. Several isotherms of the solid-liquid-liquid ternary system BH-H_2O-NaOH were thus determined under atmospheric pressure. The demixing binodal curve and limits of each domain were obtained by combination of acidimetric titrations of phases in equilibria and conductimetric measurements. The final part of this work describes some energetic properties of c-TMTZ, essential for spatial applications: temperatures end enthalpies of melting and decomposition (DSC), impact sensitivity (BAM tester) and hypergolicity character.

3. Results and discussion

For the synthesis segment, influence of the nature of the oxidizer, concentration, temperature, solvent and pH was studied for the oxidation reaction of BH, allowing optimal conditions to be identified for c-TMTZ yields higher than 70 %. For the extraction segment, several isotherms of the solid-liquid-liquid ternary system BH-H_2O-NaOH were determined (Figures 1 and 2).

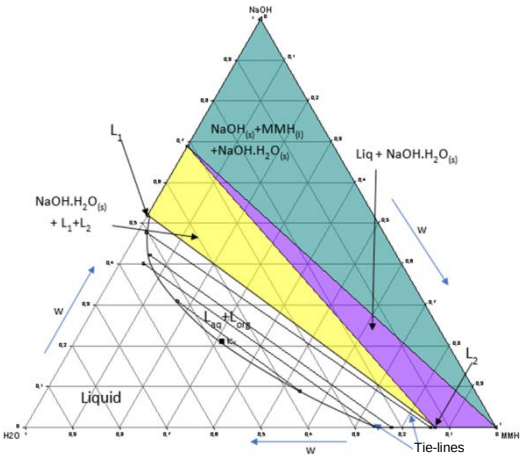

Figure 1. Isothermal 293.15K of the BH-H_2O-NaOH S/L/L ternary system (P_{atm})

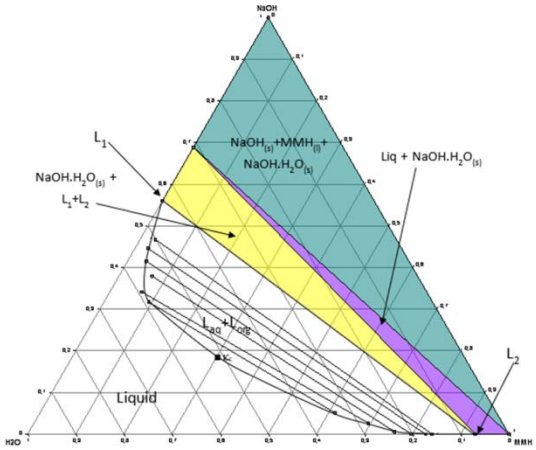

Figure 2. Isothermal 323.15K of the BH-H_2O-NaOH S/L/L ternary system (P_{atm})

These isotherms show the tendency of BH to demixing with NaOH and give the optimal quantities of NaOH to add in order to have the organic species concentrated in a single phase, separated from the salts and with a minimum of water. For the extraction of pure BH, 2 unitary operations are thus required instead of 4. Then, c-TMTZ is recovered by distillation. The characterization of the energetic properties of this propellant reveals a promising substitute: thermal stability on a large range of temperatures, no sensitivity to impact and hypergolic behavior with oxidants.

4. Conclusions

Cyclic tetramethyltetrazene holds great potential to be used as a propellant to replace hydrazines. The global process described in this work is “green” and suitable for large-scale synthesis. Moreover, c-TMTZ can be used to obtain compounds with higher propulsive performances.

Highlights

- Same reaction parameters yielding the maximum bio-oil yield for both reactors.
- Varying pyrolysis temperature impacted significantly on the product distribution while varying gas residence time did not.
- Many non-compliant observations were obtained between the semi-continuous and the continuous setups.

1. Introduction

This study aims to investigate the pyrolysis of the beech wood in a drop tube reactor (DTR) so as to examine the liquid and gas pyrolytic product distributions and also, compare these results with those obtained in a semi-continuous reactor [1].

2. Methods

The pyrolysis runs were done in a semi-continuous quartz tubular set up [1] and in a stainless steel DTR. In the DTR, the biomass was introduced using a screw-fed conveyor. A condenser and a flask, placed inside a cold bath to recover the bio-oils formed from the condensation of pyrolytic vapours were found at the end of the circuit. A sampling bag was used, in which the non-condensable gases were recovered to be later analysed. A flow of 500 mL/min of nitrogen was used as carrier gas. The cold bath and the refrigerant were both kept at a constant temperature of -10 °C. For the purpose of this study, the pyrolysis experiment was conducted in a stainless steel DTR at different temperatures of 500, 550 and 600 °C with varying vapour residence times by changing nitrogen flow rates to 500, 1000 and 2000 mL/min. Gas chromatography-mass spectrometry (GC-MS) and gas chromatography-thermal conductivity detection/flame ionisation detection (GC-TCD/FID) technologies were used to identify and quantify the various components found in the bio-oils recovered and the non-condensable gases collected. Concerning the bio-oils, the components belonging to the same chemical family, that is, possessing the same functional group, were grouped together and their percentage by weight evaluated.

3. Results and discussion

It was firstly seen that the experiment at 500 °C under 500 mL/min N_2 yielded the highest amount of bio-oil (58.8 wt. %). This coincided with the findings from the semi-continuous setup (max. yield of bio-oil: 58.18 wt. % at 500 °C). In contrast to Guizani *et al*. [2], it was seen from this study that the major chemical families present in the collected oils were carboxylic acids (58 mol. %),

phenols (16 mol. %) and alcohols (12 mol. %); this trend was not far from what was found from the semi-continuous setup [1]. However, the percentage for each family differed: the percentage of acids was higher in the DTR (58 mol. % vs. 35 mol. % in the semi-continuous setup). Then, while it was verified that varying the vapour residence times did not impact the product distributions significantly as the reaction regime did not change, varying the DTR temperature did affect the product distributions. It was also observed that both the percentages of carboxylic acids and alcohols tended to decrease with increasing temperature, while phenols demonstrated the opposite trend. This corroborated an inversely-correlated relationship between acids and phenols. This relationship was not observed in the semi-continuous reactor; the inversely-proportional relationship of carbohydrates and acids was more obvious in the latter setup.

Then, it was seen that increasing the reaction temperature favoured the dehydration reaction of the alcohol, carbohydrate and carboxylic acid groups. It was also found that the oxygen content of the bio-oils decreased with mounting DTR temperature. This observation goes along the fact that higher reaction temperatures tend to privilege cracking reactions, and hence, smaller, gas molecules formation. However, the overall oxygen content of the bio-oils remain quite elevated (29-40 mol. %) as compared to that of fossil-derived fuels (~1 %) [3], but also to the oils obtained in the semi-continuous reactor (~33 mol. %). This difference was directly linked to the higher percentage of acids present in the DTR bio-oil samples.

As for the non-condensable gases (NCG) fraction, the species present in majority was CO (58 vol. %), as for the semi-continuous reactor (45 vol. %), but, again comprising a slightly higher percentage. In the DTR, while CO_2 experienced a reduction in its percentage, the CO percentage remained quite stable, contrary to the semi-continuous reactor, where CO increased while CO_2 decreased.

4. Conclusions

It was found that despite not using the same installation, the reaction parameters yielding the maximum bio-oil yield were the same: 500 °C under 500 mL/min N_2 (~58 wt. % in both cases). Also, while varying the temperature impacted significantly on the product distribution (higher temperatures yielded higher gas products and a more acidic oil), varying the gas residence time did not quite alter the product distribution as it was found that the pyrolysis was still taking place within the intermediate regime, and that the reaction was governed by the biomass particle residence time. Finally, many non-compliant observations were obtained between the semi-continuous and the continuous setups. This fact highlighted the heightened error margin present for using results obtained in a semi-continuous or discontinuous setup to globally model pyrolysis as a continuous reaction.

Highlights

- Experimental results on olive mill solid waste gasification.
- Development of a 1D steady state stratified model.
- Validation and parametric study performed.

1. Introduction

Gasification is a promising waste-to-energy technique for waste or solid residues from biomass.

In olive-oil producing countries, large amounts of waste material are generated as by-products for which there is no ready use and which may have a negative value because of the cost of disposal. In this case, waste treatment technologies aimed at energy recovery such as gasification represent an interesting option [1].

In the gasification process, the fuel undergoes thermochemical transformations aiming to produce syngas. However, despite major economic, industrial and scientific interests associated with the development of gasification, several technological issues linked to the understanding of the involved mechanisms (chemical reactions, coupled heat and mass transfers, mechanical phenomena, etc.) continue to hinder the development of gasification process [2]. Therefore, a specific model must be developed for each type of fuel.

The objective of this paper is to provide a reliable numerical fixed-bed gasification model for olive mill solid waste, taking into account the thermochemical and fluid flow phenomena that occur during waste gasification process. The model is validated with experimental data of olive mill solid waste gasification.

2. Experiments

Experimental set up consists of a 100 kW downdraft gasifier equipped with temperature, pressure sensors, air flow controllers and syngas analyzer (figure 1).

For this study, an olive mill solid residue was collected from a two-phase extraction process industrial plant located in Spain. The residues were dried on the facility, further extracted with hexane to recover residual oil contents, and then pelletized. The main characteristics of the residue are given in Table 1.

Figure 1. Downdraft gasifier.

Lignin (% w/w of DM)	13.4

Table 1. Proximate and ultimate analysis, higher heating value and fiber analysis of olive mill solid waste (taken from [3]), DM = dry matter.

3. Model

A 1D steady state stratified model of the gasifier was developed, assuming local thermal equilibrium. The gasifier was divided into four zones: fuel drying, pyrolysis, oxidation and chemical reduction. The following phenomena were taken into account: chemical reactions with solid/gas, heat and mass transfers. For pressure drop calculation, particle shrinkage was also considered. COMSOL Multiphysics® was used to solve the set of equations.

4. Results and discussion

The model was validated thanks to experimental data. Predictions of the temperature profile, pressure drop and syngas composition are in good accordance with experimental values. The influence of operating conditions (relative fuel air ratio, particle diameter, zone length) on producer gas composition was also investigated. The optimal fuel air ratio was identified.

5. Conclusions

A reliable model for olive mill solid waste gasification was developed and validated. Further improvements will consist in taking into account other mechanical phenomena (e.g. channeling). To achieve this objective, a 2D dynamic approach will be taken.

Systematic computer aided methods and tools for lipid process technology

Olivia A. Perederic[1], Bent Sarup[2], John M. Woodley[1], Georgios M. Kontogeorgis[1]

1 Department of Chemical and Biochemical Engineering, Technical University of Denmark, DK-2800 Kgs. Lyngby, Denmark; 2 Vegetable Oil Technology Business Unit, Alfa Laval Copenhagen A/S, DK-2860 Søborg;

**gk@kt.dtu.dk*

Highlights

- State of the art for lipid phase equilibria.
- Systematic identification method for lipid predictive tools improvement.
- Process design and analysis of shea oil fractionation using developed tools.

1. Introduction

Today, chemical engineering methods and tools are widely used for the development and analysis of various processes across different industries. The thermodynamic properties of the involved chemicals, and the models used to describe them, represent the foundation of all the methods and tools used. In recent years, there has been an increasing interest in lipid compounds and their mixtures, which are used in a wide range of applications and industries. A detailed analysis of data and model availability for lipid compounds shows that there is still a need for predictive tools to cover the gaps where experimental data are missing.

The aim of this work is to develop, validate and apply systematic methods and tools for the lipid process technology. Thermodynamic and process aspects of the problem are considered: a systematic method for data analysis and phase equilibria modelling, application of the developed models to lipids processing alongside process modelling, design, analysis and improvement. Particular attention has been given to specialty fats processing using solvent, such as shea oil acetone fractionation. The most important aspects of the process are solvent recovery and product purification of solvent residues.

2. Methods

The detailed analysis of data and models available in the literature for lipid compounds and mixtures was performed and discussed. Further, a systematic method for data analysis and phase equilibria modelling was used for estimate new interaction parameters for lipid compounds. The aim of the method is to improve the quality of phase equilibria prediction for the selected group contribution based methods. The results obtained were used to perform the process modelling, design and analysis for shea oil solvent fractionation process using various tools.

3. Results and discussion

Different models, from EoS to activity and combined models are used to describe lipid phase equilibria. The general trend for increasing deviation of VLE correlation using different activity coefficient models is: NRTL ≈ Wilson < UNIQUAC. The SLE trend for increasing deviation is: UNIQUAC

< Wilson ≈ NRTL. For LLE, NRTL and UNIQUAC prove to have similar performance and both can be used to describe lipid LLE. Although these models provide good predictions, there are a limited number of interaction parameters which cover only a few classes of lipid compounds (e.g: fatty esters, fatty acids). The performance of different UNIFAC variants with their published parameters was tested, and the trend for increasing deviation (ARD%) for VLE description is: Linear UNIFAC < Lyngby UNIFAC< Dortmund UNIFAC < Original UNIFAC. For lipid SLE prediction, the deviation in prediction increase as follows: Original UNIFAC < Dortmund UNIFAC < Linear UNIFAC < Lyngby UNIFAC.

After applying the systematic identification method, the performance of the models using the new lipid-based parameters for describing lipid VLE improves for all the UNIFAC variants, as presented in Figure 1. The extrapolation of the models to SLE prediction using the lipid-based parameters shows little to no improvement compared to the models with the published parameters. Further, Original UNIFAC model with the lipids parameters was used for process modelling, design and analysis of shea oil solvent fractionation.

The shea oil acetone fractionation process consists in three parts: (I) separation by fractional crystallization of shea oil into two products, shea olein and shea stearin; (II) solvent recovery in a series of flash units; and (III) solvent purification and recycling. Improvements of the process (e.g.: heat integration) are performed based on the economic and environmental analysis of the base case scenario.

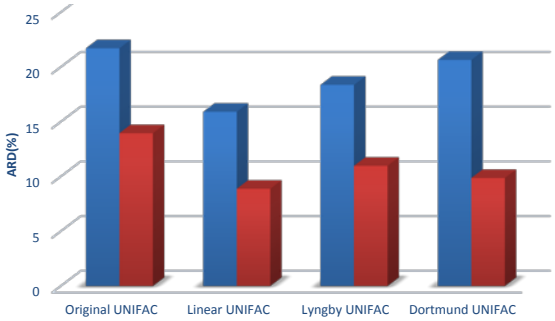

Figure 1. Average relative deviation, ARD(%) for different UNIFAC variants for lipids VLE prediction using published (■) and lipid-based parameters (■).

4. Conclusions

The detailed analysis of available models and data for lipids showed the need of having predictive models to describe lipid systems. By using a systematic identification method, new lipid-based parameters for different UNIFAC variants were estimated and analysed for extrapolation capabilities. Further, the models were used for shea oil acetone fractionation process modelling, design and analysis, and improvements of the process are proposed.

ENHANCED FIXED-BED REACTOR FLEXIBILITY THROUGH OPTIMAL CONTROL AND DESIGN FOR CO2 METHANATION

Jens Bremer[1], Ronny Tobias Zimmermann[2], Kai Sundmacher[1,2]

1 Max-Planck-Institut für Dynamik komplexer technischer Systeme, Sandtorstraße 1, 39106 Magdeburg, Germany

2 Otto-von-Guericke Universität, Universitätsplatz 2, 39106 Magdeburg, Germany;

**Corresponding author: bremerj@mpi-magdeburg.mpg.de*

Highlights

- Detailed model analysis under dynamic conditions with special focus on heat management and catalyst properties.
- Proposing operation strategies to effectively deal with reactor load changes.
- Exploring potentials for advanced control methods (optimal control).

1. Introduction

The current trend towards a more flexible production to react on markets as well as on volatile inputs (e.g., coming from renewable sources), contains many new challenges and requires concepts for dynamic process operation. Thus, the interest in prediction of the process dynamics has become more important than ever before [1-3]. The present work in particular deals with dynamic load changes of fixed-bed reactors for carbon dioxide methanation by use of hydrogen generated via water electrolysis, an important example of Power-to-X (PtX) production processes. Particularly in view of vehicles fueled with compressed natural gas (CNG), synthetic methane (SNG) is a very attractive, easy-to-distribute substitute fuel. Moreover, carbon dioxide methanation is a key reaction in the context of chemical conversion networks for the storage of electrical surplus energy. However, the reaction is strongly exothermic such that distinct hot-spots are formed within the catalytic fixed-bed that can influence the catalyst stability and process safety [4]. On top of that, these reactors are characterized by extraordinary dynamic behaviors (e.g. wrong-way behavior), due to complex interactions between heat and mass transport, reaction, and fluid flow phenomena. Consequently, intelligent dynamic interactions are required to guarantee time-optimal load transitions, while ensuring long-term stable and safe reactor operation.

2. Methods

Detailed dynamic reactor models from first-principals are used to analyze the reactor behavior under dynamic scenarios. One- and two-dimensional, pseudo-homogenous, tubular reactor model including wall and cooling channel are used to get detailed information about the reaction heat propagation and to analyze extraordinary dynamic behaviors. Additionally a heterogeneous model is compared with the homogenous model in order to show the impact of the solid catalytic phase and its corresponding diffusional limitation. Special attention is given to its impact on reactor dynamics, an often stated but rarely illustrated problem under industrially relevant conditions. Furthermore, the reactor models are embedded into frameworks for linear and advanced/optimal control. Thereby, the objective is to keep track of a constant reactor conversion in scenarios of

changing loads (realized via feed velocity and feed pressure changes). All studies are performed in-silico using MATLAB.

3. Results and discussion

Preliminary results for control trajectories performed with and without (closed- and open-loop) well-known PI-controller are illustrated in Figure 1. The changing load influences both the position and the intensity of the reactive zone (hot-spot). Wrong-way behavior occurs within the first minute and lead to a temperature overshoot of up to 100 K. Furthermore, we observed that under certain conditions a load change performed via pressure changes is much less affecting the target conversion, as compared to the velocity-based load change. However, by changing the coolant temperature after disturbing the velocity in a closed-loop set-up with a PI controller, the target conversion is effectively restored after approximately 300 seconds with reduced temperature overshoot. Further results will focus on optimal control trajectories that allow for faster transitions while considering technical restrictions (e.g. maximal catalyst bed temperature).

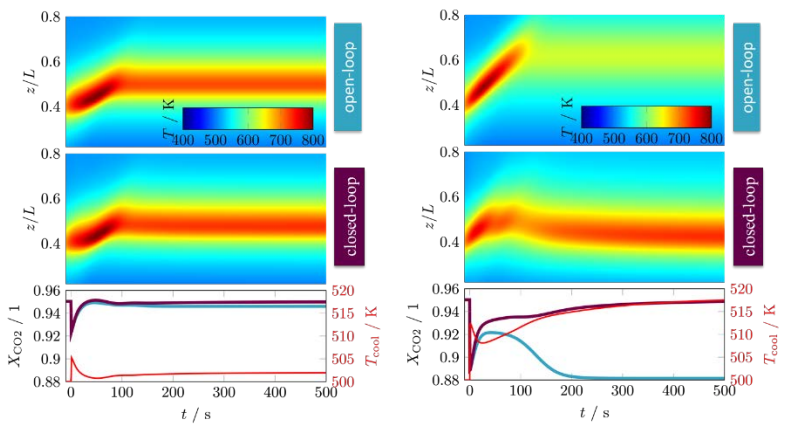

Figure 1. Load change with positive pressure step from 10 to 15 bar (left) and with positive gas flow step from 1 to 1.5 m/s (right). Upper surface plots: space-time behavior at the reactors central axis. Lower plot: control trajectories (red) and CO_2 conversion trajectories in open- (blue) and closed-loop (violet) set-up.

4. Conclusions

Our results comprehensively show how complex the dynamic behavior of the investigated exothermic reactor for methanation is. Powerful computational tools allow for an effective analysis of these behaviors and also reveal to what extent an intervention with suitable controls becomes feasible. With this, we intend to deliver a deeper understanding for dynamic reactor operation and derive new operation strategies that allow for a more flexible and sustainable production within future production concepts. Since our results are mainly related to the heat generated by the reaction, the outcomes of this study are also relevant to other exothermic reactions, e.g. methanol production from CO_2 and green hydrogen.

Hydrogenation of CO_2 to methanol in zeolite membrane reactors

Miriam Tovar[1], Raquel Raso[1], Javier Lasobras[1], Javier Herguido[1], Izumi Kumakiri[2], Miguel Menéndez[1]

1 Aragón Institute of Engineering Research, University of Zaragoza, Zaragoza, Spain; 2 Yamaguchi University, 2-16-1, Tokiwadai, Ube, Yamaguchi, 755-8611 Japan

**Corresponding author: jhergui@unizar.es*

Highlights

- Among the tested membranes, zeolite A is the most promising for the purpose.
- The combined traditional + membrane reactor outperforms thermodynamic methanol yields.
- Catalysts less selective to reverse WGS reaction than $CuO/ZnO/Al_2O_3$ are more suitable.

1. Introduction

This work focuses on the hydrogenation of CO_2 to methanol by means of reaction (1), as a way of energy storage that could be applied, for example, to deal with occasional energy overproductions from renewable sources.

$$CO_2 + 3\,H_2 \leftrightarrows CH_3OH + H_2O \qquad (1)$$

Zeolite membrane reactors were proposed [1] to allow lower operating pressure and higher yield in the process. H_2O removal from the reaction environment would ideally increase yields over the equilibrium ones achievable in a conventional reactor.

In this work, we study the separation performance of several zeolite membranes under different operating conditions. Then, the most suitable zeolite is tested for methanol production in membrane reactor using a conventional $CuO/ZnO/Al_2O_3$ catalyst.

2. Methods

Permeation behaviour of zeolite-A and mordenite membranes (prepared at *Yamaguchi University* [2]), as well as of a commercial zeolite-T membrane (provided by *Mitsui Engineering*) were tested by feeding a mixture containing CO_2, H_2, N_2 and H_2O, and using Ar as sweeping gas.

Reaction tests were carried out in both, a traditional fixed bed reactor (FBR) and a combination of it with a zeolite membrane reactor (FBR+ZMR) by feeding a H_2/CO_2 mixture in a 3/1 molar ratio. Temperatures were varied in the range 160-260°C. The non-condensable gases from the reaction were analyzed on-line by gas chromatography and the liquids were analyzed by FTIR.

A $CuO/ZnO/Al_2O_3$ catalyst was loaded in both FBR and ZMR reactors. It was prepared by co-precipitation of the corresponding salts at constant pH, following literature procedures [3].

3. Results and discussion

The separation factor (SF) H_2O/CO_2 obtained with mordenite membranes was quite low (Figure

1), which seems to do with the formation of cracks. Zeolite T provided good SF at 170ºC, but it dropped when was heated up to 240ºC. Moreover, measurements at 170ºC after heating the membrane at 230ºC showed a permanent loss of selectivity which implies that such high temperatures damaged the membrane. Zeolite A provided good separation factors (e.g., SF H_2O/CO_2 higher than 100) although they decreased at high temperatures (240ºC and above).

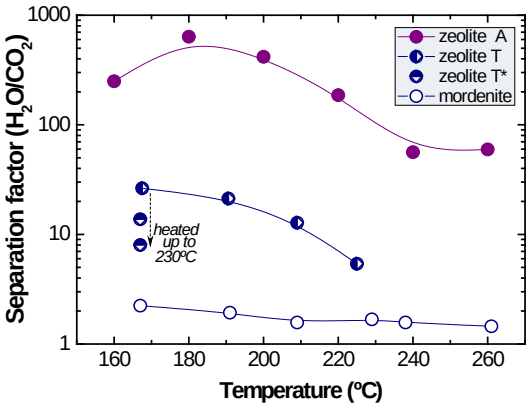

Figure 1. Separation factors for the three tested zeolite membranes

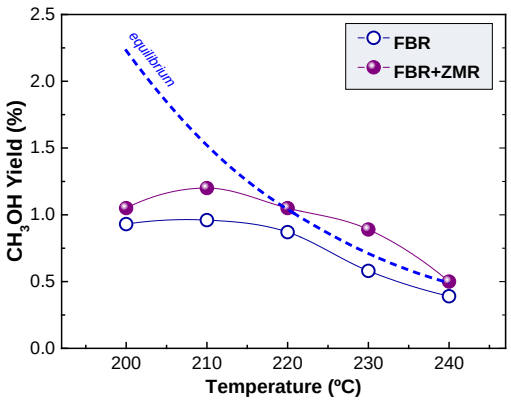

Figure 2. Yield to methanol with the traditional FBR and with the combination FBR+ZMR

An example of comparison of performance using conventional FBR and the configuration FBR+ZMR is shown in Figure 2. The FBR+ZMR combination, using zeolite A as membrane material, outperforms the FBR one in terms of methanol yield. So, yields even over the ones for thermodynamic equilibrium were reached with such a FBR+ZMR configuration.

However, at 240ºC reverse WGS reaction is favored by the removal of water through the membrane and thus the selectivity to methanol is lower with the FBR+ZMR configuration at this temperature, increasing the formation of CO. This strongly suggests that a catalyst with more selectivity to methanol at low pressure than the standard $CuO/ZnO/Al_2O_3$ should be developed, in order to fully profit from the advantage provided by the removal of water through the zeolite membrane.

4. Conclusions

The obtained results open the door for further research, since they show that the zeolite-A membrane reactor can provide higher yields to methanol than the conventional one, allowing operation at lower pressure than the current industrial processes. Further optimization of the full system is necessary to be competitive with the current technology.

OXIDATIVE COUPLING OF METHANE IN A GAS-SOLID VORTEX REACTOR

Kevin M. Van Geem[*,1]

1 Laboratory for Chemical Technology, Ghent University Technologiepark 125, 9052 Zwijnaarde, Belgium

**Corresponding author: kevin.vangeem@ugent.be*

Highlights

- oxidative coupling of methane in 3D printed reactor
- gas-solid vortex reactor optimization
- reactive simulation using computational fluid dynamics

1. Introduction

Oxidative coupling of methane is considered one of the most promising routes to directly convert methane into more valuable hydrocarbons. The uncertain economics related to the tradeoff between conversion and C2 selectivities is an important reason why OCM is currently not industrially applied.[1] In the last decades, numerous studies have focused on developing a viable catalyst that has the potential to improve the low C2 yields. However, so far, the research on catalyst development has not led to any major breakthrough. One of the reasons is that next to the catalyst aspects, reactor design is of crucial importance for OCM. The lack of an appropriate reactor is one of the primary reasons why OCM has not been commercialized at industrial scale. Previous studies based on bifurcation theory [2] have shown that the key features of an ideal OCM reactor are high thermal backmixing (i.e. high effective thermal conductivity) and low species backmixing (i.e. narrow residence time distributions). Narrow residence time distributions, i.e. plug flow behavior, is necessary to control and maximize the selectivity towards the intermediate products ethane and ethylene. High effective thermal conductivity creates the opportunity to exploit the bifurcation behavior and operate an OCM reactor autothermally, in this way utilizing the reaction heat in the best possible way. Both these characteristics can be obtained in the gas-solid vortex reactor (GSVR) that is studied in this work. In a gas-solid vortex reactor in a static geometry, gas is injected tangentially via a number of inlet slots (see Figure 1). The swirling gas transfers its momentum to the particles in the reactor chamber, which in turn start rotating. A fluidized state is obtained when the drag force exerted by the gas balances the apparent weight of the particles in the centrifugal force field. In contrast to conventional gravitational fluidized beds, higher gas throughput, lower residence times, more uniform beds, higher slip velocities and hence better heat and mass transfer can be achieved in this reactor type. Therefore, the GSVR is an excellent candidate for process intensification. As the reactor can combine short residence times and narrow residence time distributions with optimal heat transfer characteristics, it is a very promising technology for OCM. In this work, the open-source CFD package OpenFOAM is used to simulate an adiabatic gas-solid vortex reactor using an Euler-Euler approach. Detailed microkinetic models are used for different

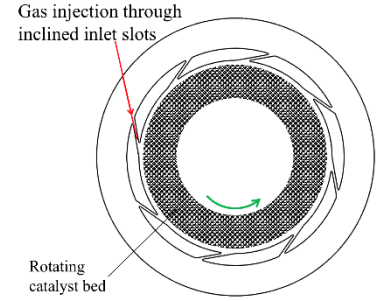

Figure 1. Gas-solid vortex reactor in a static geometry.

types of catalyst (Sn-Li/MgO, Mn/Na2WO4/SiO2, Sr/La2O3). The effect of operating conditions and reactor geometry is evaluated.

2. Methods

The simulated GSVR geometry is adopted from the work of Gonzalez-Quiroga et al. [3] It basically consists of a cylindrical unit positioned along a vertical axis with eight gas injection slots of 1 mm width, equally distributed over the circumferential wall and tangentially inclined at a 10° angle. A reactor diameter of 80 mm and length of 15 mm are defined. The reactive two-phase flow in the GSVR is simulated with an Euler-Euler approach using the open-source CFD package OpenFOAM. A dedicated solver was developed, coupling OpenFOAM and Cantera, the latter being used as mechanism interpreter. This allows to use detailed microkinetic models. In this work, the microkinetic model consists of 39 gas phase reactions and 26 catalytic reactions.[4] The same model can be used for different catalysts (Sn-Li/MgO, Mn/Na2WO4/SiO2, Sr/La2O3), provided the kinetic parameters are adjusted accordingly. The GSVR is simulated as an adiabatic unit.

3. Results and discussion

Non-reactive simulations show that narrow residence times can indeed be obtained in the GSVR. Plug flow behavior for species/mass transport is indicated by the quasi parallel streamlines (see Figure 2) and a simulated Péclet number >> 1. Preliminary reactive simulations also indicate a good thermal mixing in the reactor, without hot spot formation. High C2 selectivities ~75% can be obtained, but in the non-ignited state, methane conversion is limited because of the very small residence times (<5 ms) in the catalyst bed. Employing the effects of ignition/extinction behavior, the methane conversion can be increased while maintaining a high C2 selectivity, and at the same time working at lower inlet temperatures.

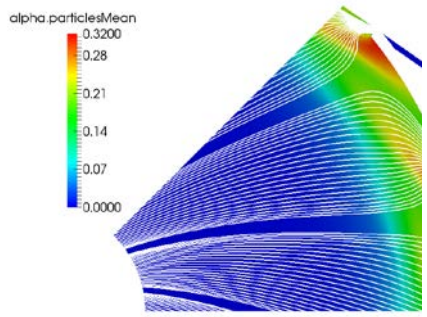

Figure 2. Gas streamlines, shown on top of the catalyst volume fraction field. Simulated conditions: 16-slot GSVR, 75 m/s slot velocity (CH_4:O_2 = 4), 11.2 g catalyst particles (2300 kg/m^3, Ø 500 µm)

4. Conclusions

In this work a new reactor technology is proposed for the oxidative coupling of methane (OCM). A gas-solid vortex reactor (GSVR) combines the two most important features required in an ideal OCM reactor: good heat management and narrow residence time distributions. This allows to utilize the exothermic reaction heat in the best possible way while also maximizing the selectivity towards intermediate C2 products. Computational Fluid Dynamic simulations are used to optimize and design the GSVR specifically for OCM. The CFD simulations show that the narrow residence time distributions and efficient heat management in the GSVR can give rise to C2 yields ~25 %.

**Corresponding author: jdfonsecag@unal.edu.co*

Highlights

- Distributed energy systems including hydrogen as energy carrier were studied
- The design of DES including hydrogen is focused on techno-economic issues
- There is a need of multi-dimensional approaches to evaluate this type of systems

1. Introduction

The constant expansion of world economy and population, as well as the concerns about climate change, represent new challenges for the energy sector [1]. In this line, the emergence of distributed energy systems (DES), and the integration of different energy networks by means of the combination of multiple energy sources, converters and carriers have represented a shift in the energy framework [2]. Among energy carriers, hydrogen has appeared as a promising alternative due to the large range of sources from it can be obtained. Additionally the possibility to use it as raw material, energy storage medium (power-to-gas) or as final energy form emitting only steam and heat in its combustion, make hydrogen a promising energy vector to be integrated in energy systems [3]. However, despite their potential capabilities, introducing hydrogen in the design of distributed energy systems (DES) is a complex problem due to the simultaneous dimensions and constraints that need to be considered, as well as to the high context dependence of this kind of projects [4]. For these reasons, in this work a literature analysis is done with the aim to identify the objectives (technical, economic, environmental and socio/political) and the specific evaluated criteria (profit, NPV, efficiency, emissions, etc) when DES including hydrogen are designed, planned or operated.

2. Methods

The methodology consists on a bibliographic analysis of scientific research papers, by means of a systematic literature review carried out according to the parameters noted in Table 1. Taking into account the great variety of terminology related with DES, the keyword field is composed of a set of terms (e.g. energy hub, microgrid, hybrid energy system), besides to hydrogen and power-to-gas ones.

Table 1. Search strategy parameters.

Field	Option Introduced
Keywords	("energy hub" OR microgrid OR "integrated energy systems" OR "distributed energy system" OR "decentralized energy system" OR "multi energy system" OR "hybrid energy system" OR "polygeneration") AND (hydrogen OR "power to gas")
Search in	Title, abstract, keywords
Period explored	2000 - 2018
Type of documents	Articles and conference papers

3. Results and discussion

Figure 1 shows the distribution of publications according to the evaluated objective. It highlights the prevalence of economic issues, which are involved in almost 80% of studies. Additionally, it appears that around 45% of documents include multi-objective analysis and nine works address economic, technical and environmental goals simultaneously.

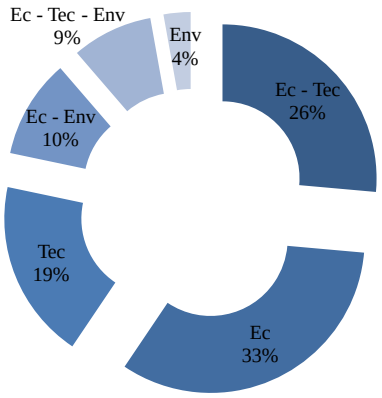

Figure 1. Performance objectives evaluated in DES. (Ec-economic, Tec-technical, Env-environmental)

4. Conclusions

Results indicate that the design and analysis of DES including hydrogen have been predominantly focused on techno-economic issues. Hence, there is an opportunity for future work to include another dimensions (e.g. socio/political), and thus improve the decision-making process for planning this type of energy systems.

Analysis of Hydrogen Supply Chains for Swiss Mobility

Cristina Antonini[1], Annalisa Guidolin[1], Paolo Gabrielli[1], Marco Mazzotti[1*]

1 Institute of Process Engineering, ETH Zurich, Sonneggstrasse 3, 8092 Zurich, Switzerland
**Corresponding author: marco.mazzotti@ipe.mavt.ethz.ch*

Highlights

- Blue hydrogen production technologies
- Biogas and natural gas reforming with carbon capture
- Swiss blue hydrogen network

1. Introduction

Most recent climate scenarios from integrated assessment models (IAMs) assessed that to reach the 2°C target in 2100 the amount of CO_2 removal required is in the order of several gigatonnes per year (Gt/a) [1][2]. In Switzerland, one third of the carbon dioxide emissions derives from the transport sector, and corresponds to 16.2 Mt_{CO2} in 2016. Considering the abundance of fossil fuels, low-carbon hydrogen production from natural gas and biogas, coupled with carbon capture and storage, seems a promising solution for reducing the emissions of the mobility sector. This type of hydrogen is the so called blue-hydrogen, and it opposes to green-hydrogen from electrolysis.
The design of a blue-hydrogen supply chain in Switzerland requires models that describe the conversion and capture technologies considered. Therefore, the goal of this work is to model the technologies with the required level of details and introduced them in the supply chain model, which should deliver an optimized configuration of a potential hydrogen network in Switzerland. The selected blue hydrogen production processes are reforming of natural gas and biogas. For CO_2 capture, absorption with methyl diethanolamine is considered as reference technology and the novel in house studied adsorption process, vacuum pressure swing adsorption (VPSA), is considered for comparison. As reference, the production of green hydrogen via electrolysis is considered. The Swiss distribution network is optimized for different criteria, where both carbon dioxide emissions and costs are considered.

2. Methods

The hydrogen production as well as the amine carbon capture process are modelled in Aspen Plus®, the adsorption processes are modelled with an in-house simulation tool. The models in Aspen Plus® are built with a step-wise approach; firstly, the key process variables are identified. Secondly, multi parameters sensitivity analysis are performed to better understand the nature of the interaction among the operation variables. Lastly, mathematical optimization is used as a tool to fine-tune the operating conditions of the process. Those models are subsequently simplified and given as input data to the supply chain problem. The geographical region of interest, in this case Switzerland, is spatially discretized and for each node a specific demand for hydrogen is given. The optimizer will define where hydrogen is produced, with which technology and at which scale. Moreover, the

solution of the optimization problem will include the distribution network of hydrogen among the nodes. The Mixed Integer Linear Programming (MILP) model is built in Matlab® and solved with commercial solvers (CPLEX®, GUROBI®).

3. Results and discussion

The technologies have been studied and modelled. The complex process flowsheets have been simplified with linear relationships, easy implementable in the supply chain model. A preliminary version of the supply chain model has been prepared based on previous work done in our group [3]. The spatial discretization has been integrated into the existing model together with the operational specifications of the network. A graphical overview of this procedure is represented in Figure 1.

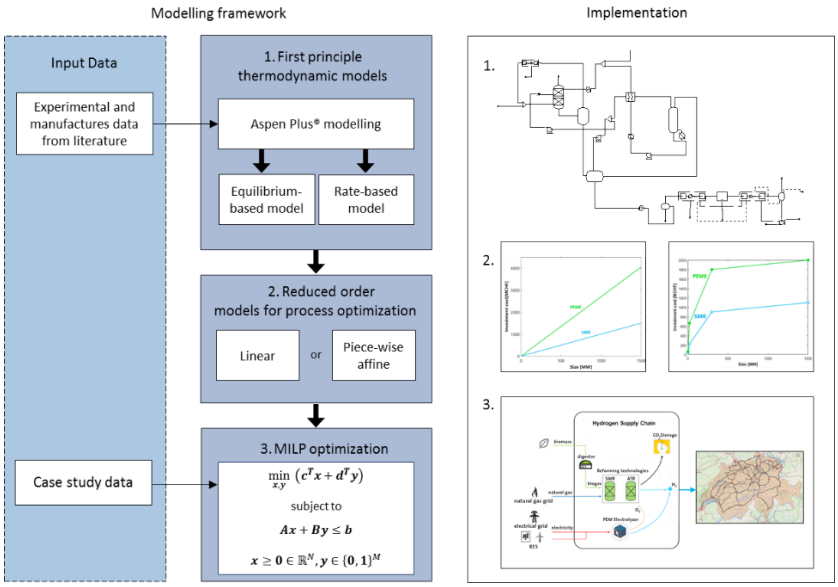

Figure 1. Overview on the modelling framework of this work.

4. Conclusions

This work will focus not only on the construction of a model suitable to shape a Swiss hydrogen network for mobility based on detailed technology descriptions; but it will also focus on the understanding of the trade off deriving from the interactions among the different players. The final goal is to make sure that all the interesting features are considered and adeguately described in the supply chain model.

1. Introduction

In order to decarbonize the transport sector several possible routes and measurements are currently investigated. For the air transport sector, a decarbonization seems not likely in the near future as this is one of the "difficult-to-electrify" sectors. However, a promising approach to incorporate renewable sources in this sector (defossilization) is the production of synthetic fuels from CO_2 and water by using renewable power sources for hydrogen production in an electrolyzer. In this Power-to-Liquid process (see Fig. 1) the CO_2 is activated at high temperature (750-950 °C) and elevated pressure (1-25 bar) via reverse water-gas shift reaction (RWGS). The produced syngas is then converted to hydrocarbons via Fischer-Tropsch synthesis (FTS). Besides the technical challenges to establish an efficient Power-to-Liquid process, the production costs and ways to reduce these costs are of major importance.

Figure 1. Principle scheme of the PtL process.

2. Methods

The process is modelled in Aspen Plus® (see Fig. 2) and the PtL-efficiency is calculated according to:

$$\eta_{PtL} = \frac{\dot{m}_{Product} \cdot LHV_{Product}}{P_{electrical}}$$

Different parameters are varied e.g. temperature and pressure in the RWGS reactor. The evaluation of the optimum process conditions is not trivial. On the one hand, increasing the temperature and decreasing the pressure leads to a higher CO_2 conversion and less CH_4 formation. On the other hand decreasing the pressure leads to an increase in power consumption

due to additional compression work, while higher temperatures require additional high temperature heat. The effect of this variation is assessed and discussed. Further the production costs are calculated using the Inhouse Tool TEPET (Techno-Economic Process Evaluation Tool) [1].

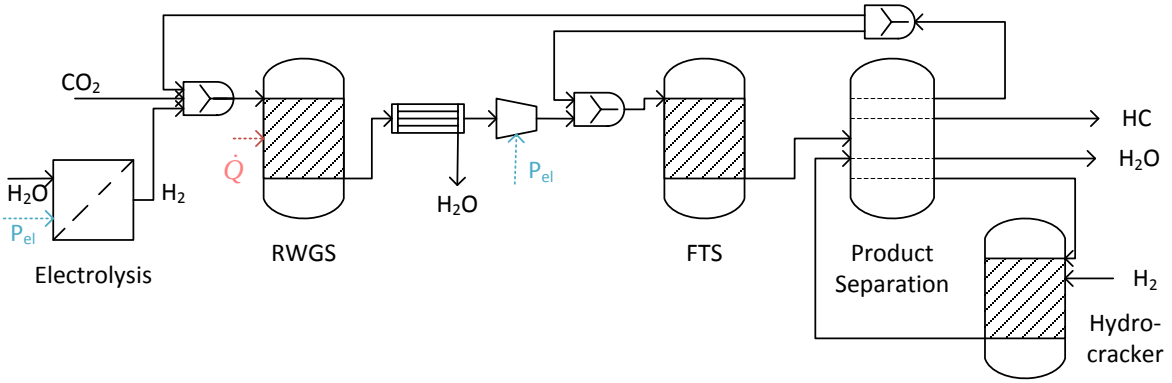

Figure 2. Simplified process scheme of the PtL process.

3. Results and discussion

The assumptions for the process model will be presented. The influence of the parameter variation on the PtL-efficiency will be discussed. Additionally the production costs and the impact of different operating conditions on these costs will be determined.

4. Conclusions

The optimum process conditions regarding the efficiencies and production costs will be presented. Major impacts will be outlined and quantified.

New insights on the ozone reactive flotation: fundamental study using virgin fibers to model recovered cellulosic fibers

Amina Ghorbel[1]*, Nathalie Marlin[1], Marc Aurousseau[1], Agnès Boyer[1]

[1] Univ. Grenoble Alpes, CNRS, Grenoble INP, LGP2, F-3800 Grenoble, France

*Corresponding author: amina.ghorbel@lgp2.grenoble-inp.fr

Highlights

- Strength properties of fibers are not altered by O_3 and drainability is improved
- O_3 decomposition into water is predominant
- Remaining O_3 mainly reacts with soluble contaminants decreasing the effluent COD

1. Introduction

Nowadays recovered papers and boards constitute the major cellulosic fiber raw material used in papermaking but the utilization rate of recovered paper depends on the paper grade. The production of white graphic papers uses in average a maximum of 10% of recovered paper (CEPI, 2016).To obtain high quality final products, deinking, i.e. ink removal, is required. Flotation process is the most common practice for deinking (Kemper, 1999): it is a physico-chemical unit operation using air bubbles flow to collect and drain ink particles out of the fiber suspension. To improve the efficiency and the sustainability of paper deinking lines, the idea is to add ozone (O_3) as a reactive gas into the gas flow (Marlin et al., 2013). Indeed, O_3 is a well-known oxidant applied for process and urban water treatment (Wei et al., 2016)and also for fiber bleaching in the pulp and paper industry (García et al., 2009). Addition of O_3 in the gas stream during flotation gave promising results with the reduction of COD effluent with 30% and an increase of the fiber yield of 1 point, whereas no effect on ink removal efficiency has been observed (Almeida et al., 2010). However, O_3 may theoretically also depolymerize the cellulosic chains of the fibers (Mishra et al., 2013; Pipon et al., 2007). To investigate more fundamentally the action of O_3 during the flotation process, and especially to examine the reactivity of O_3 with both the contaminants present in solution and the cellulosic fibers, flotation trials have been conducted on model recovered cellulosic fibers free of ink and with tap water or model process water to simulate the presence or not of soluble contaminants.

2. Methods

Recovered cellulosic fibers have been simulated by a mixture of virgin fibers representative of the fiber composition of office waste papers: 90% bleached chemical pulp and 10% mechanical pulp. Before flotation, the pulp models were diluted to 1% consistency (w dry fibers/w suspension) with a conventional alkaline chemistry (Marlin et al., 2013). Flotation trials were performed in a batch pilot flotation cell specially designed to run with corrosive gas such as O_3 (Beneventi et al., 2009), in the following conditions: 2.785 TPN L/min gas flow, 10 minutes flotation time, 40°C, using air or a O_2/O_3 mix as gas flow. In the case of O_2/O_3, O_3 concentration in the gas stream was 160 g/Nm^3, i.e. 4.46 g of O_3 in one trial. Flotation trials have been carried out either with tap water and industrial model water containing contaminants commonly found in process effluent of recovered

paper recycling lines (sodium oleate 0.4 g/L, carboxymethyl cellulose 0.7 g/L and slightly anionic starch 3.15 g/L). Pulp strength properties have been measured on pulp handsheets of 60 g/m^2 prepared according to the standard ISO 5269-3, 2008 method. Tensile strength (Ir) gives the strength of the whole fiber web (ISO 1942-2, 2008) and zero-span strength (Ir_0) measured on wet handsheets, the strength of one isolated fibers (ISO 15361, 2000). The papermaking ability of the pulp was evaluated in terms of pulp drainability via the Schopper-Riegler index °SR (ISO 5267-1, 1999). The global quality of flotation effluents was examined through Chemical Oxygen Demand (COD, mg/L - Hach method). The O_3 consumption (Cons.), expressed in g of O_3 during the trial, has been calculated using the O_3 concentration in the gas phase measured at the inlet and outlet of the flotation cell.

3. Results and discussion

Table 1. Pulp and effluent properties after air and O_2/O_3 based flotation processes

	°SR	Ir (N.m/g)	Ir_0 wet (N.m/g)	COD (mg/L)	pH	Cons. (g)
Air - tap water	40	42 ± 2	50 ± 2	372	9.9	-
O_2/O_3 - tap water	43	48 ± 3	51 ± 3	240	7.6	3.18
Air - model water	55	48 ± 4	50 ± 2	643	9.2	-
O_2/O_3 -model water	44	46 ± 1	48 ± 2	564	7.0	3.76

Inlet pulp properties: pH = 9.6, COD inlet suspension, tap water: 400, air model water: 680, O_2/O_3 model water: 868 (mg/L), °SR=39, Ir: 43±3, Ir_0 wet = 52 ±3 (N/mg)

Before any flotation, it can be observed that the use of model process water reduced the pulp drainability by increasing the °SR from 39 to 55. Air flotation does not modify the pulp drainability (°SR=40) whereas ozone improves it by reducing the °SR from 55 to 44, probably due to the consumption of the soluble contaminants by O_3. This is confirmed by COD and pH results: after air flotation, COD does not change whereas more than 30% COD reduction is obtained after O_2/O_3 flotation (tap or model water); on the same, after air flotation, pH is maintained at 9-10 whereas it decreased to 7-8 when O_3 is used which proves that acidic products are formed. Concerning pulp strength properties, Ir and Ir_0 are conserved showing that neither the fiber web nor the fiber itself is degraded by O_3. Besides, 3.76 g of O_3 is consumed in the trial with model water. As the O_3 consumption into water alone (no fiber, no soluble contaminant) is 3.00 g, O_3 is mainly decomposed by water; contaminants only consumed 0.58 and fibers 0.18 g of O_3.

4. Conclusions

Although O_3 is mainly decomposed into water, the remaining O_3 principally reacts with soluble contaminants thus (1) reducing the COD and (2) preserving the cellulosic fiber from degradation: deinked pulp papermaking ability and strength properties are not altered (Ghorbel et al., 2018).

Highlights

- An experimental Power-to-gas pilot unit has been built in Nantes, France
- PEM electrolyzer is used to produce H_2, methanation is processed in 2 fixed bed reactors
- Renewable synthetic natural gas (SNG) is produced to provide fuel at a Green-gas station

1. Introduction

Storing renewable electricity surplus in a natural gas grid is an attractive concept. Hydrogen storage via chemical conversion with carbon dioxide into methane (also referred as CO_2 methanation or *Power-to-Gas* (PtG), see equation (1)) allows the storage, distribution and reconversion to power, benefitting from the readily available natural gas infrastructure [1-3].

$$CO_2 + 4\,H_2 \text{ ” } CH_4 + 2\,H_2O \quad (1) \qquad \Delta H_R° = -165 \text{ kJ mol}^{-1}$$

Up to now, a reduced number of PtG “demo plants” have been appeared in an effort to scale up lab pilots. MINERVE project aims to show the PtG process feasibility via the first French Methanation demo plant. Experiments are carried out to understand the impact of operating parameters such as reactants volumetric flow rate, H_2:CO_2 ratio, pressure or temperature among others and to find out the optimal condition operation.

2. Material and Methods

This study focused in two main parts of the PtG pilot unit (see figure 1). In one hand, the hydrogen production is carried out by a 20kW PEM electrolysis reactor capable of generating up to 2.4 Nm^3/h of hydrogen and in the other hand, the catalytic reaction section which converts hydrogen into methane using 2 fixed bed reactors (FBR) functioning in series and a commercial Ni/Al_2O_3 catalyst. In order to determine reaction performance, an online infrared methane sensor BCP-CH4 is used as well as an on-line multi-component (CH_4, CO_2, CO, H_2 and O_2) analyzer. Gas samples are also taken at each reactor outlet and analyzed with an Agilent Technologies 3000A Micro GC.

3. Results and discussion

Methanation experiments were carried out at different pressure, temperature, H_2 excess and flow rate, and CO_2 ratio between the reactors FBR1 and FBR2 (see table 1).

Pressure (bar)	Temperature (°C)	Excess of CO_2 in FBR1 and FBR2 (%)	H_2 flow rate (NL/min)	CO_2 ratio between FBR1 and FBR2 (%)
[1-10]	[280-380]	[0-100]	[10-30]	[0-100]

Table 1. Methanation operating conditions.

Figure 2 illustrates a typical monitoring of methanation. Four steps are identified in the reactor:

- Step 1: Rise of temperature. In this step, the temperature in the reactors reaches the set point. A constant value of H_2 flow rate is imposed.
- Step 2: Rise of H_2 flow rate. The H_2 flow rate reaches the set point with a constant slot equal to 36 (NL/min). The production of methane starts and the temperature increases. The temperature is maintained as constant as possible by playing with the CO_2 ratio between both reactors.
- Step 3: Steady State. The H_2 flow rate is constant and the production of methane is stable.
- Step 4: End of the reaction.

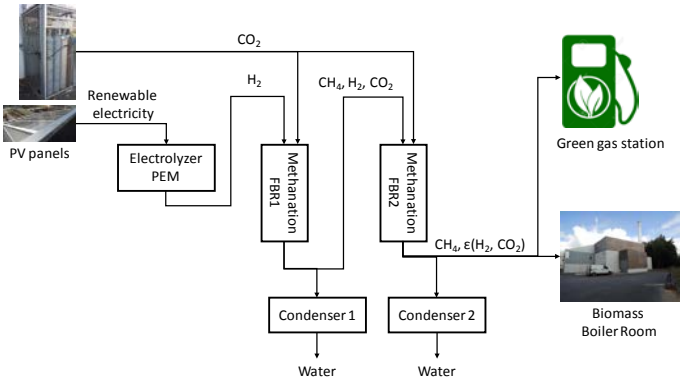

Figure 1. Schematic representation of MINERVE PtG pilot unit installed at AFUL Chantrerie, Nantes (France).

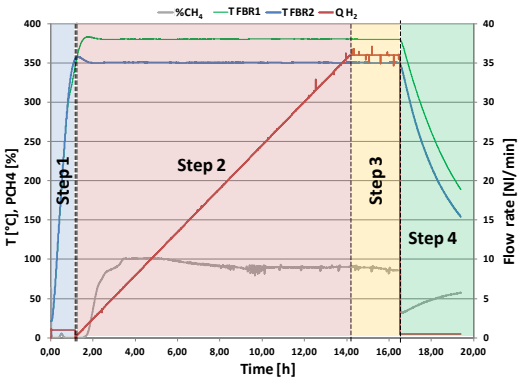

Figure 2. Methanation monitoring: Q_{H_2} = 36 (NL/min), P = 5 bar, T_{R1} = 350°C, T_{R2} = 380°C, stoichiometric conditions, CO_2 ratio = 60%.

4. Conclusions and perspectives.

A CO_2 conversion of 90% and a purity of methane equal to 86%vol were achieved in the current conditions. A parametrical study of the pilot unit is in progress to optimize it. The challenging part of the monitoring of the reactor is the control of the exothermicity of the reaction.

Plan B: Taking the Carbon out of Fossil Fuels with Catalytic Reactive Separation

Eric Mcfarland, Horia Metiu, Clarke Palmer, Jiren Zeng, Nazanin Rahimi, Dohyung Kang

There is no evidence that significant reductions in the carbon dioxide emissions associated with power generation will be cost effectively achieved using current commercial alternatives to abundant and inexpensive fossil fuels. Clean burning hydrogen has long been considered the fuel of the future, however, cost-effective production methods have not been proven. Technoeconomic comparisons of electrolysis, steam methane reforming, and pyrolysis shows that the lowest cost process for producing hydrogen and/or dispatchable electricity without CO_2 emissions can utilize pyrolysis of abundant, natural gas. The challenge is to achieve high methane reaction rates and high conversion to molecular hydrogen in a reaction environment where solid carbon can be continuously separated. Reactive separation using high temperature (~1000 ^oC) catalytic complex liquids has been investigated in several multiphase reaction systems and high rates (>1 mole/m^3-s) of methane decomposition and high selectivity for molecular hydrogen observed. When the physical properties of the liquids are selected optimally, conveniently separable solid carbon is produced from methane dehydrogenation in bubble column reactors. Solid catalysts in specific melts may also be continuously reactivated as the high temperature liquid serves as a solvent to remove carbonaceous surface deposits prior to the irreversible formation of deactivating coke. Single pass methane conversion of over 95% to molecular H_2 at over 98% selectivity is demonstrated in complex melt systems. Process designs for solid carbon synthesis with zero carbon hydrogen and/or electricity production together with relative technoeconomics will be presented.

Highlights

- Vapor pressures of alkyl pyrazoles measured by transpiration method.
- Vaporization enthalpies were derived and compared with the literature.
- Combustion experiments were performed on 1-methylpyrazole.
- Energetics of de(hydrogenation) reactions was discussed.

1. Introduction

Because of significant fluctuations in the daily power production and consumption of by the conventional and renewable energies, the development of new storage technologies for energy is necessary. Hydrogen is a very interesting option to overcome the drawbacks of other established storage options like *e.g*. storage under high pressures and very low temperatures. The reversible hydrogenation of liquid organic hydrogen carriers (LOHCs) is a new concept for a long-term storage of hydrogen. LOHCs can be efficiently used as an energy-carrying materials for mobile or stationary energy storage [1]. Generally, all unsaturated compounds could serve as hydrogen carriers. The hydrogenation of the LOHC is thermodynamically favorable [2-5]. An ideal LOHC is expected to possess the hydrogenation enthalpy at the level not higher than 40 kJ·mol-1/H_2 [6]. This paper presents studies of thermochemical properties (enthalpies of formation and enthalpies of vaporization) for pyrazole derivatives that can be potentially used for hydrogen storage. A comparative thermodynamic analysis of the hydrogenation/dehydrogenation reactions was performed.

2. Methods

Combustion calorimetry: Standard molar energies of combustion of 2-methyl pyrazole was measured with a self-made high-precision isoperibolic calorimeter with a static bomb and a stirred water bath. The samples were placed (under an inert atmosphere in a glove-box) in polythene capsules and burned in oxygen at 3.04 MPa pressure.

Transpiration method: vapor pressure measurements. Vapor pressures of furfuryl alcohol and tetrahydrofurfuryl alcohol were measured using the transpiration method. About 0.5 g of the sample was mixed with small glass beads and placed in the thermostatted U-shaped saturator. A nitrogen stream with well-defined flow rate was passed through the saturator at a constant temperature (± 0.1 K), and the transported material was collected in a cold trap. The amount of condensed sample was determined by GC analysis using the n-undecane as an external standard.

The absolute vapor pressure p_i at each temperature T_i was calculated from the amount of the product, collected within a definite period.

Computational details. Quantum-chemical calculations have been performed with the Gaussian 09 series of programs. Energies E_0 and enthalpies H_{298} of most stable conformers were calculated by using the composite G4-method.

3. Results and discussion

Experimental results are compiled in the tables below.

Thermochemical data at T = 298.15 K ($p°$ = 0.1 MPa) for pyrazole derivatives (in kJ·mol^{-1})

Compound	$\Delta_f H^o_m$(liq/cr)	$\Delta^g_{l,cr} H^o_m$	$\Delta_f H^o_m(g)_{exp}$	$\Delta_f H^o_m(g)_{G4}$
1-methyl-pyrazole (liq)	121.8±1.5	44.3±0.4	166.1±1.6	163.2±4.5
1-ethyl-pyrazole (liq)	79.3±2.2	49.2±0.8	128.5±2.3	132.4±4.5
3-methyl-*1H*-pyrazole (liq)	74.2±1.7	65.8±1.0	140.0±2.0	139.7±4.5
3,5-dimethyl-*1H*-pyrazole (cr)	18.9±1.7	83.3±0.4	102.2±1.8	102.0±4.5
1,3,5-trimethyl-pyrazole (cr)	19.9±2.0	73.1±1.3	93.0±2.4	86.5±4.5
1-benzyl-pyrazole (liq)	202.8±2.1	72.0±0.8	274.8±2.3	270.2±4.5

Results from G4 calculations of thermodynamics of hydrogenation of pyrazole derivatives, at T = 298.15 K ($p°$ = 0.1 MPa) in kJ·mol^{-1}.

Compounds [a]		$\Delta_f H^o_m$(g)	$\Delta_f H^o_m$(g)[c]	$\Delta_r H^o_m$(g)	$\Delta_r S^o_m$(g)	$\Delta_r G^o_m$(g)	Kp(g)
1-methyl-pyrazole		163.2	110.2	-47.9/24.0	-254	27.8	1□10^{-5}
1-phenyl-pyrazole		289.6	40.8	-239.3/47.8	-608	-57.8	1□10^{10}

4. Conclusions

It has turned out that according to the calculated $\Delta_r G^o_m$(g, 298.15 K), that the hydrogenation of 1-methyl-pyrazole is thermodynamically not favourable, but in contrast the hydrogenation of 1-phenyl-pyrazole is very promising for the hydrogen storage with the large gas-phase equilibrium constant K_p(g) = 1□10^{10}.

Integration of hydrothermal liquefaction in wastewater treatment plants: Biogas vs Bio-crude

Rafael Castro-Amoedo[1*], Theodoros Damartzis[1], François Maréchal[1]

[1]*Industrial Process and Energy Systems Engineering (IPESE), École Polytechnique Fédérale de Lausanne, Rue de l'Industrie, 17, 1950, Sion, Switzerland*

**Corresponding author: rafael.amoedo@epfl.ch*

Highlights

- Bio-crude is a viable option for sludge treatment, competing with current biogas.
- WWTP is particularly suitable for HTL treatment.
- Primary sludge filtration increases HTL economic feasibility.

1. Introduction

The concept of wastewater has seen in recent years a major change; rather than a mere waste that is expensive and tedious to treat, new approaches are regarding it a valuable source of energy and resources. Furthermore, given the current energy paradigm they cannot be ignored.

Typical wastewater treatment plants (WWTP) comprise a pre- and primary treatment, followed by an aerobic and secondary treatments. Besides the treated effluent, a mixed sludge (which is in reality the combination of several stages' sludges) comes as a by-product. Typically, the sludge is anaerobically digested (producing biogas), followed by dewatering and final disposal, like landfill, incineration or eventually used as a fertilizer.

A major drawback to this conversion path is the carbon potential wasted, with 70 to 75% of the original carbon content being converted, and released as CO_2. Only the remaining 25 to 30% is converted to methane. This requires the use of more efficient processes that are able to capture the intrinsic quality of wastewater. In a recent publication [1], the use of biomass as a filtration media for sludge treatment has shown the potential to increase the solid content of sludge, which in turn increases hydrothermal liquefaction performance and subsequent bio-crude yield. At the same time, it reduces the amount of biological oxygen demand (BOD) to be treated in the aeration step, dramatically reducing the electricity need of this step which is responsible for a substantial share of the total electricity consumption.

The focus of this work is, given a wastewater composition and flow, finding the optimal set of solutions that for a certain investment, minimize operating costs and implicitly, the environmental impact. For the sake of simplicity, the choice is given between biogas or bio-crude production.

The sludge used in hydrothermal liquefaction (HTL) was considered to have between 20 and 25% total solids, mainly due to the filtration step. Bio-crude is sold after HTL step and no upgrade was considered inside the WWTP facility.

2. Methods

Based on [2], a MILP formulation was applied for optimal utility selection. The main objective is to minimize the operational costs, while constraining investment values (ε-constraints), subject to a set of constraints for the mass and energy balances (heat cascade included). Furthermore, binary variables are considered for the units' use and continuous variables are associated with their size.

3. Results and discussion

The optimization procedure is able to choose, considering the mathematical formulation, the combination of units that minimize the operating cost. Figure 1 shows the flowsheet implemented.

A reference scenario considering the conventional wastewater destination for biogas production was considered. The extended model including the HTL unit allows operational savings between 10 and 30% variations are due to different scenarios assumptions, in particular the bio-crude market value and sludge water content.

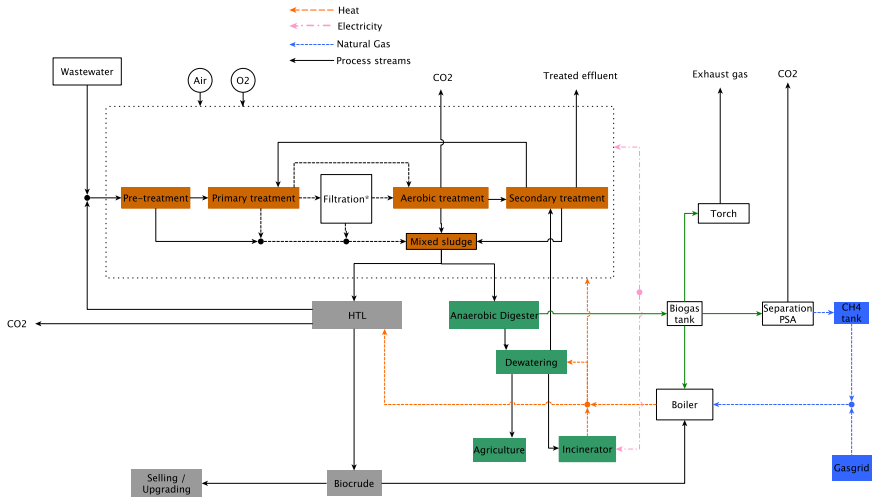

Figure 1. WWTP with HTL unit including mass and energy connections.

4. Conclusions

Hydrothermal liquefaction inserted in a wastewater facility in combination with a biomass-aided filtration is a promising solution for the increasing amounts of sewage sludge. Bio-crude can be directly sold to an upgrading facility or used as fuel for internal consumption, reducing the overall costs in a WWTP. The integration in a WWTP is especially suitable, as HTL water phase can be used as wastewater input. Furthermore, HTL is flexible enough to handle different inlet sludge compositions, even tolerating the presence of components (like plastics) that are inadmissible when anaerobic digestion is considered.

As identified in the flowsheet, a huge potential for CO_2 capture and utilization is available, in particular by making use of renewable power, especially in periods of excessive production.

Single Cell and System Modeling of Tubular Proton Conducting Solid Oxide Steam Electrolyzers for Intermittent Operation

Stefan Fogel*, Holger Kryk, Uwe Hampel

Helmholtz-Zentrum Dresden-Rossendorf e.V., Bautzner Landstraße 400, 01328 Dresden, Germany

**Corresponding author: s.fogel@hzdr.de*

Highlights

- Transient FEM simulations of a single tubular SOEC using a 2D model.
- Examination of the cell behavior for different load variation speeds & flow configurations
- Development of a quasi-2D system model of a tubular stack & system behavior simulations
- Use of different load switching speeds is proven to be insufficient for cell control

1. Introduction

Due to the constantly growing utilization of wind and solar energy, the demand for technologies for temporal and spatial decoupling of energy provision and consumption is steadily increasing [1]. The application of proton-conducting solid oxide electrolysis cells (H-SOEC) has been a main concern in recent research activities since they offer an environmentally friendly and efficient technique for the conversion of excess energy into hydrogen [2]. As renewables occur intermittently, SOEC designs and all employed materials have to be capable of withstanding large electrical transients and therefore harsh operating conditions [3]. Tubular cell designs of SOEC received increased attention in recent years due to their inherent advantages. They offer rapid startup capabilities as well as high resistance to heat, thermal cycling, thermal stresses and high-pressure application capabilities [4, 5]. Since the knowledge of the dynamic behavior of SOECs is key to their future application, this work aims to study the transient behavior of a single, proton conducting SOEC during rapid load variations and of multi-tubular stacks on a system scale under high-pressure operation. The use of different load variation speeds is discussed with respect to cell control.

2. Methods

A 2D, dynamic and axisymmetric model of a tubular, proton conducting SOEC has been developed using the commercial software package COMSOL Multiphysics® 5.3a. The cell performance characteristics during rapid, short-period load variations are simulated. The model can be divided into four sub-models: the electrochemical sub-model, the heat transport sub-model, the hydrodynamics as well as the mass transfer sub-model. The simulations are used to identify limiting operating conditions as well as beneficial process parameter combinations for an improved cell operation. Furthermore, a dynamic, system scale and quasi-2D model of a tubular H-SOEC stack has been developed within the framework of MATLAB® Simulink® including first peripheral system components.

3. Results and discussion

The cell current in each simulated case is increased from 0 A to 30 A starting at the time of 10 s. Five different load gradients are studied, for which the full-load operation of the SOEC is reached within 0.1 s, 0.3 s, 2 s, 20 s and 200 s. Figure 1 (left) shows the cell potential as a function of time for the transient analysis. Due to the abrupt current changes, the cell potential shows different electrical transients with an increase from the initial open cell voltage of 0.95 V.

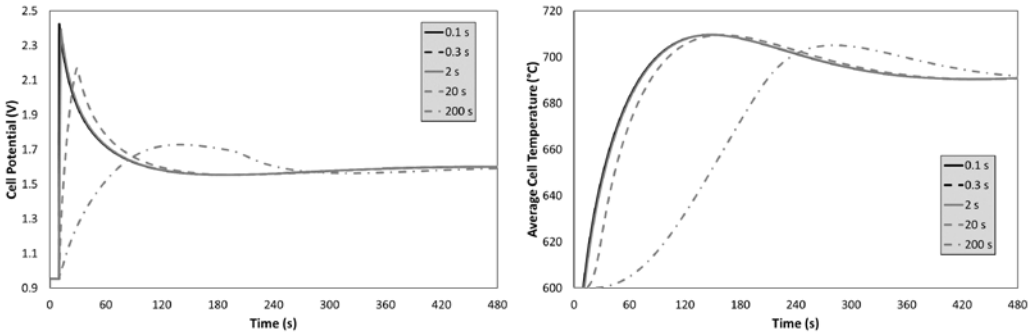

Figure 1. Cell potential (left) and temperature (right) as a function of time after different changes of the cell current from 0 A to 30 A (current changes of 0.1 s and 0.3 s show identical progressions).

For 0.1 s and 0.3 s, the time evolutions of the cell potential are nearly identical and are characterized by a large overshoot within the first seconds after the current change. The cell voltage increases to 2.42 V and decreases towards the stationary cell voltage of 1.60 V. However, the current changes within 2 s and 20 s show different potential progressions. The overshoot decreases with increasing switching time with maximum voltage values of 2.39 V and 2.17 V for the current change of 2 s and 20 s, respectively. In contrast, the cell potential progression for 200 s exhibits a noticeably reduced overshoot up to a cell voltage of 1.73 V. After applying the current changes, the average cell temperature increases from its initial value of 600 °C due to Joule heating and electrochemical heat sinks or sources as shown in Figure 1 (right). The thermal dynamics of the cell for the simulated current changes generally reveal a similar behavior with noticeable differences with respect to the apparent maximum temperature and the time needed to reach the steady state temperature. With longer current change duration, the cell needs more time to reach the steady state temperature.

4. Conclusions

The simulations show that different load switching speeds cannot be used as a sufficient operational strategy to prevent or generate specific temporal temperature progressions. Besides a distinct overshoot of the cell potential, there are no major differences in the electrical behavior of the cell, especially for fast load steps. No limiting operational states were identified.

Energy and Chemical Engineering

Evaluation of acid doped PBI membranes for the SO_2 depolarized electrolysis at high temperature

Manuel A. Rodrigo*, Sergio Díaz Abad, Mireya Carvela, María Millán and Justo Lobato
Chemical Engineering Department, University of Castilla-La Mancha, Enrique Costa Novella Building, Av. Camilo José Cela nº 12, Ciudad Real, Spain.

**Corresponding author: manuel.rodrigo@uclm.es*

Highlights

- Electrochemical comparison of a commercial and a composite TiO_2 PBI based membrane.
- Novel gas phase SO_2 depolarized electrolysis.
- Study of the effect different operation conditions on the electrolysis process.
- SO_2 depolarized electrolysis at temperatures higher than 100°C

Renewable energies are the alternative for a sustainable energy production future. Due to the weather dependence of these energies there is a need for its storage. For example, solar energy has a production peak during the day, however the production is zero at night. This production excess can be used to produce hydrogen, which can be transported and stored for later use.
Hydrogen has a strong potential to become one of the leadings energy carriers in all energy sectors such as fuel for electric vehicles, in combined heat and power plants or fuel cell applications. However, one of the main technical hurdles to overcome to make hydrogen economy [1] a real alternative is relative to hydrogen production. It is mainly produced from fossil fuels by steam reforming of natural gas or high energy consumption processes, which are not environmentally friendly [2]. Thus, new routes for hydrogen production are to be developed for a sustainable energy generation in the "hydrogen economy". By using renewable energy sources, a "Green Hydrogen" can be produced, being water the ideal raw material. Hydrogen could be produced from water by a single thermal dissociation step, however, due to the considerably high energy consumption this process is not the best candidate [3]. Nevertheless, other routes combine a chemical step and a thermal step which are the most promising technologies for hydrogen production [4].
One of the leading thermochemical cycles to produce hydrogen with a high sustainability is the hybrid Sulphur cycle, also known as Westinghouse cycle. It is a hybrid electrochemical-thermochemical cycle. It was originally proposed in 1975 [5] and developed by Westinghouse electric corporation. The process is labelled "hybrid" because of the substitution of one thermochemical reaction by the electrochemical oxidation of SO_2 with water to yield sulphuric acid and hydrogen [3]. The SO_2 is electrochemically oxidized at the anode to form sulphuric acid, protons and electrons (E^0 = 0.158 V vs SHE). The protons are conducted across a proton exchange membrane (PEM) that acts as a separator to the cathode where they recombine with the electrons to form hydrogen according to equations 1 and 2 [3].

$$SO_2(aq) + 2\ H_2O \rightarrow H_2SO_4(aq) + 2H^+ + 2\ e^- \quad (1)$$
$$2H^+ + 2\ e^- \rightarrow H_2(g) \quad (2)$$

The typical PEM used in the electrolysis cell is a Nafion membrane. However, Nafion based membranes show several limitations, including the inability to operate at elevated temperatures and the decreased performance observed when exposed to high acid concentrations [6].

This work is focused on the study of the SO_2 depolarized electrolysis at high temperature (100-200°C) using acid doped PBI membranes as PEM. Two different membranes will be studied for the electrolysis, a commercial PBI membrane and a composite membrane modified with TiO_2, this method is explained elsewhere [7], as inorganic filler with the aim to enhance the electrolyte conductivity, hence reducing the membrane resistance, by improving the acid uptake and retention. The tests are performed in a 25 cm^2 SO_2 depolarized electrolysis cell. A novel operation process consisting on working with SO_2 in the gas phase and generating steam which will be mixed with the SO_2 flow, with a determined molar ratio, before entering the electrolyzer will be tested. A platinum loading of 0.9 mg Pt/cm^2 was employed on both electrodes (anode and cathode) using 40% Pt/Vulcan carbon XC72 as catalyst by spraying a catalytic ink on the electrode surface. Different operation conditions are evaluated such as temperature, SO_2 flow and the SO_2/H_2O molar ratio. The acid uptake and the acid retention will be measured as well as the ion conductivity of the studied membranes. Polarization curves and impedance spectroscopy analysis are carried out to evaluate the performance of the cell and the ohmic and charge transfer resistances. A preliminary stability test will be performed to assess the stability of the different components of the cell (membrane and electrodes).

3D-printed magnetically induced fluidized-bed reactor for electrochemical applications

André Tschöpe[1], Matthias Franzreb[1]

1 Karlsruhe Institute of Technology, Institute of Functional Interfaces, Karlsruhe, Germany

andre.tschoepe@kit.edu

Highlights

- Fully 3D-printed novel reaction system
- Solution of the contacting problem of a fluidized-bed electrode
- Improvement of electrochemical conversion by up to 100 percent with this system

1. Introduction

Electrochemical reactions are an interesting and versatile tool in modern bioengineering. On the one hand, they can be used for e.g. waste water treatment of pharmaceutical plants. On the other hand, electrochemical synthesis offers a way to transfer small organic building blocks originating from fermentations into higher value compounds.

Electrochemical processes proceed at the boundary between the electrode and the surrounding solution. In order to achieve high conversion rates, the ratio of electrode surface area to solution volume must therefore be maximized. Due to their high specific surface area, fluidized-bed electrodes are particularly suitable for this purpose. However, in practice they are rarely used because the controlled fluidization as well as the electrical contacting of these fluidized-beds are major challenges and so far only partially solved. One approach for better contacting of the conductive particle electrodes is the magnetically induced fluidized-bed reactor. Here, the fluidized bed is intended to be under the influence of a magnetic field and at the same time serve as an electrode for the electrochemical reaction.

2. Methods

To meet these challenges a scalable magnetically induced fluidized-bed reactor was designed and afterwards fabricated by 3D-printing. The fluidized-bed reactor consists of four elements and can be closed by means of two clamps. The reactor offers standard connectors, which allow e.g. the connection of analytical equipment like flow-through spectrometer, redox-electrode or pH-electrode. For the characterisation of the novel reactor design, suitable fluidized-bed particles and a model reaction for the electrochemical conversion were chosen. A composite material consisting of activated carbon and magnetite was used as fluidized-bed electrode with a particle size distribution between 100 µm and 300 µm. Before the electrochemical experiments, the percentage of the fluidized-bed expansion was measured at different flow rates. As model reaction, the reduction of potassium ferricyanide $[K^+]_3[Fe(CN)_6^{3-}]$ to potassium ferrocyanido $[K^+]_4[Fe(CN)_6^{4-}]$ was chosen. The electrochemical conversion in the fluidized-bed reactor was compared between the magnetically influenced system and the system without any magnetic influence.

3. Results and discussion

To improve the contact between the magnetic electrode particles, an external magnetic field was generated outside the reactor. **Figure 1 left** shows the expansion behavior of the fluidized bed electrode in relation to the different flow rates. Here the expansion of the fluidized bed electrode with and without magnetic field influence rises with increasing flow rate. Under the influence of a magnetic field, however, a reduced expansion behavior can be demonstrated, so that the assumption can be made that an improved electrode particle contact exists and an improved electrochemical conversion can be achieved. **Figure 1 right** shows the influence of the magnetic field on the electrochemical conversion. First, the achievable current can be increased by the addition of magnetic electrode particles only, meaning without the additional application of a magnetic field, simply because of the increased electrode area. However, if a magnetic field is applied an additional strong increase of the achievable current and therefore of the intensity of the corresponding electrochemical reaction can be observed. At an applied potential of -0.8V this increase achieves 100 percent from -2.2 A to -4.5 A.

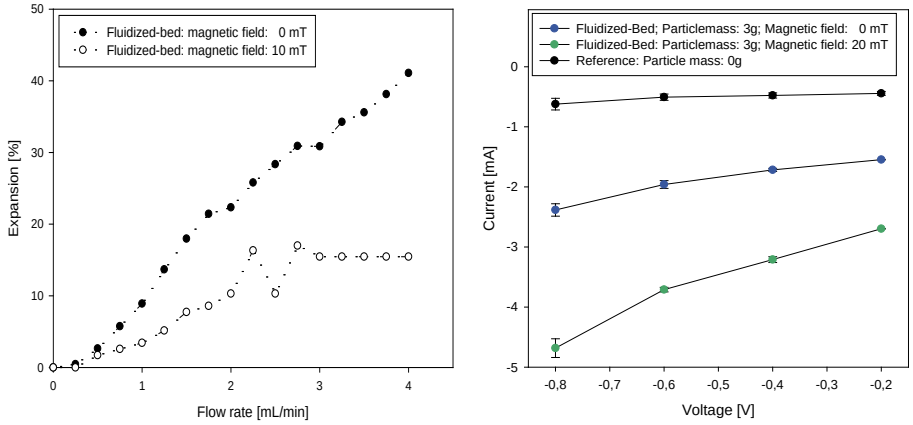

Figure 1. left: Expansion in percent of the fluidized bed plotted against the flow rate in mL/min: Comparison with and without magnetic field at 10 mT; **right**: Current of the electrochemical model reaction: reduction of a 3 mM potassium ferricyanide solution in a magnetically induced fluidized-bed reactor

4. Conclusions

With the developed magnetically influenced electrochemical reaction system, the efficiency of fluidized particle electrodes can be strongly improved. This offers new potential applications of electrochemical reactions within solutions with suspended solids, which would quickly plug conventional particle or wire mesh electrodes.

Highlights

- Process simulation for 500 MW_e air and oxy-coal power plants with CO_2 capture
- Amine absorber unit (AAU) and CO_2 processing unit (CPU) for CO_2 capture
- Oxy-combustion with CPU was more efficient than air-combustion with AAU

1. Introduction

Carbon dioxide (CO_2) has been considered as a major greenhouse gas (GHG), and the fossil fuel combustion produced about 41% of global GHG in 2010 [1]. The CO_2 capture and storage (CCS) is important for the coal-fired power plant to meet future targets on reduction of GHG emissions [2]. The amine absorber unit (AAU) is typically used in the air-coal combustion power plant for CCS [3.4]. The CO_2 processing unit (CPU) with a cold box is applied to the oxy-coal power plant due to high CO_2 content in flue gas [2]. However, few researchers have addressed the energy and economic analyses under the same operating parameters of the two plants with CCS. There remains a need for a comparison between the two plants to identify the economic feasibility. This study aims to develop the process flow diagram (PFD) of the two plants with and without CCS, and to evaluate economic values such as the total capital investment (TCI), total production cost (TPC), capital investment cost (CIC), carbon capture cost (CCC), and levelized-cost of electricity (LCOE).

2. Methods

The PFDs of the two power plants were simulated by a commercial code (ASPEN Plus) to calculate the mass and energy balances. The PFD of the air-coal power plant consisted of five main areas: A100 (coal pretreatment), A200 (circulating fluidized-bed combustion-CFBC), A300 (electricity generation), A400 (flue gas desulfurization-FGD), and A500 (AAU). In the oxy-coal power plant, A400 was replaced by a flue gas conditioning (FGC), A600 (air separation unit-ASU) was added, and A500 was substituted with A700 (CO_2 processing unit-CPU).

The operating parameters applied equally to the two plants included: (1) The coal feed rate is fixed at 3080 t/d, (2) The CFBC is operated at 875°C and 1 atm, (3) The heat loss of CFBC is 5 % of LHV during coal combustion, (4) The equivalence mass ratio (O_2 to fuel) is 2.5, (5) Ultra super-critical (USC) steam (600°C and 300 bar) is generated, (6) 90% SO_2 is removed inside the combustor by CaO

(limestone), (7) The CFBC includes SCR with aqueous NH_3 for NOx removal, and electrostatic precipitator (ESP) for dust removal, (8) The produced CO_2 over 95 % purity and over 90% recovery in the gas phase aims to be sequestrated under the ground, (9) The produced CO_2 at 8 bar and 20 °C contains water under 250 ppm, and (10) The total amount of CO_2 captured are the same. Three cases were considered to compare the energy and economic analyses: Case 1 (air-coal power plant without carbon capture), Case 2 (air-coal power plant with AAU), and Case 3 (oxy-coal power plant with CPU). The energy and economic analyses included the net thermal efficiency, heat penalty, TCI, CIC, CCC, LCOE.

3. Results and discussion

The process performance of the three cases is shown in Table 1. Case 1 has the highest net electricity and net thermal efficiency because of no carbon capture. The heat penalty of Case 2 (air-coal power plant with AAU) is higher than that of Case 3 due to high amine regeneration heat in AAU. As mentioned earlier, the CO_2 captured is the same for Cases 2 and 3. The TCI of Cases 2 and 3 is higher by 66.42 and 91.3 M$, respectively, than that of Case 1. The LCOE increases by 39.4 and 25.6 $/MWh for Cases 2 and 3, respectively, because of CO_2 capture. The CIC and CCC of Case 2 are higher than those of Case 3 and higher the CO_2 price (26.3 $/t) was reported by Moioli *et al*. (2017) [5]. Therefore, Case 3 (oxy-coal power plant with CPU) shows the better energy and economic performances than Case 2.

Table 1. Process performance of air- and oxy-coal power plants.

Performance indicators	Case 1	Case 2	Case 3
Net electricity (MW_e)	502	403	420
Net thermal efficiency ($\%_{HHV}$)	45	36.1	37.6
Heat penalty (%, based on Case 1)	–	20.5	16.8
CO_2 captured (t/d)	–	7278.7	7282.4
TCI (M$)	361.2	427.6	452.5
LCOE ($/MWh)	78.5	117.9	104.1
CIC ($/kWh.y)	132.9	307.0	280.2
CCC ($/t)	-	28.08	25.50

4. Conclusion

The CO_2 capture is important for the coal-fired power plant to reduce the CO_2 emission. The energy and economic performance was evaluated for the 500 MW_e air-coal and oxy-coal power plants with CO_2 capture under the same operating parameters. It was found that the oxy-coal power plant with CPU was more efficient than the air-coal power plant with AAU in terms of LCOE, CIC and CCC. It would be better to design effectively heat networks.

Bio-ethanol a building block of the future.

Elio Santacesaria*[1], Riccardo Tesser[2], Martino Di Serio[2]

1 Eurochem Engineering srl, Milano, Italy; 2 Dipartimento di Scienze Chimiche Università di Napoli, Italy

**Corresponding author: info@eurochemengineering.com,www.eurochemengineering.com*

1. Introduction

Bio-ethanol production is growing in different countries for the convenience of using it as biofuel. It is well known that an intensive use of a raw material, as a vector of energy, promotes the use of the same material for the production of chemicals as occurred in the past for coal and petroleum originating respectively carbochemistry and petrochemistry. Ethanol can easily be transformed in other useful molecules such as, for example: ethylene by dehydration, acetic acid by oxidation, ethyl acetate or acetaldehyde by dehydrogenation. Bio-ethanol could become, therefore, a building block allowing the production of acetic acid derivatives with simple processes occurring in mild conditions. The mentioned processes require the improvement or development of opportune catalysts able to increase the yields of the desired products.

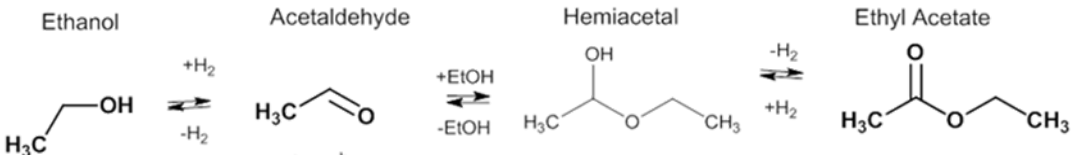
2. Methods

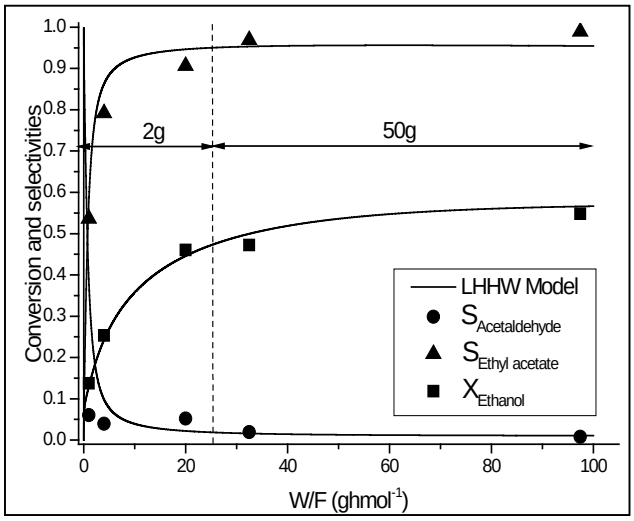
The kinetic runs have been carried out in a packed bed tubular reactor, alternatively filled with 2 or 50 g of catalyst, approximately isothermal, by feeding pure ethanol together with a mixture of nitrogen and hydrogen as carrier gas. Kinetic runs have been made by changing the temperature, in the range of 200-260°C, the pressure between 10 and 30 bars and the space time from 1 to 100 ($g.h.mol^{-1}$). We have verified, at first, that inter-phase and intra-phase mass transfer limitations were negligible in the adopted conditions.

3. Results and discussion

Catalysts promoting ethanol dehydration to ethylene and ethanol oxidation to acetic acid will be reviewed together with the operative conditions and related performances. A particular attention will be devoted to the reaction of ethanol dehydrogenation to obtain ethyl acetate [1], in one step reaction in the presence of the commercial catalyst: $CuO/Cu/CuCr_2O_4/Al_2O_3/BaCrO_4$ pre-reduced catalyst (BASF Cu-1234-1/16-3F). The mentioned catalyst has been reduced with hydrogen before the use and tested in a fixed bed laboratory reactor by feeding ethanol in a stream of H_2 diluted in N_2 (H_2/N_2=6/94 mol/mol), by exploring a temperature range of 200-260°C and a pressure range of 10-30 bars. This catalyst has shown high activity, selectivity and thermal stability. The best results have been obtained by operating at 220-240°C, 20 bars and 98 (grams hour/mol) of ethanol contact time, corresponding to 65% of conversion and 98-99 % of selectivity to ethyl acetate. The conversion is the maximum obtainable at the equilibrium and the selectivity is the highest value obtained until now for this reaction. Therefore, this catalyst is a good candidate for developing a new process to produce ethyl acetate. It is important to point out that the same catalyst allows to obtain also acetaldehyde in a good yield just reducing the pressure in

the reactor [2]. At last, it is worth of mention that this process has the advantage to produce pure hydrogen (exempt of CO) as by-product useful to be employed in the fuel cells [2]. A detailed kinetic [3] approach for this catalytic process has been made giving interesting suggestions about the reaction scheme and mechanism:





A Langmuir-Hinshelwood-Hougen-Watson kinetic model has been used for interpreting all the experimental data collected. This model corresponds to a mechanism in which the first step is the dissociative adsorption of ethanol on the surface, giving an adsorbed ethoxy group. Then, two other consecutive steps give place to respectively acetaldehyde as intermediate and ethyl acetate. This kinetic model allows a satisfactory fitting of all the performed experimental runs with a standard error below 15% for the runs performed with 2g of catalyst and less than 12% for the runs made with 50 g of catalyst.

4. Conclusions

Ethanol can give place to different interesting reactions and become a building block for producing some different commodities provided that its cost as fuel decreases at a competitive level. Clearly catalysis plays a fundamental role in promoting new innovative processes like the ones described in this presentation

Experimental study of a novel finned and tube phase change material storage for low-temperature applications

Giorgio Besagni[1], Lorenzo Croci[1]

1 Ricerca sul Sistema Energetico - RSE S.p.A., Power System Development Department, via Rubattino 54, 20134 Milano (Italy)

**Corresponding author: giorgio.besagni@rse-web.it*

Highlights

- A pilot-scale phase change material storage is build and tested.
- The effect of operating parameters have been evaluated.
- The energy stored is 80% higher compared with a water storage.

1. Introduction

Thermal energy storage (*TES*) is a matter of intense research and discussion, to decouple the "*demand-side*" and the "*supply-side*". This field of study is of paramount importance interesting in the residential sector, to support the large-scale deployment of renewable energy-based technologies to support the decarbonistaion pathways. A promising solution to reduce the primary energy consumption at the household scale regards solar-assisted systems (i.e., solar assisted heat pumps, *SAHPs*). In this perspective, this paper contributes to the existing discussion by developing a "*pilot-scale*" finned and tube phase change material storage for low-temperature applications (viz., storage temperatures in the range of 20 - 30 °C, accordingly with the experimental outcomes of Besagni et al. [1])

2. Methods

A novel "*pilot-scale*" phase change materials storage is proposed, designed and tested. To this end, a laboratory test facility has been designed and build; it aims testing the influence of a variation in the boundary conditions (flow rate, temperature, heating load) on the global and local performances and charging/discharging times (Figure 1, see Table 1 for the details of the instrumentation). Following the discussion of Palomba et al. [2], a fin-and-tube heat exchanger is selected (see Table 1). The phase change material used is paraffin *RT26* [3].

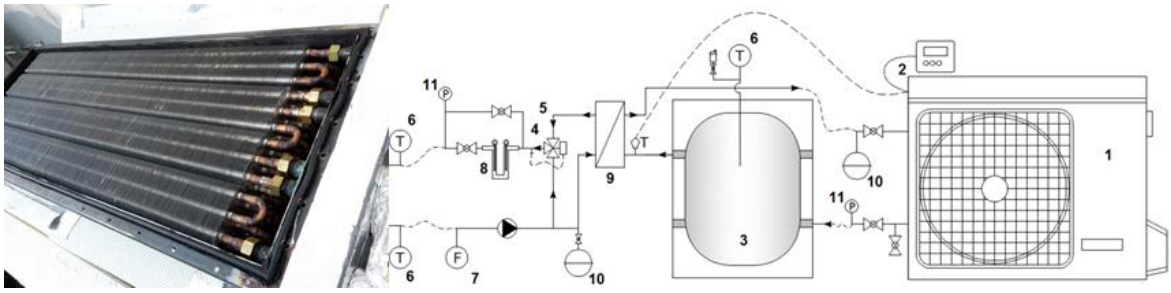

Figure 1. Test facility (details of the experimental system is Table 1).

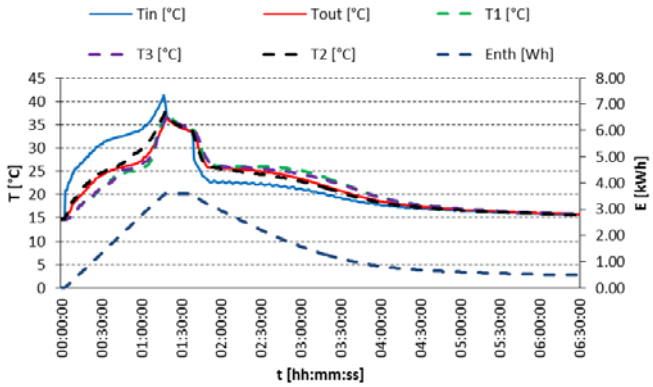
Table 1. Details of the experimental system.

Code name (Figure 1)	Equipment and details
1	Reversibile heat pump (MAXA, i-HWAK//V4 06, R410A)
2	Remote control system for the reversible heat pump
3	Buffer storage tanks for heat pumps; 51l, water storage
4	Deviation valve
5	Variable speed circulation pump
6	Temperature probe - RTD Pt100 (1/5DIN)
7	Electromagnetic flow meter
8	Two electrical resistances (1500 W each)
9	Plate heat exchanger
10	8dm^3 expansion tank
11	Pressure Transducer

3. Results and discussion

The heat exchanger was tested in two different configurations (viz. series and parallel), to investigate the influence of the non-uniformity of heat exchange on the global (energy storage) and local (local temperature inside the storage). For example, Figure 2a shows the energy storage inside the storage unit for given inlet (T_{in}) and outlet (T_{out}) temperatures. Conversely, (the locations of T_1, T_2 and T_3 are displayed in Figure 2b. It was found that the exchanger in the parallel configuration was able to achieve better performances, stored approximately 80% higher compared with a water storage (temperatures in the range of 15 ° C - 40 ° C). This increase is higher than that the one previously shown in the previous literature [2].



(a) heating load 2.8 kW, parallel configuration

(b) location of internal probes

Figure 2. Test Experimental results.

4. Conclusions

A "*pilot-scale*" finned and tube phase change material storage for low-temperature applications was built and tested, showing promising performances (i.e., energy stored is 80% higher compared with a water storage). In future studies, the obtained data can also be used to calibrate and validate a numerical model.

Highlights

- A novel process for H_2 production by the SEWGS of blast furnace gas is proposed
- A Cu/CuO chemical loop supplies the energy required for the regeneration of the sorbent
- A process design has determined the operating windows for each stage of the system
- Results show theoretical viability of the process and potential for further development

1. Introduction

Steelmaking is the main energy-consuming industry in the world, accounting for 27 % of the total CO_2 emissions from industrial processes [1]. CO_2 Capture and Storage (CCS) is the only alternative that can lead to a drastic reduction in CO_2 emissions far beyond that currently achievable in the steelmaking industry and achieve the climate change mitigation targets set as long term objectives after COP21 [2]. The implementation of pre-combustion capture systems on the blast furnace gas (BFG) appears to be an attractive option to achieve higher carbon capture rates in the steelmaking process [3], since BFG contains 60-80% of the total carbon entering the steel mill in the form of CO and CO_2. The Sorption Enhanced Water Gas Shift (SEWGS) can be particularly suitable to decarbonize the BFG and produce a H_2-enriched fuel gas that can be easily integrated throughout the steel mill [4]. In the SEWGS, a high-temperature sorbent (typically a hydrotalcite-like or a CaO-based material) removes the CO_2 from the gaseous phase as soon as it is produced [5]. The WGS equilibrium is then shifted towards a higher production of H_2 according to the Le Chatelier's principle. As a result, the almost total conversion of CO can be achieved. CaO-based materials exhibit very high theoretical energy recovery and also have higher CO_2 carrying capacities: up to 45% wt. in newly developed CaO materials compared to 8% for hydrotalcites. The main challenge for the scaling-up of the SEWGS is the need to find an efficient and low-priced method for the regeneration of the CO_2 sorbent. The Ca-Cu chemical looping process, patented by CSIC in 2009 [6], is based on the "unmixed reforming" concept [7], but with the key difference that the heat needed for $CaCO_3$ calcination is supplied in situ by the exothermic reduction of CuO to Cu with a gaseous fuel. Significant progress in reactor modelling, thermal integration and materials durability have been made over the last years in the Ca-Cu looping process [8]. This concept has also been experimentally validated in fixed beds at TRL4 [9]. In recent works [10], the Ca-Cu process has been proposed to decarbonize the off-gases of steel mills using an arrangement of interconnected fluidized-bed reactors operating at atmospheric pressure. In this work, an

advanced configuration based on several fixed-bed reactors operating in parallel is proposed to integrate the Ca-Cu looping process in a steel mill. This configuration facilitates the performance at high pressure, which allows higher energy efficiencies to be achieved and avoids the need for downstream solid-gas separation devices.

2. Process description

The proposed Ca-Cu looping process follows a sequence of at least three reaction steps. A H_2-rich gas is first obtained through a sorption enhanced water gas shift (SEWGS) process of BFG at 600-650ºC and 20 bar, while CO_2 reacts with CaO to form $CaCO_3$. In a second stage, Cu oxidation takes place at 20 bar with diluted air (about 3% of O_2) by recirculating part of the N_2 obtained as product to limit the temperature of the bed material below 880ºC, thereby minimizing the calcination of the CO_2 sorbent (i.e., the CO_2 slip during this stage). In the third stage, the necessary heat to calcine $CaCO_3$ is directly supplied by the exothermic reduction of CuO-based solid with a gaseous fuel (that can be coke oven gas or external natural gas), thereby producing a highly concentrated stream of CO_2 and H_2O(v). An appropriate $CuO/CaCO_3$ ensures that the heat generated during the CuO reduction is sufficient to decompose completely the calcium carbonate.

3. Results and discussion

Balances of a steel mill integrated with the Ca-Cu process are solved and compared with those obtained for a reference steelworks plant with post-combustion CO_2 capture through amine absorption. Using exclusively the coke oven gas (COG) available in the steel mill as reducing gas in the reduction/calcination stage around 30% of the BFG can be decarbonized in the SEWGS reactor. An overall CO_2 capture efficiency in the steel plant higher than 90% can be achieved if additional natural gas is used as fuel in the reduction/calcination reactor together with the COG. The proposed Ca-Cu looping process offers great CO_2 capture rates with moderate energy consumption. A specific primary energy consumption for CO_2 avoided (SPECCA) in the Ca-Cu looping process of 2.3 MJ/kg CO_2 has been calculated, which is much lower than the energy consumed in the reference plant with CO_2 capture using amine absorption (i.e. 4.3 MJ/kg CO_2).

Oil-Water Biphase Chaotic Mixing Enhanced by Elastic Combination Impeller in Mixer-Settler.

Zuohua Liu[1], Chuang Wang[1], Deyin Gu[1], Facheng Qiu[1], Changyuan Tao[1], Yundong Wang[2]

1 School of Chemistry and Chemical Engineering, Chongqing University,Chongqing400044,China; 2 State Key Laboratory of Chemical Engineering, Department of Chemical Engineering, Tsinghua University, Beijing 100084,China

**Corresponding author: Prof. LIU Zuohua, liuzuohua@cqu.edu.cn*

Highlights

- The spring of the elastic impeller is easy to stretch and bend, which can change the way of impeller disturbing the flow field structure.
- The elastic combined impeller strengthens the energy dissipation mode of the flow field through the deformation and energy storage of the spring, and improves the chaotic mixing degree of the liquid and liquid biphases.

1. Introduction

The problem of low energy consumption and high efficiency exists in the traditional liquid-liquid biphase extraction in the mixer-settler. By means of Lab View software, pressure pulsation signals in the mixed fluid in the disturbing and clarifying tank of the rigid impeller, rigid -flexible combined impeller and elastic combined impeller are respectively collected. And then get the largest Lyapunov exponent (LLE) and multiscale entropy (MSE) which are reflects the degree of chaos in the fluid. At the same time, the fluid field's visualization technology was adopted to observe fluid mixing performance, the influence of the length, diameter and outer diameter of the spring on the chaotic characteristics of the flow field is also investigated. The results indicated that compared with the rigid impeller and the rigid-flexible combined impeller, the elastic combined impeller strengthens the energy dissipation mode of the flow field through the deformation and energy storage of the spring, and improves the chaotic mixing degree of the liquid and liquid biphases. The LLE was over zero, testifying the fluid mixing system in chaotic state. In the elastic combination impeller system, not only are the values of LLE and MSE significantly higher, but also the time of complete decolorization is the shortest in the visualization experiment.

2. Methods

Experiments are conducted in the mixer settler and control room temperature 24 ℃ - 27 ℃, water and kerosene as experiment medium oil-water and two chaotic mixing experiment, the experimental process control the volume flow of water and kerosene ratio of 1:1. The pressure pulsation signal is collected on the mixed indoor wall of the mixing clarifying tank. After that, the pressure sensor, data acquisition card and data acquisition system composed of workstation are converted and processed on the Lab View working platform and then output. The output data are programmed and calculated by Matlab software. Where, each group of experiments was sampled

for 15 min with a sampling frequency of 65 Hz. The mixer-settler and impellers used in the experiment are shown in Fig. 1 and Fig. 2 respectively.

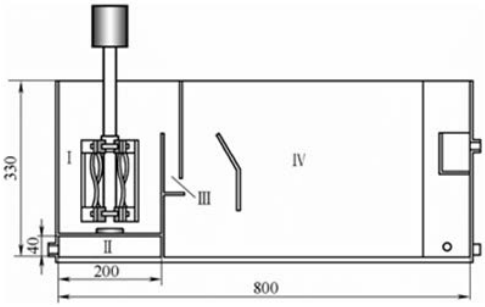

Figure 1. Structure of mixer-settler

Ⅰ-mixing chamber; Ⅱ-submersible mixing chamber;

Ⅲ-overflow area; Ⅳ-clarification chamber

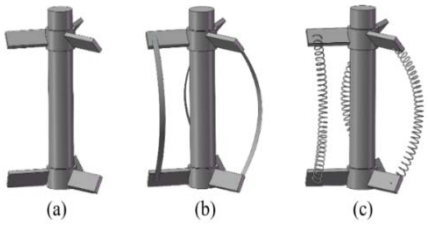

Figure2. Impellers used in experiment

(a)rigid combination impeller (b)rigid-flexible combination impeller (c)elastic combination impeller

3. Results and discussion

The LLE is an important parameter to measure the dynamic characteristics of the system. It reflects the average exponential rate of convergence or divergence between adjacent orbits in the phase space system [1]. Multi-scale entropy (MSE) is to calculate the sample entropy of time series at multiple scales, which reflects the irregularity of time series at different scales. It has good anti-noise and anti-interference ability, and the analysis of time series is more systematic. The experimental results are shown in figure 3 and 4.

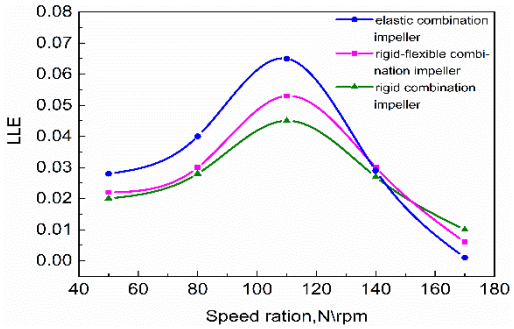

Figure 3. Effect of impeller type on LLE

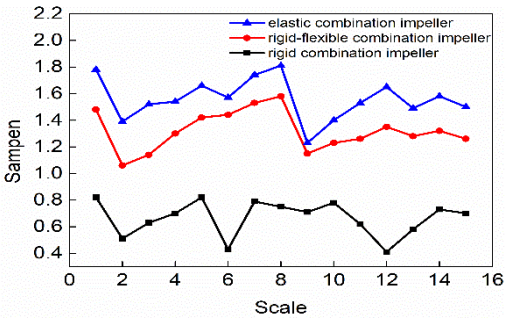

Figure4. Effect of impeller type on MSE

4. Conclusions

Due to the spring's characteristics of being easy to stretch and bend, the elastic combination impeller can effectively destroy the stability of the flow field structure near education and regulate the flow field, thus strengthening the chaotic mixing of the flow field. The mixing effect is obviously better than that of the rigid-flexible combination impeller and rigid combination impeller.

Effect of Surfactant on Velocity and Oxygen Mass Transfer of a Single Bubble Rising in a Liquid.

Gaëlle Lebrun[1,*],Feishi Xu[1],Gilles Hébrard[1] and Nicolas Dietrich[1]

LISBP, Université de Toulouse, CNRS, INRA, INSA, Toulouse, France
**Corresponding author: Gaelle.Lebrun@insa-toulouse.fr*

Highlights

- Effect of contaminant on hydrodynamic of a bubble rising in a liquid.
- Combined effects of polymer and surfactant on oxygen mass transfer.

1. Introduction

Dispersion of bubbles in liquid for oxygen transfer found applications in a wide range of fields such as medicine (oxygenation of blood) or environment (wastewater treatment). It is known that presence of surface-active agent in liquid lead to an inhibition of gas-liquid mass transfer [1]. Indeed, they can affect the oxygen mass transfer from a bubble via the modification of the hydrodynamic of the bubble such as its velocity, shape and diameter, but also by affecting directly the diffusion coefficient of oxygen [2]. Although researches about this subject increased, interfacial phenomenon that occurs during the mass transfer is not clearly understood. Surface contamination by surfactant of a bubble rising in a liquid is a time dependent parameter. Indeed, the kinetic of adsorption depends on the diffusion coefficient of the surfactant which is linked to the nature of both surfactant and bulk [3], improvement of the knowledge about contamination kinetic could be useful for a better understanding of interfacial phenomena.

The aim of this study is to highlight the effect of surfactants in different bulks on the bubble hydrodynamic and mass transfer. For that purpose, we studied hydrodynamic of bubbles in different liquids compositions and compared with pure water. In addition, to link this phenomenon with mass transfer, the same solutions has been used and mass transfer of oxygen has been determined by Planar Laser Induced Fluorescence Inhibition (PLIF-I) method [4]. This method has already been used in literature to identify an important decrease of mass transfer when polymer [5] and surfactant [1] are added to water; here the combined effect of each has been investigated.

2. Methods

The column where oxygen transfer occurred was filled with the different compositions: pure water, surfactant (SDS and Triton X-100), polymer (polyacrylamide and polyalkylene glycol) and surfactant mixed. Surfactants were characterized by their composition, density, static and dynamic surface tensions. The liquid has been deoxygenized with nitrogen before each experiment. A single bubble was generated with a syringe pump and injected through a stainless steel needle into the column. To excite fluorescence, horizontal laser sheet was generated by a laser (Nd:YAG laser: DANTEC Dynamics Dualpower 200-15, 15Hz, 2×200 mJ) . The image of fluorescence in the wake of the bubble were recorded by a Charged Coupled Device camera (CCD camera: DANTEC Dynamics

flowsense CM, 12 bits, 15 fps, 2048×2048 pixels) located at the bottom of the column and focused on the laser sheet. In order to avoid recording the light provided by the laser sheet, a 570 nm high pass filter was placed in front of the lens. The fluorophore used was ruthenium complex ($C_{36}H_{24}Cl_2N_6Ru;xH_2O$, Sigma-Aldrich) at a concentration of 70 mg/L. The hydrodynamics properties of bubbles in the column where obtained from the sequences of images recorded by a high speed camera (Photon SA3, 8 bits, 2000 fps, 1024×1024 pixels), and images recorded gave access to the velocity, the shape and the diameter of bubble along the column.

3. Results and discussion

For each solution prepared, the diameter, the shape, contamination have been determined, along with adimensional numbers (Reynolds, Schmidt, Scherwood). In these last solutions, results obtained from the PLIF-I method allow to quantify the flux of oxygen in the wake of the bubble and thus the diffusion coefficient. The results showed a drastic change in the hydrodynamic parameters of solutions, accompanied by a decrease of amount of oxygen transferred when surfactant are present in the solution. We calculated a division by 20 of the mass transfer coefficient when triton X-100 is added to water at a concentration lower than the CMC. This effect was even more marked when polymer and surfactant were both added to water.

4. Conclusions

Our experimental set up allowed us to visualize in the same times changes in hydrodynamics conditions of bubbles rising in liquids and oxygen mass transfer. The effect of both polymer and surfactant have been studied and showed a drastic decrease of the amount of oxygen transferred. This can be explained by changes in hydrodynamic conditions, but others effects can play a role in this diminution. Results highlighted the importance of improving our knowledge about the interface and organization of surfactant in this area for a better understanding of gas-liquid mass transfer phenomenon.

Highlights

- This paper presents information on how geothermal energy is trapped, transported and also about the recent methods applied for geothermal systems.
- Production of geothermal energy as an alternative source of fuel is possible.
- Selection of materials used for the transportation of geothermal energy.
- Geothermal energy in mining developments.

1. Introduction

Renewable energy is energy that is collected from renewable sources, which are naturally replenished on a human time scale, such as sunlight, wind, tides, waves and geothermal heat. Geothermal energy is thermal energy generated and stored in the earth. The geothermal energy of the earth's crust originates from the original formation of the planet and from radioactive decay of materials. The heat present inside the earth's crust can never be perishable and it is simply power. It is present from the shallow ground to deep down beneath the surface of the earth to the extremely hot molten rock called magma. The process of heat production from the earth's core is similar to that of petroleum production which involves drilling, and complete wells and produce fluids from wells present in the marked formations beneath the surface. The ultimate goal in the extraction of geothermal energy is the heat and not the fluid as in case of petroleum production. The energy required for the total world population is 2.2 terra watts and the energy produced from geothermal source is 44 terra watts which is more than sufficient for the world population. By trapping some parts of this source, we can reduce the usage of non-renewable sources which will deplete on further use. There is a lot of risk involved in the production of heat from the geothermal mines due to its high temperature and also requires high initial cost for the setting up of the plant. Trapping of hot steam from the earth's crust is the basic instinct during the usage of geothermal energy. For the process of trapping of steam, selection of materials is very essential. Materials that are heat resistant and which have high melting points can be used as the temperature of steam coming from the earth's crust is nearly 1300^0C for the transport of the energy. The first major hydrothermal developments were located in areas with high tectonic activity marked by volcanoes, geysers, hot springs and large hot water reservoirs. These resources are relatively shallow and often flow to the surface naturally.

2. Methods

Today, engineers and geophysicist are bringing techniques for enhanced geothermal systems (EGS) to high temperature dry reservoirs at a depth of 3-10 kms. At these depths, the rock is hot enough to convert water to superheated steam. The hot dry rock system recovers the earth's heat from hot but dry regions through the closed loop circulation of pressurized fluid. This fluid, injected form the surface under high pressure,

open spree existing joints in the basement rock, creating a man-made reservoir. The fluid injected into the reservoir absorbs thermal energy from the high temperature rock surface and then serves as the conveyor for transporting the heat to the surface for practical use.

There are 3 types of power plants for the extraction of geothermal power.

- Dry steam power plants are the most basic style of geothermal power plants. Steam piped from a hydro thermal reservoir directly enters turbine to generate electricity. As the steam cools and condenses, the water is gathered and injected back into the reservoir.
- Flash steam plants use hot water that is below the boiling point while at reservoir pressure but that flashes to steam at lower surface pressure.
- Binary power plants use a closed system to exploit even cooler reservoirs whose water temperatures are less than 150^0C. Water flows or is pumped to the surface and enters a heat exchanger where it brings a second fluid, to its boiling point, which must be below that of water. This fluid maybe circulated and this powers electricity generating turbines.

Geothermal energy can be extracted without burning of fossil fuel such as coal, gas or oil. Geothermal fields produce only about 1/6th of carbon dioxide that a relatively clean natural gas-fueled power plant produces. Though geothermal energy involves many risks, they can be transported through pipelines which are made up of heat resistant materials as the natural gas transportation is done in the recent times. Carbon nanotubes can be used for transportation of geothermal energy for its applications in many aspects. They are very economical and can withstand high temperatures up to 3400K. The multi walled carbon nanotubes do not burn at all, an intriguing property of carbon nanotube is their ability to harbor heat. Mining and geothermal production also share a dependence to the concepts of accessibility and extractability. Mineral deposits must have sufficient economic value to be mined at a profit. In geothermal production, it is the fluid's heat content, accessibility and extractability that determines whether a geothermal resource is economically valuable and warrants production.

3. Results and discussion

The geothermal energy trapped and transported using the above methods can be used in the production of electricity, as a fuel, as an alternative for fossil fuels. The low temperature geothermal energy can be used for fishing, household purposes. Balneotherapy is the treatment of diseases by spa which requires hot springs and geysers produced from a geothermal power plant is pumped over a lava bed rich in Sulphur and silica content. These elements react with the hot water from the power plant and imbibe healing properties. Geothermal energy also shows high efficiency of about 86-95% which is very high compared to other renewable energy sources and whose supply is continuous and reliable.

4. Conclusion

Geothermal energy is an alternative and a considerable energy source in the present era as we are becoming deficit of non-renewable energy sources. Due to the use of geothermal energy, emission of greenhouse gases can also be minimized which in turn could reduce global warming.

Highlights

- The calculation of the increment angles of reflection of rarefied flows is proposed.
- Distribution functions over the states of the macrosystems are taken into account.
- The basis is the results of stochastic modeling of mixing of flowing media with brushes.
- The effectiveness of the intermediate stage of mixing with the bump is analyzed.

1. Introduction

The urgency of the problem of mixing loose components is explained by the diversity of the purpose of the mixtures obtained for the needs of various industries and the agro-industrial complex. The development of methods for mixing loose components in a regulated ratio of 1:10 or more requires the designers of the respective equipment to perform a system-structural analysis of this process. The basis of this analysis is a theoretical prediction of the efficiency of the mixing process at each stage. The gravitational method for obtaining a free-flowing mixture with the specified ratio of components in the finished product proposed in [1] implies the presence of three mixing stages on trays with two steps in each. In this case, the first step involves the use of additional mixing elements in the form of brushes, and the second - fender surfaces.

2. Methods

The aim of the work is to develop a method for calculating the average value for the volume fraction of the key bulk component at the intermediate stage of gravity mixing using an inclined - bump stop surface. This characteristic of the mixing process is necessary in assessing the quality of the mixture with a regulatory ratio of 1:10 components, as an indicator of the effectiveness of the intermediate stage of the process under study. The proposed expression for the desired characteristic of the key component was obtained on the basis of the stochastic approach [2, 3], taking into account the results of modeling the formation of rarefied streams of solid dispersed materials. In this case, at the first step for the stage of intermediate mixing, the use of brush elements on a rotating drum is supposed [4-6]. At the second step, an impact surface is used [7–9] for shock interaction with rarefied streams of mixed materials formed after scattering with brushes. The specified expression uses the function for the volume fraction of the key component depending on the angles of reflection of each of the two bulk materials from the bump stop surface [8]. In addition, the latter function takes into account the method proposed earlier by the authors for calculating the volume fractions [10, 11] for the mixed portions of the components, which correspond to the intermediate

stage of this process. Note that a convenient in this case, the criterion for assessing the quality of the mixture is its coefficient of heterogeneity, which is determined in the traditional way [10, 11].

3. Results and discussion

The calculation of the maximum values for the reflection angles of each of the bulk components from the bump stop surface at the studied intermediate stage of their mixing is performed taking into account their increments. These increments are calculated depending on the scattering angles of the particles of the components in their rarefied flows, formed after scattering with brush elements. An expression for the nonequilibrium differential distribution function of each component in the scattering angle from brushes was used [4-6]. This function is obtained taking into account the design and operational parameters of the mixer unit "drum-brush elements". When describing the relationship between the scattering angle from the brushes and the angle of reflection from the bump stop [7, 8], the recovery factor is used, which characterizes the directions of the average velocities of the sparse fluxes of each component when striking the bump stop and when they are reflected from it. Modeling the desired average value for the volume fraction of the key bulk component at the intermediate stage of gravitational mixing using an inclined impact surface allows you to calculate the corresponding coefficient of heterogeneity.

4. Conclusions

Using the example of model mixing of two non-humidified components, comparable in size and density (sand and semolina), the heterogeneity coefficient of the resulting mixture for the intermediate stage was calculated. For this stage, mixing is assumed in equal proportions between the resulting mixture after the initial stage and the new portion of the key component (sand). The results of the work can be used in the formation of an engineering method for calculating a new gravity mixer of non-humidified bulk components in predetermined ratios of 1:10 or more with additional mixing elements (brushes and bump stops).

Highlights

- Manufacture of electrolytic solution using glycerol as reducing agent.
- After the electrolytic solution was prepared from a low-concentration sulfuric acid-supported electrolyte, a sulfuric acid solution was added.

1. Introduction

One of the safest of large-capacity energy storage system is the vanadium redox flow battery.

In the vanadium redox flow Battery, the electrochemical reaction of oxidation and reduction takes place in the stack, and the energy storage is stored in an electrolyte stored in a separate electrolyte tank. The electrolytic solution accounts for about half of the cost of the vanadium redox flow battery. For this reason, the development of efficient electrolytes is essential. In this study, we have experimented to manufacture electrolytes to improve the efficiency of vanadium electrolytes[1].

The reaction formula of the anode and the cathode of the vanadium redox flow cell is as follows.

Positive electrode reaction: $$VO^{2+} + H_2O \underset{Discharge}{\overset{Charge}{\rightleftharpoons}} VO_2^{+} + 2H^{+} + e^{-} \quad E^0 = 1.0\ V$$

Negative electrode reaction : $$V^{3+} + e^{-} \underset{Discharge}{\overset{Charge}{\rightleftharpoons}} V^{2+} \qquad E^0 = -0.26\ V$$

2. Methods

The preparation of the electrolyte solution was carried out in the following order.

First, V(IV) solution was prepared by using VOSO4 in a low aqueous sulfuric acid solution. Second, V (III) solution and V (V) solution were prepared from V (IV) solution using charge/discharge cell. Third, the V(V) solution is reduced to V(IV) using a glycerol reducing agent and then mixed with the

V (III) solution to prepare a 3.5-valence electrolyte solution. Finally, sulfuric acid was added to the 3.5 valence electrolyte solution to prepare

3. Results and discussion

Figure 1 shows the electrical properties of the prepared electrolyte solution by Cyclic Votammetry(CV). Both curves show the electrical characteristic curves of a typical vanadium electrolyte. Figure 2 shows the results of charge/discharge test of the completed vanadium electrolyte solution for 50 times by adding 2M H_2SO_4 to the supporting electrolyte 1M H_2SO_4. Figure 3 shows the results of charge/discharge test of the completed vanadium electrolyte solution for 50 times by adding 1M H_2SO_4 to the supporting electrolyte 2M H_2SO_4. In the case of energy efficiency and voltage efficiency, better efficiency was obtained when the initial H_2SO_4 concentration was 1M.

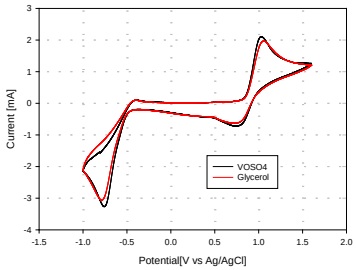

Figure.1 CV curve of V (IV) electrolyte solution prepared with $VOSO_4$ and V (IV) electrolyte solution reduced with glycerol reducing agent.

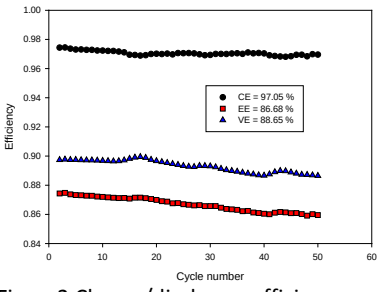

Figure2 Charge/discharge efficiency curve for 50 cycles (1M H_2SO_4 electrolyte solution + 2M H_2SO_4 addition).

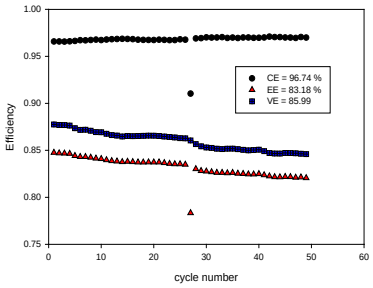

Figure 3 Figure2 Charge/discharge efficiency curve for 50 cycles (2M H_2SO_4 electrolyte solution + 1M H_2SO_4 addition).

4. Conclusions

Energy efficiency increased from 83.18% to 86.68%, and voltage efficiency increased from 85.99% to 88.65%. It was confirmed that the completion of the vanadium electrolyte using a low concentration of the supporting electrolyte in the preparation of the electrolyte solution, and then the addition of the concentration of H_2SO_4 to the final completion of the electrolyte solution can be improved in the improvement of the energy efficiency and the voltage efficiency.

High performance dual-electrolyte aluminum-air flow battery

Pemika Teabnamang[1], Soorathep Kheawhom[1,2,*]

1 Department of Chemical Engineering, Faculty of Engineering, Chulalongkorn University, Bangkok, Thailand; 2 Research Unit of Advanced Materials for Energy Storage, Chulalongkorn University, Bangkok, Thailand

**Corresponding author: soorathep.k@chula.ac.th*

Highlights

- Dual-electrolyte cell using methanol anolyte suppresses anode corrosion.
- Flowing anolyte prevents passivation of aluminum anode.
- Higher water content improves discharge current density.
- Higher water content increases self-corrosion.

1. Introduction

Recently, climate change has become increasingly significant putting considerable pressure on various aspects of our environment. To address this problem, a sustainable solution for energy generation and storage are actively investigated. Electrical energy storage (EES) systems are essential for the effective utilization and integration of renewable energy sources to the power grid. EES systems offer many benefits including improving the way energy is delivered, consumed and generated. Rechargeable batteries are the most common energy storage system.

Rechargeable aluminum-air batteries are a promising EES system. Aluminum-air batteries have a high specific capacity of 2.98 Ah/g. Furthermore, the aluminum anode is an inexpensive, abundant and environmentally friendly metal with high recyclability. Nonetheless, corrosion of the aluminum anode is a critical issue for traditional aluminum-air batteries. The anodic corrosion results in the accumulation of hydrogen gas in the cell and increases the hydrogen explosion possibility. Besides, it causes unacceptably high energy losses. Various works have attempted to inhibit aluminum self-corrosion by alloying aluminum with other elements or modifying the electrolyte using certain additives. Nevertheless, these efforts have shown limited success and have often increased the complexity of the battery system. To address this issue, aluminum oxidation should take place in a non-aqueous environment with high aluminum anode activity while suppressing the corrosion rate. Methanol (CH_3OH) used as the electrolyte was found to provide a high capacity under a dual-electrolyte system in an aluminum-air battery whereby a non-aqueous electrolyte was used for the anolyte and an aqueous electrolyte was used for the catholyte. Hence, this work proposes a dual-electrolyte aluminum-air flow battery with a structure of an aluminum anode | methanol electrolyte || gel polymer electrolyte | air cathode.

2. Methods

The corrosion behavior of the aluminum anode in methanol with varying the amount of deionized water (0%, 5%, 10% and 20%) and 3 M KOH-methanol mixed solution was examined by measuring the volume of evolved hydrogen gas as a function of time. Also, the half-cell test was carried out

using a three-electrode cell was used to study the electrochemical measurement and characterization. The battery cell structure consisting of aluminum anode | anolyte | anion exchange membrane | catholyte | air cathode was fabricated as shown in Fig. 1. The anolyte is 3 M KOH in methanol containing different percentages of deionized water. The catholyte is a gel polymer electrolyte based on Carbopol 940. Performances of the batteries were then examined.

3. Results and discussion

The volume of hydrogen evolved can speculate how much aluminum consumed without discharging. The results showed that hydrogen evolution is higher when the percentage of water is raised. The highest weight loss of aluminum occurred in the condition of 20% water; this condition contained the highest deionized water percentage. The results of electrochemical impedance spectroscopy showed that water in the anolyte had various effects such as decreasing aluminum double-layer, increasing mass transfer owing to the decrease in electrolyte viscosity and enhancing conductivity. Thus, increasing of deionized water leads to higher anodic corrosion.

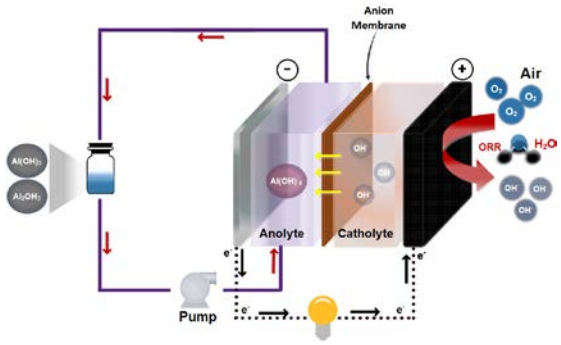

Figure 1. Schematic diagram of a dual electrolyte aluminum-air battery.

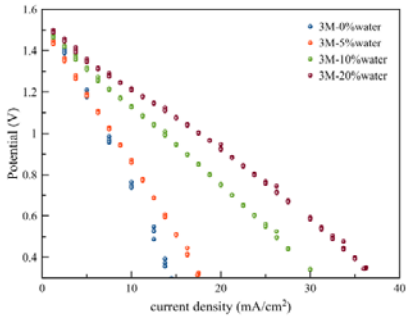

Figure 2. Polarization characteristics of the aluminum-air flow battery using different anolytes.

Figure 2 shows the polarization characteristics of the aluminum-air battery. The limiting current density for each condition slightly increased as follows: 14.97 mA/cm^2, 17.50 mA/cm^2, 30 mA/cm^2 and 36.3 mA/cm^2 at 0, 5, 10 and 20% water, respectively.

The anhydrous methanol anolyte achieved a specific capacity of 2,328 mAh/g for around 40 hrs. When the deionized water increased, the specific capacity decreased consecutively: from 1,700 mAh/g, 1,130 mAh/g and 465 mAh/g at the condition of 5, 10, and 20% water, respectively. Simultaneously, when the deionized water was increased, discharge voltage also increased, but the aluminum utilization percentage decreased. In the anhydrous methanol anolyte, the corrosion of aluminum is significantly inhibited, but the corrosion substantially increased when the amount of water increased.

4. Conclusions

The dual-electrolyte system using methanol-KOH anolyte completely suppressed the anodic corrosion and provided the highest specific capacity of 2,328 mAh/g discharging at 10 mA/cm^2. The aluminum consumption had more than 75%. In addition, the discharge voltage of the battery increased when the electrolyte contained water. However, the presence of water in the anolyte decreased the specific capacity as the corrosion increased. Trade-off between discharge performance and corrosion can be done adjusting the water content in the methanol-KOH anolyte.

Power-to-Syngas Processes by Reactor-Separator Superstructure Optimization

Andrea Maggi[1]*, Marcus Wenzel[1], Kai Sundmacher[1, 2]

1 Max-Planck-Institute for Dynamics of Complex Technical Systems, Sandtorstr. 1, 39106 Magdeburg, Germany; 2 Otto-von-Guericke-University Magdeburg, Universitätsplatz 2, 39106 Magdeburg, Germany

**Corresponding author: maggi@mpi-magdeburg.mpg.de*

Highlights

- Power-to-Syngas process superstructure for different syngas compositions introduced.
- Optimal energy pathways to syngas from renewables identified via LP.

1. Introduction

The transition from fossil (coal, oil, gas) to renewable feedstock and energy carriers (solar, wind, water, biomass) has become a matter of uttermost importance in the chemical industries. Moreover, the current large CO_2 emissions represent both a threat for the climate and an opportunity for an alternative carbon source. Schack et al. [1] showed how the shift towards sustainable production scenarios could be accomplished by identifying well-suited target products. In this regard, syngas is an ideal candidate: as reported by Wenzel et al. [2], it bridges the inputs from renewables and state-of-the-art downstream processes to fuels and chemicals by adjustment of the H_2/CO ratio. Reactor-separator processes are the tool allowing for such bridging. Different process alternatives available in this context suggest the deployment of a superstructural representation wherein different technologies can be embedded. Categories of available separation methods to purify and adjust the syngas to the requirements of the desired downstream processes include membrane separation, pressure swing adsorption, scrubbing and cryogenic operations.

2. Methods

In our superstructure approach, different types of catalytic conversion steps and separation methods are combined. The superstructure is the basis for the formulation of a Linear Program (LP) used for process optimization. The complexity of the system is reduced by assuming Gibbs reactors and sharp-split separation tasks. As shown in Figure 1, the feedstocks considered are water and biomass. The most promising reactor technologies considered are reverse water gas shift (RWGS) and steam reforming of methane (SR).

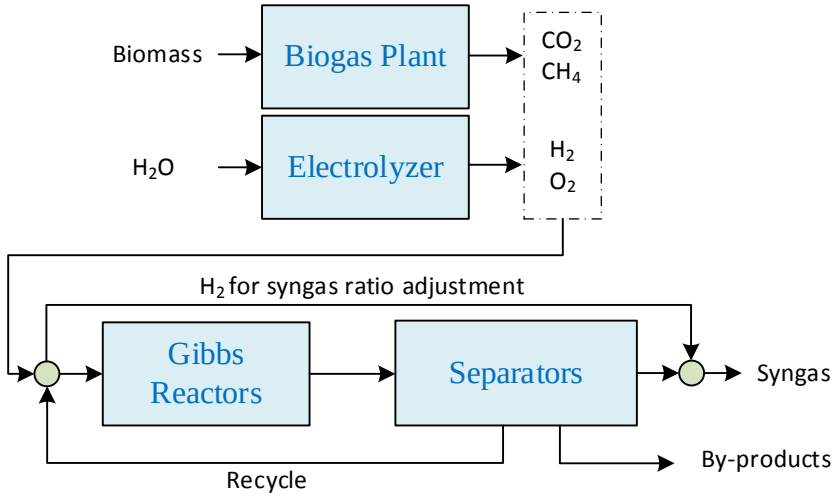

Figure 1 Schematic representation of a syngas plant. Biomass and water are converted into the reactants required for the generation of the final product.

The first objective to be minimized is the total energy requirement. Furthermore, pseudo prices are applied to the variables in the objective function to allow for the differentiation between day and night plant operations, therefore accounting for the intermittency of the renewable power sources. The solutions depend on the hydrogen to carbon monoxide ratio which the syngas must fulfil to meet the product specification.

3. Results and discussion

Preliminary results indicate that, for RWGS, the optimal syngas production route consists of water removal followed by a sequence of pressure swing adsorption steps for the adjustment of the hydrogen to carbon monoxide ratio. This approach is extended to scenarios where SR is included in the same optimization problem. Water electrolysis proves to be a bottleneck for the syngas production, possibly mitigated by the synergy between SR, yielding a high H_2/CO ratio, and RWGS.

4. Conclusions

The derivation of the method presented in this work is motivated by the need for an effective screening tool to identify the most energy efficient process within a large number of alternatives. The energy efficiency is of foremost importance in the context of Power-to-Chemical conversion systems, where the energy and raw chemicals are to be supplied from renewable sources. Nevertheless, this approach does not contrast with economic based optimizations but it offers a complementary standpoint.

Highlights

- CaO based catalysts were prepared by mechanochemical treatment.
- $3CaO{\cdot}SiO_2$ mixed oxide showed better stability than CaO·ZnO.
- Deactivation was caused mainly by adsorbed organic compounds on active sites.

1. Introduction

The synthesis of biodiesel, a mixture of fatty acid methyl esters (FAME), applying heterogeneous catalytic process could solve most of the economic and environmental drawbacks of the conventional homogeneous process. Solid catalyst can be easily separated from the reaction mixture, regenerated and reused, what make the biodiesel synthesis cost-effective and also enables the continuous process development [1]. However, one of the main problems associated with solid catalysts is their deactivation, caused by poisoning of active sites, leaching of active component into the reaction mixture, or structural change of the catalyst.

CaO based catalysts, CaO·ZnO and $3CaO{\cdot}SiO_2$ mixed oxide prepared by mechanochemical treatment and subsequent calcination exhibited excellent activity in transesterification of sunflower oil at 60 °C [3-5]. In this work, stability and deactivation of these CaO based catalysts was studied and compared to the activity and deactivation of pure CaO. The possibility to reuse the catalysts in consecutive runs was examined, as well as the leaching of the active component of the catalyst in the reaction mixture. The characterization of catalysts after reaction was performed in order to find out the cause of deactivation.

2. Methods

The fresh and reused catalysts were characterized by XRD, TGA/DSC, FTIR, SEM/EDX and base strength using Hammett indicator method. The details on the preparation of catalysts and the used instruments for their characterization are described elsewhere [2-4]. The methanolysis of sunflower oil was carried out in a 250 ml three-necked glass flask with a condenser and magnetic stirrer at 60 °C, methanol to oil molar ratio of 10:1 and 2 wt% of catalyst based on oil weight.

3. Results and discussion

The results showed that CaO·ZnO catalyst could be reused only 2 times without losing its activity, while already in the third cycle the FAME yield declined to 47%, and in fourth cycle the catalyst was practically not active (Figure 1). $3CaO{\cdot}SiO_2$ showed better stability, maintaining very good activity and high FAME yield, above 97%, for 4 cycles. For comparison, the activity of pure CaO

decreased in four consecutive runs [5]. To evaluate leaching of the active component, the catalyst sample was placed in contact with methanol under reaction conditions. After the catalyst was removed by filtration, methanol was mixed with the fresh sunflower oil. When CaO·ZnO was used, FAME yield was 0.21%, revealing negligible leaching of active component, while for $3CaO·SiO_2$ FAME were not detected. This finding confirmed the stabilization of CaO by the presence of another phase, since CaO, when used as pure compound, is partially dissolved in methanol [1].

The FTIR spectra of fresh and 4-times used $3CaO·SiO_2$ catalysts are very similar, indicating the stability of the catalyst during its use in transesterification of sunflower oil, and only negligible adsorption of organic compounds on the catalyst surface (Figure 2). XRD patterns of reused CaO·ZnO revealed only peaks assigned to ZnO, while peaks corresponding to CaO were not observed, indicating that they were blocked by products or intermediates. FTIR analysis confirmed the presence of organic compounds on the surface of CaO·ZnO catalyst.

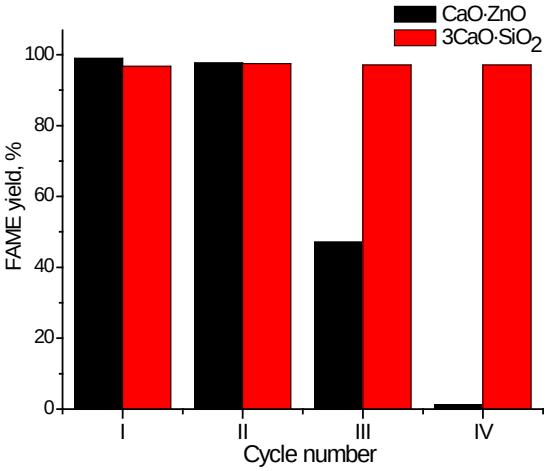

Figure 1. Number of repeated use.

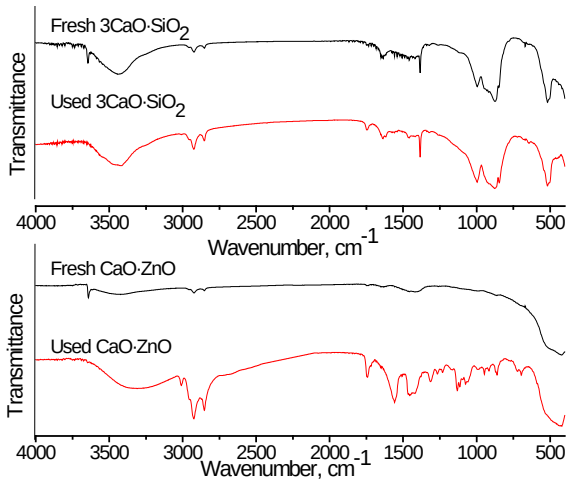

Figure 2. FTIR spectra of fresh and used catalysts.

4. Conclusions

$3CaO·SiO_2$ catalyst showed good stability in transesterification of sunflower oil, while drop of activity occurred already in the third reuse cycle when CaO·ZnO catalyst was used. The observed catalyst deactivation was probably the result of active site blockage by adsorbed organic compounds from the reaction mixture.

"Egg-Yolk" Catalyst Particle Design for Improved Flexibility of Industrial Scale Fixed-Bed Reactor used for CO_2 Methanation

Ronny Tobias Zimmermann[1], Jens Bremer[2], Kai Sundmacher[1,2]

1 Otto-von-Guericke Universität, Universitätsplatz 2, 39106 Magdeburg, Germany;

2 Max-Planck-Institut für Dynamik komplexer technischer Systeme, Sandtorstraße 1, 39106 Magdeburg, Germany

**Corresponding author: ronny.zimmermann@mpi-magdeburg.mpg.de*

Highlights

- Combined catalyst particle and reactor optimization.
- Dynamic and flexible fixed-bed reactor operation.
- Reduced parametric sensitivity of reactors filled with "egg-yolk" particles.

1. Introduction

Surplus electrical energy harvested from renewable energy sources can be efficiently stored by generation of hydrogen via electrolysis of water. Due to the missing hydrogen infrastructure, it is favorable to convert hydrogen together with carbon dioxide into synthetic methane. Methane can be readily distributed in existing pipeline networks and is a key substance of the chemical industry. However, the high exothermicity of the methanation reaction imposes a challenge for the operation of the typically employed fixed-bed reactors. Due to catalyst deactivation, safety constraints and the thermodynamic equilibrium of the reaction, the temperature of the fixed-bed has to be limited [1]. For dynamic operation of these reactors, according to the availability of surplus energy, high parametric sensitivity and wrong-way behavior further amplify this aspect [2]. Much research has been done to keep the fixed-bed temperature in defined bounds, mostly focusing on the manipulation of variables on the reactor scale [3]. However, the knowledge about the influence of the catalyst particle design on the reactor behavior is rather limited. Therefore, in this contribution, the influence of the catalyst particle design on the reactor behavior has been investigated.

2. Methods

The influences of the catalyst particle activity, permeability and heat conductivity on the performance of the reactor have been examined by employing a dynamic heterogeneous reactor model. Homogeneously active particles and particles with multiple zones, focusing on particles with an "egg-yolk" configuration, were compared. Subsequently, the carbon dioxide conversion of the reactor was optimized subject to these degrees of freedom for the different particle concepts without surpassing the catalyst particle deactivation temperature. The optimized concepts were further compared by sensitivity analyzes regarding coolant temperature, reactor inlet flow rate and reactor pressure as well as by dynamic simulation studies.

3. Results and discussion

The sensitivity analysis regarding the coolant temperature reveals a reduced temperature increase on the ignition curve of the reactor filled with optimized "egg-yolk" catalyst particles in comparison

to the reactor filled with optimized homogeneously active catalyst particles as shown in Figure 1. This allows for the operation of the fixed-bed reactor at high carbon dioxide conversions without surpassing the critical catalyst particle deactivation temperature in a broad range of coolant temperatures. The same is not possible with homogeneously active particles.

Similar results were obtained from the sensitivity analyzes of the inlet flow rate and the reactor pressure. The carbon dioxide conversion and the maximum particle temperature of reactor filled with homogeneously active particles show a large sensitivity with regard to these parameters. In contrast, the carbon dioxide conversion and the maximum particle temperature are almost constant in the reactor filled with “egg-yolk” particles in the investigated parameter range.

Furthermore, the dynamic simulation studies show a fast transition between the operation points of the reactor filled with “egg-yolk” particles. The transition of the operation points of the reactor filled with homogeneously active particles takes much longer and can exhibit significant wrong-way behavior.

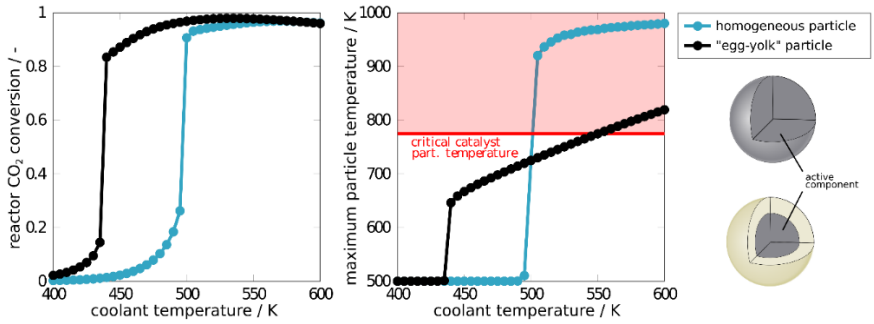

Figure 1. Comparison of the ignition curves of a catalytic fixed-bed tubular reactor filled with optimized homogeneously active particles and optimized “egg-yolk” particles fed by a stoichiometric and undiluted mixture of CO_2 and H_2.

4. Conclusions

The high exothermicity of the methanation reaction imposes a challenge for fixed-bed methanation reactors during steady state and dynamic operation, as the fixed-bed temperature has to be limited, mainly due to catalyst deactivation. Therefore, the carbon dioxide conversion of an industrial scale fixed-bed methanation reactor has been optimized by variation of degrees of freedom on the particle scale without surpassing the critical catalyst deactivation temperature for different particle concepts. Subsequent sensitivity analyzes and dynamic simulation studies revealed beneficial behavior of reactors with “egg-yolk” particles in comparison to the typically used homogenously active catalyst particles. Reactors filled with “egg-yolk” particles show a much broader range of operation points with high carbon dioxide conversion without surpassing the critical catalyst deactivation temperature and faster transition between operation points.

Conceptual and Basic Design of an Innovative Catalytic Reactor for Dehydrogenation of Liquid Organic Hydrogen Carriers

S. Ehsan Emamjomeh[1]*, Arian Shoshi[1], Yongdan Cen, Eberhard Schlücker[1]

1 Institute of Process Machinery and Systems Engineering, University of Erlangen-Nuremberg, Germany

**Corresponding author: ehsan.emamjomeh@fau.de*

Highlights

- Most of existing LOHC dehydrogenation models suffer from a low reaction yield.
- Followed concept promises an efficiency enhancement, modularity & scalability.
- The optimized basic design is achieved by series of analyses & simulations.

1. Introduction

The greatest hurdles in terms of traditional energy storage are the improvement of efficiency and the minimization of final costs, whereby sustainable resources are both seasonal and daylight-dependent. The storage of energy in the form of liquid organic hydrogen carriers, the so-called LOHC, is a new, progressive trend. LOHC are hetero- or homocyclic aromatic hydrocarbons and because of their unsaturated chemical structure, they are able to store additional hydrogens (as energy carrier) in a chemically bonded form. In addition, these energy-carrying materials will not be consumed during their utilization, but instead will be recycled for further loading and unloading cycles. A whole storage system includes a water-electrolyze unit, a water reservoir, a hydrogenation reactor, two LOHC tanks, a dehydrogenation reactor and a hydrogen-burning unit. The division into sector steps is a significant benefit of this new system, e.g. the division into hydrogenation unit and dehydrogenation unit. The dehydrogenation side is highly endothermic (70 kJ/mol H_2) and its thermal efficiency is very crucial in the energy aspects of the overall system. We have developed a concept, which is positively remarked in the evaluations. This concept is inspired by helical heat exchangers, which benefit from a high thermal efficiency and relatively lower pumping energy [1].

2. Conceptual design

The existing reactor models are based on horizontal shell-and-tube heat exchangers in which the bottom halves of the tubes are filled with catalyst pellets. The loaded LOHC is pumping through the reaction tubes, which are heating to the reaction temperature and after passing the residence time, the hydrogen will release on the surface of the catalyst and can leave the reaction zone via empty top halves of the tubes [2]. The heat transfer values are in the expected range. Nevertheless, the overall performance of the reactor is not satisfactory. This is probably due to the large volume of hydrogen released (9 mol H_2/mol LOHC), which pushes the LOHC out of the reactor, reducing the residence time.

Our new concept solves the problems of the large volume increase during the reaction and poor heat transfer. The Figure 1 shows the general structure of this concept. The idea here is to run the hydrogenated LOHC (loaded form) on an open plate, where a semi-helical heat exchanger provides the necessary temperature and heat flux for the dehydrogenation reaction. The hydrogen releases by bringing the reactants in contact with the heating coils along an open coiled channel filled by catalyst pellets or granules, which are small enough to cover all the empty spaces.

Being modular and scalable in this particular concept is very advantageous. The basic components of reaction plate are designed for a simple modification or extension. This makes the concept unique and it eases to reconstruct the reactor plate on different capacities or stack-on more parallel plates in a pressure vessel for any demanded purposes and power-outputs.

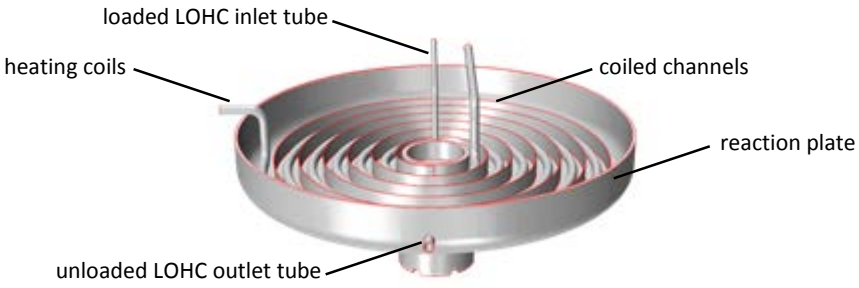

Figure 1. General schematics of a single internal plate of the reactor

3. Basic design

In the next step, mathematical & theoretical analyses, simulations and experimental investigations are concerned. The reaction kinetics of perhydro-dibenzyltoluene are studied and verified [2]. Maintaining the residence time and heat of reaction are the key parameters, which are followed as the functionality basics of any concepts, and in addition to developing a reasonable and functional dehydrogenation reactor, finding the essential influencing parameters on thermal efficiency and reaction progress are mainly in focus. Optimization of the thermal efficiency addresses mainly the reaction zone inside the plate and channel geometries. Here the channel size and paired heating-coil measures must be optimized. Regarding plate's outside, the inlet temperatures, flow directions, vessel's pressure must be studied and optimized. In case of stacked-on plates, the plates' gaps and similarity for the even heat and flow regulations are particularly important. As an example, the temperature profiles by three different channel widths are shown in Figure 2.

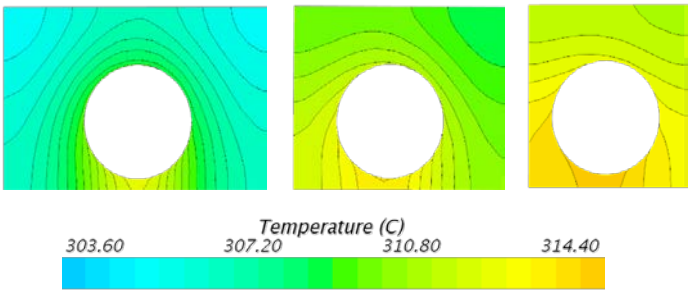

Figure 2. Temperature profiles in cross section of channel with 3 widths

4. Conclusions

Currently, the semi-helical structure reports to be known as the most promising concept for dehydrogenation of LOHC. Very less limitation concerning released amount of hydrogen gas makes this concept already attractive in the conceptual design step, in addition to notable improvements on heat transfer and residence time in the optimized basic design. After experimental verification of optimized parameters in series of empirical studies, the detailed engineering step follows.

Experimental study and CFD simulation of thermal energy storage (TES) in a pilot scale packed-bed

Philippe Béard[1], Ludovic Noël[1], Pierre Balz[1], Sofiane Bekhti[1], Guillaume Vinay[2], David Teixeira[2]

1 IFP Energies nouvelles, Etablissement de Lyon, BP 3, 69360 Solaize, France

2 IFP Energies nouvelles, 1 & 4 avenue de Bois-Préau, 92852 Rueil-Malmaison cedex, France

**Corresponding author: philippe.beard@ifpen.fr*

Highlights

- Experiments and transient CFD modelling of TES during a full cycle.
- Influence of physical properties variations with temperature.
- Good agreement between experimental and numerical results.

1. Introduction

Compressed air energy storage exists since 1978 in the form of improved gas power-plant with an energy efficiency of only 50 %. In these older Compressed Air Energy System (CAES), heat produced by the compression is lost. A more advanced concept, AA-CAES (Advanced Adiabatic CAES), has the advantage of storing the heat of compression and achieving a much higher efficiency. IFPEN proposes a system (Figure 1) based partly on already existing components such as compressors and turbines but also on new components such as Thermal Energy Storage (TES) systems. The load is achieved by air compression and heat storage. Electricity production is realized through a turbine in which the compressed air is expanded after being reheated in TES.

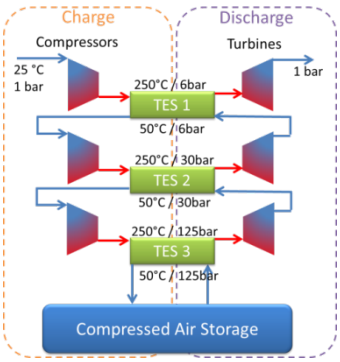

Figure 1. AA-CAES principle.

In recent years, due to the development of AA-CAES and of Concentrated Solar Power (CSP) in particular, sensible heat storage in packed beds has received much interest [1,2].

2. Methods

Complete TES cycles were studied in an insulated glass tank (diameter 0.3 m) filled with uniform 10 mm concrete beads (Figure 2) and equipped with 26 thermocouples to map the temperature.

Figure 2. Experimental TES test rig with and w/o insulation.

CFD (Computational Fluid Dynamics) calculations were performed with ANSYS® Fluent® using a non-equilibrium thermal model in the porous bed zone. The sensitivity to physical properties was investigated as few data are available for concrete at high temperatures [3]. The beads specific heat was measured within the considered temperature range (15-250 °C).

3. Results and discussion

The temporal evolution of the temperature in the bed during the different phases of the cycle is well predicted, in particular along the axis (Figure 3). It was shown that the most influencing property is the specific heat and that an accurate description of the insulation is required.

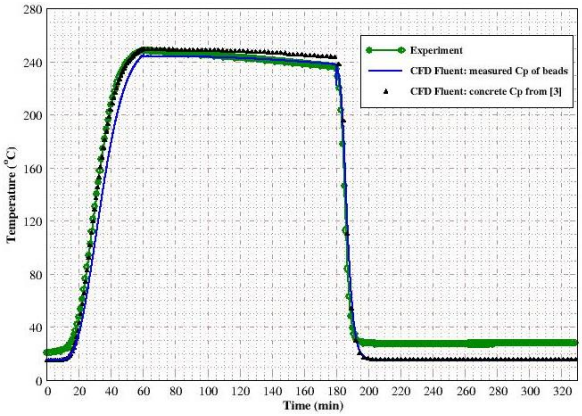

Figure 3. Comparison between experimental and numerical results on the bed axis during a full cycle.

4. Conclusions

The agreement between measured and numerical results during a full TES cycle is quite good. Those results will be assessed in a larger experimental set-up in the near future prior to be able to design industrial systems.

Biogas to Methanol: comparison between CHP and different CHCP plant configuration

Daniele Previtali[1], Giulia Bozzano[1], Carlo Pirola[2], Flavio Manenti[1]

[1] Politecnico di Milano, Dipartimento di Chimica, Materiali ed Ingegneria Chimica "Giulio Natta", Piazza Leonardo da Vinci 32, 20133 Milano, Italy; 2 Università degli Studi di Milano, Dipartimento di Chimica, Via Golgi 19, 20133 Milano, Italy

*Corresponding author: flavio.manenti@polimi.it

Highlights

- Biogas is used in CHP plant for electricity production causing net CO_2 emissions.
- CHCP plant can use Biogas for bio-methanol production avoiding CO_2 emissions.
- CHCP plant is economically feasible considering actual incentives.

1. Introduction

Biogas is a mixture of methane (CH_4) and carbon dioxide (CO_2), produced by anaerobic digestion of organic matter (sewage, manure, organic/agricultural waste, etc.). It is currently considered an important resource by the European Union, since many claims that it allows production of heat and electric energy at zero carbon emissions [1]. Therefore, biogas is usually converted into heat and/or electricity as is, using a Combined Heat & Power (CHP) plant, and/or upgraded to bio-methane, via removal of CO_2 and other impurities, and then injected into the natural gas distribution grid. Although these two techniques for energy production (thermal and/or electrical) may be considered greener than those currently in use, they still have a non-zero carbon footprint. The latter is comprised of the CO_2 emissions of all the processing steps needed to produce the feedstocks, synthesize biogas and use it. Thus, it is important to consider alternative uses of biogas, associated with no carbon emissions, e.g. the novel concept of Combined Heat, Power and Chemical (CHCP) plant. A CHCP plant converts biogas into bio-methanol (MeOH) such that part of the carbon of the biogas feedstock is not released back into the atmosphere as CO_2 (bio-methanol is a solvent and a building-block that can be utilized to produce other chemicals, e.g. dimethyl ether, acetic acid and formaldehyde). This chemical conversion process takes place in two principal unit operations, namely a reformer and a methanol synthesis reactor, of which the first converts biogas into syngas while the second transforms syngas into methanol [2]. Compared to most conventional biogas conversion processes, CHCP plants offer a lower environmental impact and generate valuable chemicals. CHCP plant was studied analyzing 2 different configurations for syngas production: steam reforming (SRtoM) and tri-reforming (TRtoM) [3]. The aim of this work was the comparison between CHP and different CHCP configurations.

2. Methods

We hypothesized three different biogas composition (30%, 40% and 50% of CO_2) and three different flowrates (100, 200, and 500 kg/h). In CHP plant all biogas is burnt to maximize the electricity production, instead of CHCP process, where biogas is partially used for the methanol

synthesis and partially burn to supply the duty necessary to reforming section. Only in this way the CHCP process can be considered energetically self-sustainable. Operative conditions of reformer and methanol synthesis reactor were optimized in order to maximize the methanol productivity. Profits depend on electricity production in case of CHP plant, and on methanol production in case of CHCP. Methanol and electricity prices have been studied evaluating the importance of government incentives. The different processes were simulated using PRO/II® 10.0, a steady-state simulation software. The economic evaluation was performed using the model costing technique [4].

3. Results and discussion

SRtoM and TRtoM process are both technically feasible. The latter can produce more syngas but nitrogen, added as air, acts as inert increasing the dimension of the methanol synthesis section. The economic profitability of CHP and CHCP processes is strictly related to CO_2 content and process configuration. Generally, higher the scale (500 kg/h of biogas) lower is the payback time and higher is the methane content lower is the profitability. Biogas with a high CO_2 content (50%) increases the payback time at over 10 years and makes CHPC process economically unfeasible while CHP could be interesting since the payback time is slightly lower, 7 years. In all the simulation and considering incentives, the lower payback time is obtained with SRtoM process due to the high value of methanol. TRtoM is less competitive than SRtoM since the methanol synthesis section is bigger, and so more expensive.

4. Conclusions

The aim of the work was the comparison of different process for biogas use. Results show that government incentives and CO_2 content are the main limits for economic feasibility. With actual government incentives the CHCP process has the lower payback time. CHP can be considered a better option with high CO_2 concentration. Considering also the lower carbon emissions CHPC plant could be an interesting alternative to CHP.

Feasibility studies on biomass waste utilization for alternate energy generation

Hammad Siddiqi[1*], B. C. Meikap[1,2]

1 Department of Chemical Engineering, Indian Institute of Technology (IIT) Kharagpur, West Bengal-721302, India

2 Department of Chemical Engineering, School of Engineering, Howard College, University of Kwazulu-Natal, Durban, 4041 South Africa

**Corresponding author: hsiddiqi@iitkgp.ac.in*

Highlights

- Alternate energy from biomass waste.
- Thermo-kinetic studies to access its feasibility.
- Prediction of reaction model using master plots.

1. Introduction

Rising energy consumption and the acute energy crisis lead to a long-term cleaner and renewable alternative that is abundantly available, easily accessible and also have positive footprints on the environment along with its economic feasibility. Another major challenge that is also associated with population rise is waste management. Therefore, utilization of this waste for energy production will be most viable solution to these two problems. Present work focuses on generation of alternate energy from a biomass waste, a detailed thermo-kinetic analysis to evaluate its energy potential. The effect of various physiochemical properties will be investigated to correlate its effect on final product distribution via thermochemical conversion

2. Methods

Physiochemical characterization include proximate and ultimate analysis which was carried out using ASTM standards. Also the components of cell wall consisting of hemicellulose, cellulose and lignin have been determined using chemical process. Thermo-gravimetric analysis at different heating rates for non-isothermal heating have been performed to determine the kinetic factors and further the reaction model.

3. Results and discussion

The activation energy of the sample was determined using different differential and integral isoconversional models and the average value is calculated as 109.90 kJ/mol. Also the physiochemical analysis indicate the energy potential in the feedstock. Further the pre-exponential factor was evaluated along with the reaction model which indicate a two stage process. The values of change in enthalpy, entropy and free energy suggests spontaneity of the process and its thermodynamic feasibility.

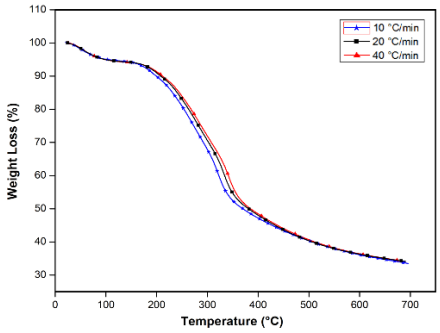

Figure 1. Weight loss curve at different heating rate.

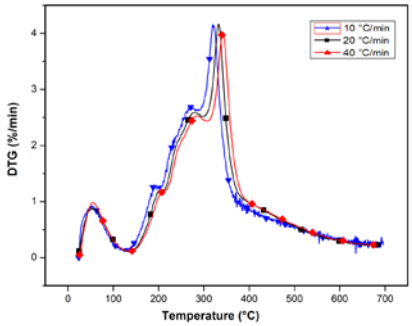

Figure 2. DTG curve at different heating rate.

4. Conclusions

Detailed physiochemical characterization of feedstock clearly indicates that energy can be extracted from it and it can be utilized as an alternate source of energy giving various liquid, gaseous and solid products. The various kinetic parameters indicates the mechanism taking place for the thermochemical conversion of this biomass. It indicates system is very reactive at the beginning and its reactivity decreases with extent of reaction. Further these studies will be significant in design of reactors, mass and energy balance and process optimization.

Comparison of CuO-ZnO-X catalysts (X = Al_2O_3, MnO, ZrO_2) for the reverse water gas shift reaction at low pressure

A. Portillo*, A. Ateka, J. Ereña, A.T. Aguayo, J. Bilbao

Dep. Chemical Engineering, Univ. of the Basque Country UPV/EHU, P.O. Box 644, 48080 Bilbao, Spain;

Highlights

- The r-WGS reaction at low pressure allows obtaining high CO yields from CO_2.
- r-WGS is interesting as a preliminary stage of the synthesis of hydrocarbons from CO_2.
- The CuO-ZnO-ZrO_2 catalyst is the most suitable for the r-WGS reaction.

1. Introduction

CO_2 valorization to fuels and chemicals plays a key role in the current commitment for reducing the consequences of global warming. In this regard, the direct synthesis of hydrocarbons (Fischer Tropsch, FTS) and the indirect synthesis through methanol (MeOH) as intermediate receive great attention. In both routes the r-WGS reaction plays a relevant role, since CO is more reactive than CO_2 [1]. Nowadays, the indirect synthesis is receiving more attention, since in this process catalyst deactivation and methane formation are lower.

Therefore, the aim of this work is to compare the activity of different CuO-ZnO based catalyst, doped with Al_2O_3, MnO or ZrO_2 (named CZA, CZMn and CZZr, respectively) for the r-WGS reaction at low pressure. The activity and stability of these catalysts for the synthesis of MeOH has already been established [2] and the low pressure study conducted here will allow to: i) identify CO yield avoiding its conversion to MeOH, and, ii) evaluate future prospects of these catalysts for the r-WGS reaction at low pressure as a previous stage in the hydrocarbons synthesis processes, given the advantages over CO_2 valorization, thus, greater reactivity of CO and lower water concentration in the medium (which attenuates reaction and favors catalyst deactivation)

2. Methods

CuO-ZnO-XO (CZX) metallic functions have been prepared by precipitation of the aqueous nitrate solution (1M) with the desired Cu/Zn/X ratio of 2/1/1.5 (being X= Al, Mn, Zr) with Na_2CO_3 (1M) at pH=7 and 70°C. The following stages consist of aging the precipitate at 70°C for 1 h, filtering and washing the precipitate to remove the remaining Na^+ ions, drying and calcination (300°C, 10h).

The runs have been conducted in a fixed bed reactor (Microactivity-Reference, PID Eng. Tech.) connected on-line to a Varian CP4900 micro gas-chromatograph for the continuous analysis of the products. Reaction conditions are as follows: H_2/CO_2 molar ratio in the feed, 3; temperature, 200-300 °C; pressure, 1.6-6 bar; space time, 5-13.5 $g_{cat}h(mol_C)^{-1}$; time on stream, up to 24 h.

3. Results and discussion

As an example, Figure 1a and 1b show the effect of pressure and temperature on the yield of the CO_2 hydrogenation reaction products (CO and MeOH) and CO/MeOH molar ratio, with CZMn catalyst and 13.5 $g_{cat}h(mol_C)^{-1}$. In light of the results in Fig. 1a, as predicted thermodynamically, higher pressures lead to higher MeOH production, while CO yield is lightly affected. However, increasing temperature (Fig. 1b) gives way to higher CO yield, as WGS equilibrium is highly dependent on temperature. Furthermore, MeOH production shows a maximum at 225ºC, justified both by the improvement of the kinetics at higher temperature, and to the thermodynamic limitations of exothermic reactions, as it is the case.

Fig 1c shows the catalytic behavior of the three studied catalysts. For CZZr catalyst, a remarkably higher CO yield is achieved at 3 bar and 350 ºC, which is the pursued goal for the selection of the most suitable catalyst to be used in the CO_2 valorization processes.

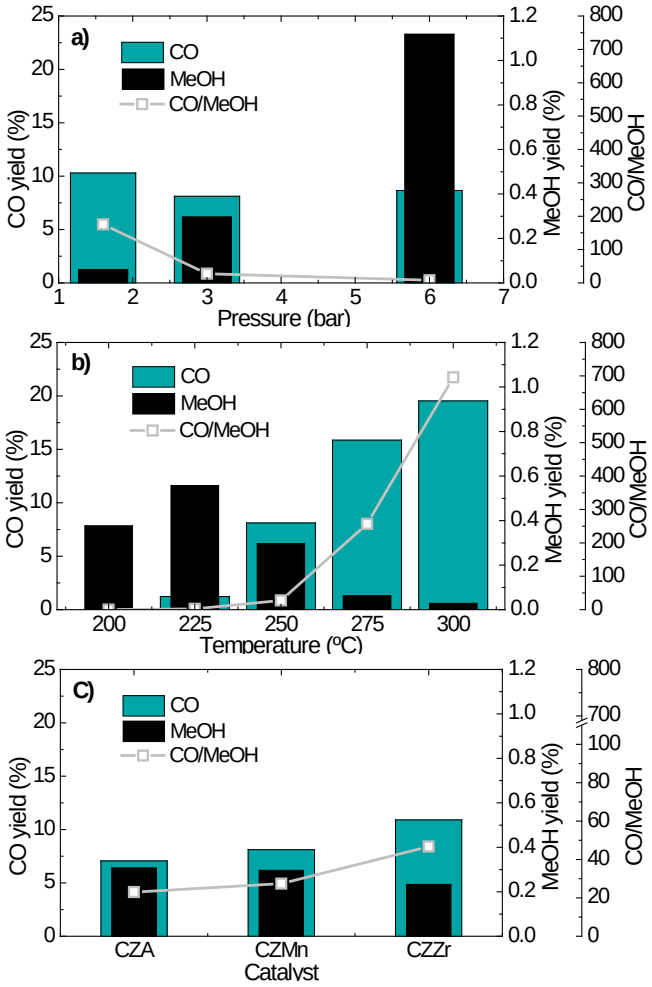

Figure 1. CO and MeOH yields and CO/MeOH ratio for CZMn at 13.5 g_{cat} h mol_C^{-1} and 250 ºC; 3 bar (b); and at 250 ºC and 3 bar for CZA, CZZr and CZMn.

4. Conclusions

Low pressure experiments have allowed ascertaining the activity for the r-WGS reaction of catalysts commonly used for the synthesis of MeOH, among which the activity of CZZr stands out. These results are interesting to contemplate the installation of a low pressure r-WGS unit (of moderate costs) as a previous stage to the synthesis hydrocarbons (at high pressure), with the advantages of the higher reactivity of CO and the presence of water in the feed, which would be separated at the outlet of the r-WGS unit).

Highlights

- Methane was catalytically decomposed to hydrogen and carbon black.
- Various carbon-based catalysts were tested.
- Pore size and content of disordered carbon affected the catalytic activity and stability.
- Carbon black catalysts were active and stable for long operation time.

1. Introduction

Biogas produced from municipal waste typically contains methane and carbon dioxide as main products. Since methane concentration in the biogas is generally around 50%, it is combusted as a fuel for heating or cooking. Combined with the removal process of CO_2, methane can also be used in a gas engine to convert its energy into electricity and heat or compressed as CNG to power motor vehicles. Since methane is combusted in the gas or motor engines, production of CO_2 is inevitable. The thermal decomposition of methane (TDM) to hydrogen and carbon black using renewable energy is considered as a promising route to use efficiently the energy of methane without emitting greenhouse gas CO_2. The carbonaceous solid product can be either sequestered without CO_2 release or used as a valuable material commodity in different applications. It can also be applied as reducing agent in metallurgical industry. The generated H_2-rich gas mixture can be directly used as fuel for internal combustion engines or further processed to high purity H_2 for being used in fuel cells [1]. TDM (non-catalytic) typically requires temperatures higher than 1,300 ^oC in order to achieve reasonable reaction rates. Consequently, the use of catalysts (either metallic or carbonaceous catalysts) was investigated in order to operate at lower temperature and improve the process kinetics [2].

2. Methods

In this work, carbonaceous catalysts were prepared by pelletizing commercial carbon black with chemical binders and iso-propyl alcohol and thermal aging process. The prepared catalysts were characterized by SEM, XRD, BET, TGA, FT-IR. The activity of the catalysts toward methane decomposition was evaluated in a conventional fixed bed reactor. The catalysts, under a stream of CH_4/N_2 (50%vol CH_4/ N_2 at a total flow of 100mLmin^{-1}), were heated from RT up to 1,000 ^oC at 10 ^oC min^{-1} and kept constant at 1,000 ^oC for 4h.

3. Results and discussion

Four type of carbon-based catalysts, activated carbon(AC) derived from palm trees, commercial carbon blacks(CB) in bead and pellet form and mesoporous carbon were tested. From the analysis of N_2 adsorption isotherms, CB bead and mesoporous carbon showed an isotherm pattern having mesoporous pore structure. The methane decomposition was carried out at 1,000°C with the residence time of 1.02s. Among the catalysts tested, CB catalyst in bead form showed the best activity and stability with 200 minutes of reaction time. All other catalysts showed an incremental deactivation or poor initial activity. The catalyst activity is summarized by comparing the values of maximum and stabilized conversion level. The physical properties of the used catalysts were found to dramatically change with the reaction. A deep loss of BET SA was observed with all the tested catalysts, especially with those having mainly micro pore structures like the AC and CB pellet form catalysts. Pore re-construction was thought to be present due to the deposition of carbon within the pore structure of the catalysts. Average pore diameters tended to increase after the reaction. Graphitic mesoporous carbon had poor activity towards methane decomposition. Among the tested catalysts, CB bead form catalyst retained its mesoporous structure within after exposure to the high temperature reaction temperature, carbon nano-tubes were found to be formed with the pores of the catalysts. Initial turbostratic carbon and mesoporous pore structure present in the CB bead catalyst was found to be resistant for the pore re-construction and blockage leading to catalyst deactivation.

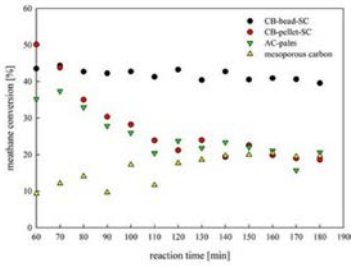

Figure 1. Catalyst activity.

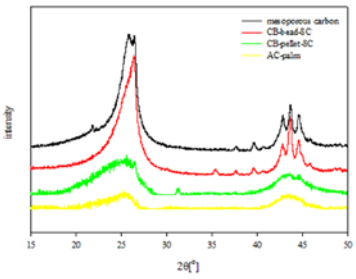

Figure 2. XRD patterns

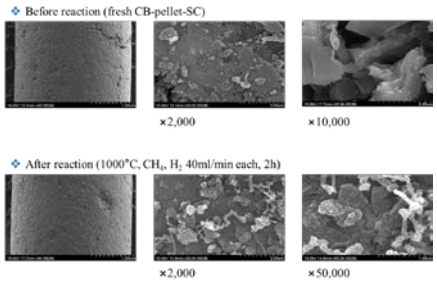

Figure 3. SEM images of CB pellet catalyst

4. Conclusions

Pore re-construction has undergone during methane decomposition. Filamenteous carbon growth blocked the mouth of micro-pores, which decreased severely the BET SA and developed new meso-pores. Catalytic activity of methane decomposition catalysts was related to the nature of carbon present on the surface in the order of amorphous > turbostratic > graphitic.

CFD simulation of steam distribution in vertical tube bundle at high pressures.

Arijit Ganguli[1]

1 School of Engineering and Applied Sciences, Ahmedabad University, Ahmedabad, Gujarat, 380009

**Corresponding author: arijit.ganguli@ahduni.edu.in*

Highlights

- CFD simulations in header and tube assembly to quantify extent of non-uniformity.
- Mal-distribution at high pressures
- Attempt to design innovative distributor to reduce mal distribution

1. Introduction

The distribution of a fluid stream into a number of parallel substreams by means of the channels is accompanied by fluid pressure changes owing to the change of fluid momentum in the conduits, while the effect of wall friction in the conduits is negligibly small compared with that in the channels (Bassiouny and Martin, 1984). Such arrangements are found in industrial equipments (heat exchangers) where the flow is distributed from a main header to a number of tubes. Ample amount of research has been done on this problem by researchers over the past (Acrivos et al., 1959; Bassiouny and Martin, 1984). In such cases, the sudden changes in flow direction make the pressure rise in the top header and fall in the bottom header (Gandhi et al. 2011). Gandhi et al. (2011) have carried out simulations at high pressures and eliminated the middle tube for achievement of uniform flow distribution. However, in some situations where the geometry is such that the middle tube is exactly beneath the feed pipe then the use of internals may help in achieving better distribution. CFD studies for pressures around 60-70 atm is difficult and is rarely found in the literature

2. Methods

A three dimensional grid has been considered in the study. A non-uniform hexahedral mesh has been created for each configuration. For the geometry the mesh size is 18,634 hexahedral cells with fine cells inside the tubes and walls and uniform mesh at the headers. The grid independency for the geometry was carried out with three different grids namely 128,000, 186,000 and 232,000 and the centerline axial velocity was checked. Since the difference between the magnitude of centerline axial velocity was 1% for the 186000 and 232000 grids, 186000 grids was selected for investigation. The basic governing equations of continuity and momentum in Cartesian co-ordinates have been used. The k-ω turbulence model has been used for modeling the turbulence. The commercial software Ansys FLUENT 18 has been used. In case of k-ω model, Quadratic upstream interpolation for convective kinetics (QUICK) discretization scheme was used for the

turbulence parameters. For final sweep over each segment, upwinding has been performed using the QUICK with a second order pressure scheme. The QUICK formulation has a third order accuracy and which helps to mitigate the unfavorable effect of artificial diffusion that can occur when using low order upwinding schemes. All the discretized equations were solved in a segregated manner with the PISO (Pressure Implicit with Splitting of Operators) algorithm. In the present work, steady simulations were performed. All the solutions were considered to be fully converged when the sum of residuals was below 10^{-5}.

3. Results and discussion

The pressure drop is calculated as: Pressure Drop $(\Delta P) = \sum_{x/L=0}^{1} \left(P_{(x/L)_T} - P_{(x/L)_B} \right)$.

The pressure drop profile is shown quantitatively in Figure 1A. Further, the velocity distribution has also been shown in Figure 3B. The dimensionless velocities at the top and the bottom headers show high velocities at the inlet. This indicates that all the fluid passes from the center of the tubes as shown in Figure 1B.

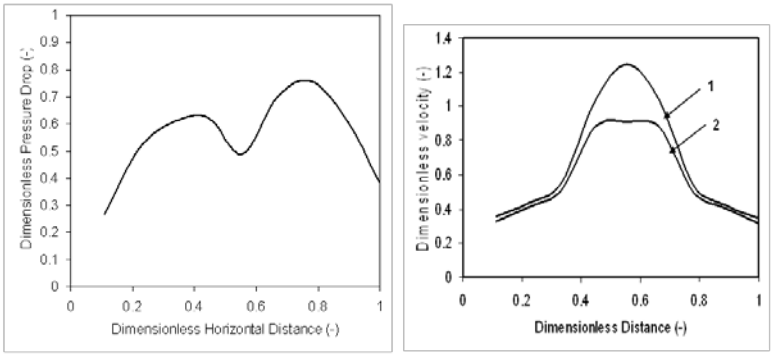

Figure 1. (A) Effect of dimensionless pressure drop with dimensionless horizontal distance (B) Effect of non-dimensional velocity on non-dimensional horizontal distance (1) At the inlet of the central tube (2) At the outlet of central tube.

4. Conclusions

CFD simulations have been carried out for header tube geometry where inlet and outlet are at the middle of the top and bottom headers. It is seen that at low pressures the extent of non uniformity increases with an increase in pressure when conventional geometry is considered. For very high pressures upto 70 bars the mal-distribution is significantly lower than the parent one

Energy and Chemical Engineering

The development of an exergoeconomic indicator to define the optimum blending fraction in processing crude oils

P. S. O. Silva[1], F. G. Martins[1*]

1 LEPABE - Laboratory for Process Engineering, Environment, Biotechnology and Energy, Faculty of Engineering, University of Porto, Rua Dr. Roberto Frias, 4200-465 Porto, Portugal]

**Corresponding author: fgm@fe.up.pt*

Highlights

- Heavy crude oils have a better exergy efficiency.
- Conventional crude oils are more profitable.
- An indicator is proposed to achieve a compromise between sustainability and profitability.

1. Introduction

The reserves of typical crude oils (CO) are scarce, although the society still heavily depends on them. The society is consuming this resource in a non-sustainable way which will make it collapse. 70% of the CO resources are available as heavy CO, oil sands and bitumens, which are less attractive to refineries. Refining these types of CO is more expensive due to their high viscosity and high sulfur content but they are very cheap. Refineries must often blend different types of CO to achieve the desired products specifications. An objective of blending is using heavy CO without compromising the quality of products while increasing the profitability and sustainability of the refining processes.

2. Methods

In this work, it is evaluated the impact of the blend composition on the performance of the topping distillation unit. The blend considers the CO: Sahara Blend and Tia Juana Heavy. The mass fraction of each CO is the manipulated variable while the other operatory conditions are kept constant.

Energy analysis is performed to quantity heating and cooling requirements. This is combined with an exergy analysis to identify how energy quality is conserved during the process. Exergy is strongly related to sustainability because it allows reducing the degradation of energy quality.

Exergy is divided into physical and chemical exergy. Chemical exergy is difficult to quantify, especially in petroleum cuts. Each of these cuts is defined as a pseudo-component because its chemical composition cannot be specified. In order to obtain this value, a set of correlations has to be used [1].

Feed composition affects the products obtained in the distillation unit. Heavy CO yield higher percentages of residues which have a lower economic interest. An economic analysis has also performed to identify which compositions are more profitable.

Analyses, where the economic and exergetic perspectives are combined, have been proposed in some literature and are called exergoeconomics analysis [2]. In this work, a new exergoenomic indicator is proposed because improving the exergy efficiency may incur in additional costs and it may not be attractive for a company to implement the proposed optimization.

3. Results and discussion

Heating and cooling duties vary during this analysis because a lighter blend requires more heating due to a higher content of light-ends to be distilled (Figure 1).

Exergy efficiency decreases with the amount of typical CO (Figure 2). Heavy CO yield a greater amount of fractions with high boiling points and, according to the definition of exergy, a stream with higher temperature has more energy quality.

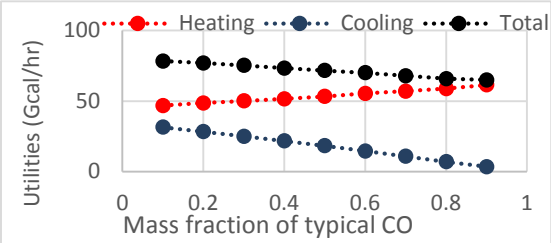

Figure 1 – Effect of the feed composition on the utilities consumption.

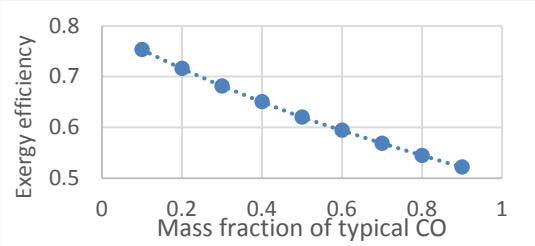

Figure 2 – Effect of the feed composition on the exergy efficiency.

Economically, conventional CO increase the profitability of the process because the fractions obtained have higher economic interest (Figure 3). This indicator measures the added value to the production. Since exergy and economic indicators have contrasting results, a new indicator was proposed to evaluate both aspects simultaneously. This indicator is a compromise between the profitability and sustainability of the process and is obtained through the multiplication of the previous indicators (Figure 4).

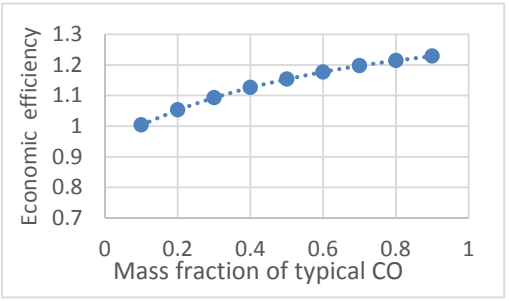

Figure 3 – Effect of the feed composition on the economic efficiency.

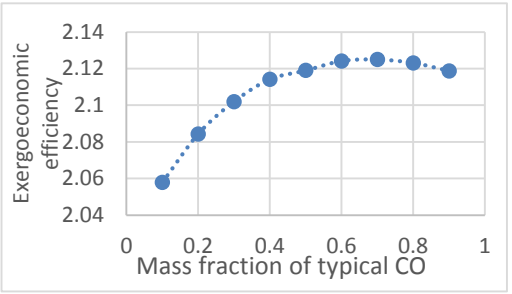

Figure 4 – Proposed exergoeconomic indicator.

4. Conclusions

In this work, it was evaluated the effect of crude oil composition on the overall performance of the topping distillation unit. Energy, exergy and economic analyses were performed. Heavy CO have higher exergy efficiencies while conventional CO are more profitable. A new indicator was proposed to achieve a compromise between profitability and sustainability indicating the optimum blend fraction.

Highlights

- Hydrogen generation coupling Electrolyser with MFC device
- Hydrogen production with only 1 V of cell voltage
- Wastewater valorization

1. Introduction

Wastewater is a huge reservoir of biomass energy already collected but still generating more costs than added-value products. Microbial electrochemistry technology development is a real opportunity to take advantage of this energy source. Freshly we have validated the proof of concept of an innovative device associating a bioelectrochemical system and a decoupled water electrolysis in order to produce hydrogen [1]. This architecture consists of two reactors running separately linked through a redox mediator cycle : i) a Microbial Fuel Cell (MFC) cascade system which oxidates wastewater while reducing potassium hexacyanoferrite ii) an electrolysis cell using a semipermeable separator which produces H_2 while regenerating the mediator.

,2. Methods

Microbial fuel cell (MFC) is a spontaneous electrochemical process that allows current recovery between two reactions: acetate oxidation at the anode and HCF(III) reduction at the cathode.

$$C_2H_3O_2^- + 4H_2O \rightarrow 2HCO_3^- + 9H^+ + 8e^- \quad (1)$$

$$[Fe(CN)_6]^{3-} + e^- \rightarrow [Fe(CN)_6]^{4-} \quad (2)$$

In the electrolyser, two reactions occur at anode electrode, the HCF(II) oxidation and the water reduction in the catholyte solution. The anolyte pH must be maintained to high values (alkaline) to avoid an acidic reaction on HCF (II). In addition, NaH2PO4 buffer solution is employed and K2SO4 salt is added to increase ionic conductivity. Therefore, catholyte had the similar pH value and similar buffer composition.

[Fe(CN)6]4- → [Fe(CN)6]3- + e- (3)

According to De Silva Munoz et al. [2] two steps of electrochemical reduction are possible in phosphate buffer:

$$H_2PO_4^- + e^- \rightarrow H_{ad} + \mathrm{H}PO_4^{2-} \quad (4)$$

$$e^- + H_{ad} + H_2PO_4^- \rightarrow H_2 + \mathrm{H}PO_4^{2-} \quad (5)$$

And the acid-base equilibrium:

$$\mathrm{H}PO_4^{2-} + H_2O \rightarrow H_2PO_4^- + OH^- \quad (6)$$

With the acid-base equilibrium leads to water reduction as follow:

$$2H_2O + 2e^- \rightarrow H_2 + 2OH^- \quad (7)$$

3. Results and discussion

On one hand, organics acid oxidation is coupled to HCF(III) reduction. On the other hand, oxidation of HCF(II) is coupled to water splitting. HCF couple appears to be an interesting opportunity as a mediator in electrolyser for several reasons : i) a low overpotential at low current density which will overcome MFC system limitation using oxygen reduction reaction; ii) a low thermodynamic redox potential which reduces energy costs for water splitting (vs anodic water oxidation); iii) a high reversibility and stability which justifies its wide use in electrochemical system. The aim of this work is to validate the feasibility of such coupled systems as a proof of concept. Using a simple architecture, our MFC cascade system fed with glucose produces a current density up to 1.9 $A.m^{-2}$ (with a COD removal rate of 30 mol.m-2.d^{-1} and a HCF(III) reduction rate of 8.9 $mol.m^{-2}.d^{-1}$).

4. Conclusions

The apparatus can lead to hydrogen production by water electrolysis at cell potential below 1V with a current density up to 30 $mA.cm^{-2}$. This technology offers new perspectives for microbial electrochemistry technology development while limiting several bottleneck of direct energy recovery using microbial electroactivity. Decoupling hydrogen production and biocatalyzed biowaste oxidation permits to i) avoid oxygen reduction reaction limitations in both units, ii) produce energy vector in low cost reactor ant to yield high rate hydrogen in usual electrolyzer. In order to propose low cost system, we have developed mediator electrolyser using carbon and stainless steel electrodes.

Carbon flows in macro energy planning: The case of the Swiss energy system

Xiang Li[1], Theodoros Damartzis[1], Zoe Stadler[2], Stefano Moret[1], Boris Meier[2], Markus Friedl[2], François Maréchal[1]

[1]*Industrial Process and Energy Systems Engineering (IPESE), Ecole Polytechnique Fedérale de Lausanne (EPFL) Valais, 1951, Sion, Switzerland;* [2]*Hochschule für Technik Rapperswil, Oberseestrasse 10, Rapperswil, Switzerland*

**Corresponding author: xiang.li@epfl.ch*

Highlights

- Macro energy systems planning by prospective optimization modeling based upon Energyscope.
- Complete carbon flow chain from *cradle to grave* in different scenarios.
- Exploration of the role of CCUS (carbon capture, utilization and sequestration) and a broad set of Power-to-X technologies in energy transition.
- Analysis on the quasi-neutrality of carbon emission.

1. Introduction

Decarbonation as one of the core objectives delivered by Paris Agreement [1] in 2015, is expected to be approached by: 1) massive introduction of renewable energy sources; 2) deployment of CCUS technologies. Some prospective energy models declare that the anthropogenic carbon emissions in Switzerland in 2050 could be optimized to below 5-10 Mt/year, which is however difficult to get further mitigated taking into consideration the emissions during construction periods in the perspective of a Life Cycle Analysis (LCA).

Compared to intermittent renewables, the emission of biomass technologies in construction period is trivial, despite relatively important emissions during the operational periods, which is yet possible to be recovered by applying carbon capture technologies. The captured GHG (Green House Gases) could be either sequestrated directly underground, or take the role as a storage medium for intermittent electricity from renewables, e.g. by participating in electrolysis and methanation processes known as Power-to-Gas. Up to now, merely 4% [2] of fossil carbon is used in non-energy use to make products in Switzerland. Therefore, it is promising to produce chemical products such as plastics, commodity chemicals and energy carriers free from fossil CO_2 by carbon reutilization technologies. This article aims at estimating the possible carbon demand for different usage in long terms, and exploring the optimal configuration of carbon flows by linking the carbon sources and carbon sinks in techno-economic and ecologic perspectives.

2. Methods

The methodology of the research is categorized into 3 steps: first the carbon sources and carbon sinks in Switzerland are identified, including the demand for carbon-related chemical products; then a broad set of conversional technologies are modelled and integrated based upon existing

technologies and newly added biomass and CCUS technologies in Swiss Energyscope (SES) [3], an open-source MILP (Mix Integer Linear Programming) optimization tool for energy system developed by EPFL. The model takes a “snapshot” of the optimized Swiss energy system in 2050, with the objective of minimizing the total cost subjected to various constraints [4] such as supply-demand, availability of resources, as well as the potential of conversional technologies. CCUS technologies are categorized into CC (carbon capture), CCS (carbon storage) and CCU (carbon utilization) in order to precisely depict the carbon flows. Each technology within its corresponding category is associated with a specific cost and an energy penalty coefficient. In this model, the carbon sources are divided into two branches: carbon-intensive energy industries, such as fossil-based power plants, cements etc., and carbon from the atmosphere. It is assumed that only the DAC (Direct Air Capture) technology could be applied to atmospheric carbon capture. The total Global Warming Potential (GWP) is then expressed as a trade-off between the carbon emissions and the reduction by deploying CCUS, which is subjected to an ε-constraint limiting the upper bound of GHG emissions. The third step lies in scenario generation for understanding the impact of different pathways of carbon flows into the energy system.

3. Results and discussion

The energy system will become inevitably more expensive by increasing carbon mitigation. Carbon flows Sankey diagrams illustrate the carbon sources and sinks and the corresponding conversional technologies. In a low carbon scenario with high penetration of renewables, more biomass technologies are used to produce bio-diesel or synthetic natural gas for satisfying in principle the mobility demands. The CCUS technologies do not appear until the total emission threshold reaches 5 - 10 Mt/year, where amine gas treating becomes dominant among carbon capture technologies. Carbon sequestration is less competent compared to carbon utilization contributing to reduce the total cost by decreasing chemical products import expenses.

4. Conclusions

The study sheds light on the optimized configuration of carbon flows in the horizon of 2050 for Switzerland, displaying the importance of biomass in the future energy system as the dominant carbon source in operation. CCUS implementation is obligatory in order to realize quasi-neutrality of carbon emission: the results demonstrate that the total GWP emission in the point of LCA could be controlled within 4 - 6 Mt and 0 - 3 Mt respectively in the absence and presence of CCUS technologies, respectively.

Hydrogen Storage in LOHC and the Chances for Energy Supply, Mobility and Society

Eberhard Schluecker[1]

1 University of Erlangen-Nuremberg, Germany, Cauerstr. 4, D-91058 Erlangen

**Corresponding author: sl@ipat.uni-erlangen.de*

Highlights

- Hydrogen Storage in LOHC; 2,1 KWh/Kg.
- Examples for the developed and used Equipment.
- Decentral energy supply, effects on society, chances for mobility
- Examples for energy efficiency due energy networks

1. Introduction

Due to the ongoing observed developments and trends of our climate, it can no longer be denied that human impact on global cycles cause our planet great, perhaps even irreparable damage that future generations will have to bear. We therefore need to think about regenerative energy technology goals and decentral energy supply, for the preservation of mankind and the planet.
This presentation will therefore focus exclusively on the Hydrogen LOHC storage method for the use as energy supply of the future, but also the chances for mobility and society.
When we think about our future, we have to live independent from fossil resources. Therefore, hydrogen is the most favourable for a certain basic energy supply. Hydrogen is available in water but at the same time, we do not want to consume it, rather to put it into a cycle. Hydrogen as a basis for chemical processes is very energy-rich at 33 - 39.41 KWh/Kg calorific value, but it also has some disadvantages in energy storage. It has the lowest density of all gases and difficult to store. The classical storage method, to achieve the necessary density, therefore used are the compression up to 70 MPa or the cryogenic state (liquid hydrogen). Unfortunately, the high pressure and/or the extreme cooling requirements are problematic and cost-intensive. Last, but not least, there are still safety considerations regarding to compressed hydrogen and also to free hydrogen.

2. Methods

The new method of hydrogen storage technology – presented - eliminates all these problems and concerns by storing the hydrogen in chemically bound form on a LOHC (Liquid-Organic-Hydrogen-Carrier). Of necessity, this chemical must be chemically very stable so that the thermally driven separation of the hydrogen (recovery) does not destroy the molecules. At the same time, the molecules should not produce any toxins (i.e. no nitrogen, chlorine, etc.) if they should be burned as residues and only the pure aromatics remain. To prevent the toxicity di-benzene-toluene was chosen. Here 18 atoms hydrogen can dock and also “REACH” documentation (safety documents) exist for this chemical. The energy that can be stored in it is 2.1 KWh/litre, which is roughly

equivalent to the amount of hydrogen in 70 MPa containers. Another advantage is, the liquid is absolutely safe against ignitions.
The presentation shows the whole system but also some special apparatuses and further equipment used.

3. Results and discussion

With this energy storage technology, with an exothermal reaction process (250°C, waste heat), you now have a liquid that fits exactly into our heating oil and petrol infrastructure. The LOHC is oil-like and therefore readily pumped. The disadvantage that needed to be overcome was the relatively high temperature (300°C) necessary for dehydration. This was the focus of recent research which showed it was possible to reduce the required temperature to approx. 130°C using a clever combination of parameters (patent pending). This means that LOHC technology can now be used in many different ways as dehydrogenation can now be carried out with the waste heat from a fuel cell, which we use to convert hydrogen into electricity. But in addition, sunlight or other waste heat sources can be used.
One example of this is in sewage treatment plants. Here the oxygen can be used for the purification process of the sewage and the waste heat for drying sludge, while the hydrogen is stored and used for energy consumption elsewhere (equipment run with hydrogen, hydrogen filling station, etc.). It quickly becomes clear that other business models are also possible and, for example, a sewage treatment plant can become an energy seller.
There are also possibilities in urban or industrial environments always in combination with hydrogen storage:

1. Oxygen for efficient combustion processes or for steel mills
2. Waste heat for local and distributed heating supply but also for cooling devices in summer
3. Waste heat utilisation for seawater desalination, for thermal production processes (extraction, rectification, reaction) and for cooling or for greenhouses in winter
4. Boosting the geothermal capacity with LOHC waste heat: Build the reactor into the upflow of geothermal energy. The Carnot efficiency could thus be increased from 16 - 20% to approx. 50%. And the remaining residual heat could still be used in heat networks.

4. Conclusions

The described new energy storage method allows to store huge amounts of energy just in tanks and is a big chance for decentral energy supply but also can be used for mobile applications like ships, trucks, or cars. Furthermore the shown LOHC-System can be a basis for high efficient energy networks and may be a basis for the change of the society (participation or identification)

Explosion Parameters of Hydrocarbons from Fischer-Tropsch Synthesis

Jan Skřínský

Energy Research Center, VŠB-TU of Ostrava, 17. listopadu 2172/15, 708 00 Ostrava, Czech Republic

**Corresponding author: jan.skrinsky@vsb.cz*

Highlights

- Explosion parameters of HCs from F-T synthesis for the first time.
- Preliminary investigation in the 20-L vessel before being scaled-up to 1.00 m^3.
- Comparison with pure HCs.

1. Introduction

Nowadays there is a worldwide demand to develop energy efficient and economical processes for sustainable production of alternative chemical compounds and fuels as a substitute for those emerging from petroleum [1]. Small-scale characterisation in the liquid phase towards understanding explosion deflagration over a range of fuel concentrations, temperatures and pressures has been published limitedly [2-6]. In comparison with the pure liquid-fuels for the more complex mixtures, no studies are available. The present paper describes a series of preliminary experiments performed to study the explosion parameters of complex hydrocarbons (HCs) fuel produced from micro-scale Fischer-Tropsch Synthesis (FTS). Such metodology allows rigorous insightful chemical interpretation of well-defined sample and deeper experimental view into a chemical explosion problem. The results could be in the future used to evaluate mass burning rate and flame development duration and combustion duration.

2. Methods

A micro-scale FT plant with fixed bed reactor was designed and used at ERC, VŠB-TU of Ostrava to study the production of liquid hydrocarbons over Co-based FT catalysts. A simulated N_2-rich syngas (containing: H_2, CO and N_2) was used to feed into the reactor inlet for the production of synthetic liquid hydrocarbon fuels. The liquid hydrocarbon products were analyzed off-line using a DB1 column combined with a gas chromatography-mass spectrometry (GC–MS) PerkinElmer. These products include light hydrocarbons (C1 and C2), olefins, LPG (C3-C4), naphtha (C5-C11), diesel (C12-C20) and wax (>C20) fractions. Explosion parameters values of the pure liquids and the mixtures were determined experimentally according to the EN 15967:2011. The 0.02 m^3 oil-heated spherical vessel setup was used to record pressure-time curves. The 0.02 m^3 apparatus incorporated a digitally adjustable external control device Presto A30 (SN: 10291377, JULABO GmbH, Seelbach, Germany). The dynamic pressure in the vessel was measured by a pair of quartz pressure sensors (SN: 4512821 and SN: 4512822, model 701A, Kistler, Winterthur, Switzerland) and recorded with a charge amplifier (Kistler, model 5041E0). Programmable logic controller (model 5073A211 in 0.02 m^3, Siemens, Munich, Germany) connected to a PC was used with the interface (PROMOTIC system, MICROSYS, spol. s.r.o., Ostrava, Czech Republic) to automatically control the whole testing procedure.

3. Results and discussion

Figure 1 plot examples of the normalized explosion pressure, p_{max}/p_0, versus the concentration for FT–air mixtures. The normalized explosion pressures were obtained at initial temperature (78 °C). The maximum value of explosion pressure and the deflagration index were found at the concentration close to 12 vol. %. The shape of the explosion pressure versus concentration show a reasonable agreement with the previous studies [2-6] with the exception for the explosion pressure difference between the lower/upper explosion limit and its subsequent concentration. As compared with the published experimental results, the presented values sharply drop to zero from 4.8 bar and 5.8 bar, respectively. Such a behaviour involves the lower ignitability in comparison with the pure liquid-fuels. The described behaviour needs more rigorous experimental investigation from the chemical point of view to elucidate the possible mechanisms of action behind the presented experiments.

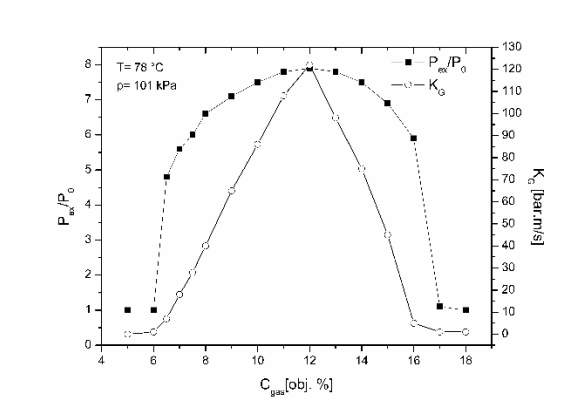

Figure 1. The explosion pressure and the deflagration index at different concentrations.

4. Conclusions

The explosion pressure p_{exp} and and the deflagration index K_G, were examined on the basis of combustion pressure history and compared with the pure liquid-fuels.

1. Explosion pressure and deflagration index of the F-T mixture reach maximum values at the stoichiometric concentration C = 12.0 vol. % within the studied range from 5.0 to 18.0 vol. % at representative initial temperature of 78 °C and initial pressure of 101 kPa.
2. The maximum explosion pressure, p_{max}, was determined as the highest p_{ex} found for the mixture compositions investigated and is equal to 7.9 ± 0.2 bar.
3. The deflagration index was calculated from the experimentally determined $(dp/dt)_{max}$ value and is equal to 122 ± 10 bar.m/s.

Hydrothermal carbon materials for energy and biomass conversion

Natalia Rey-Raap[1], Lucília S. Ribeiro[1], Rafael G. Morais[1], José J.M. Órfão[1], José L. Figueiredo[1], M. Fernando R. Pereira[1]*

** Corresponding author: fpereira@fe.up.pt*

Highlights

- The properties of hydrothermal carbons can be easily controlled.
- Well-developed microporosity results in materials with higher electrocatalytic activity.
- Total conversion of cellulose and a sorbitol yield of 59 % is attained after 3 h.

1. Introduction

Energy and biomass conversion are two of the most important issues to achieve a sustainable society. Fuel cells are one of the most efficient technologies for energy conversion. The performance of a fuel cell is mainly controlled by the oxygen reduction reaction (ORR) that takes place at the cathode. The most efficient electrocatalysts for ORR are based on platinum (Pt/C), which is costly and scarce, and hence, replacing platinum by materials with lower cost and broader availability has become a major challenge. A sustainable society is also focused on the direct conversion of biomass into valuable chemicals, being sorbitol one of the most promising platform molecules. Ruthenium catalysts supported on carbon materials have shown to be very effective supports for the direct conversion of cellulose to sorbitol. However, the best results to date are obtained using long reaction times, high metal loadings or expensive carbon supports. Thus, further research needs to be carried out in an attempt to match or surpass the results obtained to date by using cheaper carbon supports. In this context, the perspective of processing waste biomass into valuable carbonaceous materials has gained an increasing interest in the field of materials science. Carbon-based materials are highly promising catalysts for several applications, due to their high catalytic activity, cost-effectiveness, and durability. The optimization of the catalytic activity of carbon-based catalysts lies in the appropriate design of the materials' properties. To this end, it is essential to understand the influence of the textural and chemical properties on the performance of carbon-based catalysts. Accordingly, this work aims to prepare glucose-derived carbons with tailored textural properties via hydrothermal carbonization and subsequent physical activation, in order to study the effect of porosity and chemical composition on the performance of the catalysts in two different applications related to energy and biomass conversion.

2. Methods

Glucose-based carbon materials were prepared by hydrothermal carbonization (HTC). The solid/water ratio (w/v) was fixed at 1:5 and the HTC process was performed at 180 ºC for 12 h. The

materials were then carbonized at 700 ºC under N_2 for 2 h (CG) or physically activated at 900 ºC under CO_2 atmosphere for 4 and 6 h (AG_{4h} and AG_{6h}). The prepared materials were then directly used for the ORR testes, which were performed in a three-electrode cell by cyclic and linear sweep voltammetry measurements. For the biomass conversion, ruthenium catalysts were prepared by incipient wetness impregnation of Ru (0.4 wt.%) on the prepared carbon supports and the one-pot hydrolytic hydrogenation of cellulose into sorbitol was performed in a reactor at 205 ºC for 5 h. All materials were characterized by nitrogen adsorption, microscopy (SEM and TEM), elemental analysis, TGA, TPD, XRD, XPS and ICP.

3. Results and discussion

All the prepared materials display a type I isotherm, which is characteristic of microporous solids. In addition, the microporosity increases due to the rise in the temperature and time of activation applied. The electrochemical results show two main differences: i) the onset potential shifts to more positive values by increasing the time of activation, which can be related to the more graphitic structure that is generated during activation; and ii) the value of the limiting current density increases with microporosity, which can be related to the more developed porous structure [1]. On the other hand, the prepared Ru catalysts were highly efficient for the one-pot reaction, yielding 100 % cellulose conversion after just 3 h. The conversion rate seemed to increase for the materials with the most developed porous structure. Moreover, the production of sorbitol increases with the surface area (Table 1), probably due to the faster access to the metal, favoring the hydrogenation of glucose into sorbitol [2].

Table 1. Textural properties and catalytic results

Sample	Supports			Ru catalysts	
	S_{BET} ($m^2\ g^{-1}$)	V_{DR} ($cm^3\ g^{-1}$)	E_{onset} (V)	Yield of sorbitol (%, 3 h)	Conversion (%, 3 h)
CG	573	0.22	0.683	33	100
AG_{4h}	936	0.38	0.751	53	100
AG_{6h}	1984	0.85	0.782	59	100

4. Conclusions

The appropriate combination of activation conditions during the polymerization of glucose led to the most efficient catalyst for both the oxygen reduction reaction (onset potential 100 mV higher) and the production of sorbitol (59 % of sorbitol was achieved after just 3 h of reaction).

Fouling Detection in Industrial Heat Exchanger

Using Neural Network Models

Željka Ujević Andrijić[1*], Nenad Bolf[1], Adriana Brzović[1], Hrvoje Dorić[1]

1 University of Zagreb, Faculty of Chemical Engineering and Technology, Zagreb, Croatia

Highlights

- There is a need for continuous detection of fouling formation on heat exchangers
- NN models are developed for predicting heat exchanger outlet temperatures.
- By applying models on-site more stable operation and significant savings are expected.

1. Introduction

Companies are more than ever aware of the potential that lies in machine learning for improving predictive maintenance in order to increase process efficiency and address concrete process issues.

One of the major problems in operation of a refinery plant is the heat exchanger fouling build-up, so there is a need for continuous detection of fouling formation on heat exchangers in order to optimize servicing within preventive maintenance programme.

Traditional diagnostics of the fouling formation methods have a number of limitations, with some requiring stationarity of the process. In more than a few instances fundamental models are difficult to develop. On the other hand data-driven models can be developed using identification methods.

In our research an online monitoring system is developed for a shell and tube heat exchanger at hydrocracking plant. Neural network models are developed using inferential variables (temperature and flow rates of hot and cold stream) for predicting heat exchanger outlet temperatures. The deviation between predicted and actual values indicates performance degradation due to fouling. The developed models are designed to establish an on-line monitoring system for maintaining operating efficiency of refinery plants.

2. Methods

The first step was choosing the data representative for the overall dynamical process and selecting data from the period when fouling does not yet appear (right after cleaning). The model inputs for predicting outlet temperatures of hot and cold streams are: the inlet cold stream temperature ($T_{C,i}$), the inlet hot stream temperature ($T_{H,i}$), the hydrogen mass flow rate ($\dot{m}$). The neural networks models were developed using R software. Data preprocessing included detection and removing outliers. Heat transfer coefficient for clean and dirty heat exchanger is calculated using (1) and (2):

$$U_{\text{fouling}} = \frac{\dot{m} * c_{\text{p}} * \left(T_{\text{H,i}} - T_{\text{H,o}}\right)}{A * F * \frac{\left(T_{\text{H,i}} - T_{\text{C,o}}\right) - \left(T_{\text{H,o}} - T_{\text{C,i}}\right)}{\ln\left(\left(T_{\text{H,i}} - T_{\text{C,o}}\right) / \left(T_{\text{H,o}} - T_{\text{C,i}}\right)\right)}} \quad (1)$$

$$U_{\text{clean}} = \frac{\dot{m} * c_{\text{p}} * \left(T_{\text{H,i}} - T_{\text{H,o,model}}\right)}{A * F * \frac{\left(T_{\text{H,i}} - T_{\text{C,o,model}}\right) - \left(T_{\text{H,o,model}} - T_{\text{C,i}}\right)}{\ln\left(\left(T_{\text{H,i}} - T_{\text{C,o,model}}\right) / \left(T_{\text{H,o,model}} - T_{\text{C,i}}\right)\right)}} \quad (2)$$

U_{fouling} is calculated based on the measured outlet temperatures, while U_{clean} is calculated based on the predicted outlet temperatures. The heat exchanger performance is then assessed by comparing results of clean and fouled systems. Any trend observed at the model residual indicates that the performance is decreased due to fouling. The fouling factor is calculated according to the (3).

$$R_f = \frac{1}{U_{\text{fouling}}} - \frac{1}{U_{\text{clean}}} \quad (3)$$

3. Results and discussion

Good matching between actual outlet temperature and the model prediction right after the cleaning is observed. Over the longer period the deviation constantly increases as a result of emergence fouling. From Fig.1 it can be seen that initially, the fouling factor fluctuates close to zero indicating no fouling is occurring. After a while the fouling factor begins to rise indicating deposition. Calculated value of fouling factor is similar to the design fouling value of this heat exchanger.

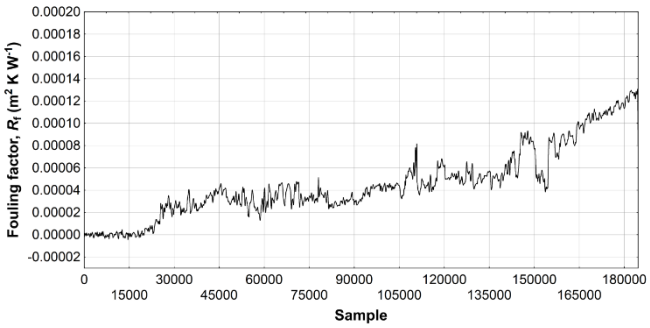

Fig. 1. Fouling factor

4. Conclusions

The performance criteria of developed models together with residual monitoring indicate that the neural networks effectively detect fouling formation. By applying developed models on-site more stable plant operation and significant savings could be expected.

Highlights

- Complete process flowsheet for SRF derived syngas to methanol.
- Alternative CO_2 capture technologies for syngas are assessed.
- Methanol synthesis loop is optimized
- Positive profitability indices are obtained.

1. Introduction

Waste production is constantly growing in the developing countries, while in the developed areas, techniques for the exploitation of waste have been gradually introduced. Wastes are used in order to obtain raw materials (separate collection) or to produce energy by thermal treatments (waste-to-energy, gasification). Solid recovered Fuel (SRF) is a type of fuel derived from the processing of non-hazardous solid urban waste. The aim of producing a fuel derived from waste is the creation of an energy carrier with standard features allowing exploitation in energy production processes [1].

A possibility to valorize waste material consists in gasification to produce syngas and subsequently high-added value products, as methanol [2]. Challenges arise to reach the specific features from the obtained raw syngas, in terms of gas pollutant concentration to avoid catalysts deactivation and of H_2/CO ratio. Alternative solutions to purify and to condition the syngas were proposed in the literature [2]. These analyses indicate that the purification and conditioning processes require significant additional capital costs, in particular for the CO_2 capture units. Improvement of process integration of these two plant sections is necessary to obtain convenient economic indices.

In this work, the process design and the preliminary cost assessment of purification and conditioning section of syngas obtained from a gasification plant of RDF and of the methanol synthesis section are proposed.

2. Methods

Process flowsheet was simulated by means of Aspen Plus© V8.8 in order to perform mass and energy balance and to carry out the optimal design of main process units. For this purpose, rigorous models taking into account kinetics were employed to design reactors and rigorous stage by stage methods were used for separation columns accounting non ideal vapor liquid equilibria and mass transfer resistance. Process heat integration was addressed and heat exchanger network was

designed by means of Aspen Energy Analyzer V8.8. Cost analysis was carried out with the help of Aspen Process Economic Analyzer V8.8.

3. Results and discussion

Main results of the simulation work concern the conditioning section of syngas obtained by gasification of SRF was carried out. Syngas was purified from Sulphur organic compounds (mainly COS and CS2) and from HCN by a hydrolysis reactor with Al_2O_3-TiO_2 catalyst which was properly sized to obtaining conversion larger than 99%. H_2S was converted to elemental Sulphur by means of Lo-Cat® technology and remaining traces were further removed by PURASPEC™ adsorption technology. Next, the hydrogen content in the clean syngas was increased from 16% to 31% by a high temperature Water Gas Shift stage (Fe_3O_4/Cr_2O_3 catalyst), which was sized to obtain 87% CO conversion. Subsequently the CO_2 capture was addressed by two alternative absorption processes: Selexol® process and MEA absorption process. For both cases, a CO_2 recovery equal to 95% and a CO_2 purity equal to 99% were fixed as process specifications. An economic comparison between the two CO_2 capture processes was carried out. Comparable operating costs resulted for both processes, while in term of investment costs the Selexol® process appeared more convenient than absorption by MEA.

The Methanol synthesis loop was designed to feed the methanol reactor with a stream with an optimal molar ratio (H_2-CO_2)/(CO+CO_2) by mixing the fresh syngas with the recycled reactants and pure hydrogen separated by PSA. The multitubular fixed bed reactor with heat exchange was designed to attain an optimal temperature profile to minimize the catalyst bed weight for methanol conversion of about 40%. Methanol separation and purification was obtained by a distillation train.

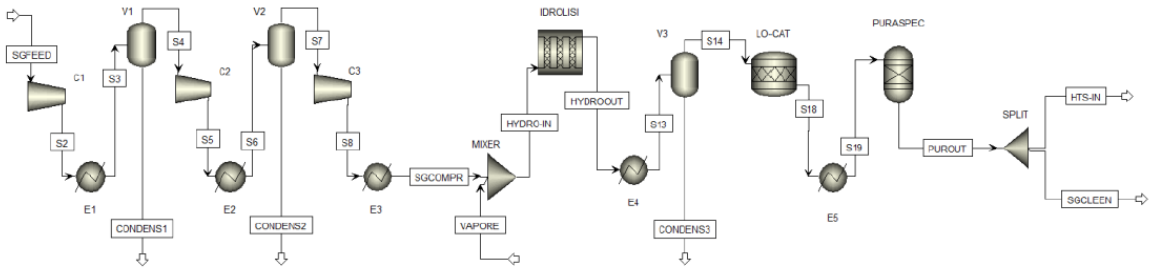

Figure 1. Simulation flowsheet of the syngas cleaning section.

4. Conclusions

A complete flowsheet for the production of methanol from SRF derived syngas was simulated. CO_2 capture was also addressed. Selexol® process resulted the optimal solution in terms of costs. Methanol synthesis loop was optimized to maximize the methanol production. Process heat integration was performed to limit the utilities cost. Final economic analysis provides positive net present value and satisfactory rate of return of the investment confirming the profitability estimated in a previous approximate analysis [2].

Highlights

- Energy radiative balance.
- Production of hydroxyl radicals.
- photocatalytic efficiency.
- photocatalytic activity with different sources.

1. Introduction

It has been demonstrated that photocatalysis is efficient in the degradation of a wide range of organic pollutants present in water [1]. Although the potential advantages of using photocatalytic reactors in the degradation of refractory contaminants, there are still problems to face. One of the main problems is the lack of adequate radiation models, as well as kinetic models and design procedures to scale up photocatalytic reactors [2], [3]. The main deficiencies in heterogeneous photocatalysis are: i) that there are no studies describing kinetics and radiation adequately, ii) no in-depth study has been carried out on the production of hydroxyl radicals and their correlation with the radiative, iii) it is not known if the rate of formation of hydroxyl radicals depends on the wavelength with which the photocatalyst is activated, and d) there is no model that describes with certainty the process of production of hydroxyl radicals, and thus perform a scale up reactor. A lot of research still needs to be done about those topics, as the research that is done till now resulted in kinetics and optical parameters that included several phenomena such as hydrodynamics, mass transfer and radiation. In addition, no comparison between the use of different light sources and the obtained specific extinction coefficients has been made and no intrinsic kinetic study about the production rate of the •OH using titanium dioxide (TiO_2) as a catalyst was done.

2. Methods

A tubular photoreactor 10 cm length, 2.2 cm diameter where the suspended photocatalyst flows was used to get the experimental data

2.1 Radiative characterization

2.1.1 Calculation of the extinction coefficient

For the optical parameter, extinction coefficient of the catalyst, experiments were carried out irradiating with an external source (one LED in front of the reactor) to the reactor using the approximation of Beer-Lambert Law and the energy balance was calculated.

2.1.2 Isoactinic conditions

To achieve that the radiative energy was constant at different positions of the reactor, a strip of LEDs was placed around it, thus allowing to reach isoactinic conditions and avoid the change of the production of hydroxyl radicals at different positions inside the reactor.

2.2 Production of hydroxyl radicals

•OH radicals have a low stability and consequently a high reactivity. For this research, terephthalic acid was used to react with the formed •OH. This reactant reacts with •OH to form a highly fluorescent product 2-hydroxyterephtalic acid (2-HdA), fluorimetry is used to detect 2-HdA.

3. Results and discussion

the extinction coefficient can give an initial idea about the activation of photocatalysts, as the first result it was expected to be able to calculate the coefficient of intrinsic form (independent of the concentration of the catalyst) which was achieved when it is irradiated with wavelengths inside of the absorption spectrum of the material Figure 1a, on the other hand this parameter, since it does not depend on other phenomena.

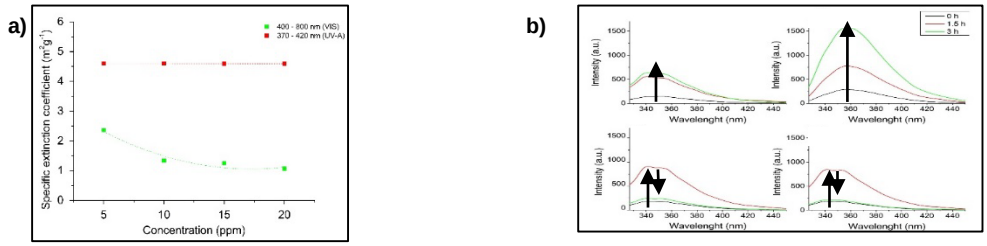

Figure 1. a) Specific extinction coefficients of 400-800 nm and 370-420 nm in front of the reactor, b) Production of 2-HdA after reaction (3 hours) between •OH and terephthalic acid with different TiO_2 concentrations.

The measured intensities of the 2-HdA are shown in function of the wavelength and corresponds to the formed amount of •OH. At 5 and 10 ppm of TiO2, the intensity of the formed 2-HdA increases over time and consequently also the produced •OH. when the solution passes for a longer time through the reactor, more catalyst particles are activated by the radiation source and the production increases Figure 1b.

4. Conclusions

Higher intrinsic specific extinction coefficient (4.6 $m^2 g^{-1}$) with purple LED, more absorption by TiO_2 whit the same LED, production of •OH is influenced by the catalyst concentration.

CO_2 Reduction Using Glucose in Hydrothermal Media in a Continuous Plant

María Andérez-Fernández,[1]* Joao P.S. Queiroz[2], Eduardo Pérez,[1] Ángel Martín,[1] M. Dolores Bermejo[1]

[1]*BioEcoUVa. Research Institute on Bioeconomy. High Pressure Processes Group. Department of Chemical Engineering and Environmental technology. Universidad de Valladolid, Valladolid, 47011, Spain*

Highlights

- For the first time, hydrothermal reduction of $NaHCO_3$ using glucose has been performed in a continuous pilot plant.
- Yields to formic acid up to 63% were achieved after 10min at 300ºC in batch reactions.
- This work is a starting point to use residual biomass as reductant.

1. Introduction

Several alternatives have been proposed in order to mitigate the potential irreversible damages that can cause the increasing levels of CO_2 in atmosphere. Hydrothermal reduction is one of the most promising procedures for CO_2 conversion into chemicals, such as formic acid, by means of water at high temperature and pressure (high temperature water, HTW), which owns outstanding properties compared to those of water at room temperature, being able of acting in the reaction as solvent, catalyst or reactant. Furthermore, due to the depletion of fossil fuels, lignocellulosic biomass has been envisioned as a plausible substitute for obtaining chemicals and fuels, and HTW has been intensively studied during the past years as an excellent method for its liquefaction and conversion into useful products.

Previous works showed the possibility of combining both CO_2 reduction using several biomass derivatives, from isopropanol to lignocellulosic derivatives[1,2]. However, these studies have been performed at laboratory scale. In this study, the hydrothermal reduction of sodium bicarbonate ($NaHCO_3$, as source of CO_2) and glucose conversion was carried out in a continuous pilot plant, showing the possibility to implement the process in CO_2 production focus.

2. Methods

Reactions were performed by two different procedures: batch mode and continuous mode. Batch reactions were previously described[2]. Continuous mode reactions were carried out in a pilot plant, in which a solution of $NaHCO_3$ and glucose (1.0M and 0.1M, respectively) was pumped up to operational pressure and mixed with a preheated water stream, achieving an instantaneous heating of reactants. Reaction temperature (300ºC) and pressure (200 bar) were kept through the reactor, placed in an oven, and reaction was stopped by a decompression valve and cooling down the outlet. Liquid samples were analyzed using HPLC techniques. Experiments were repeated at least twice to ensure reproducibility, achieving less than 15% of deviation.

3. Results and discussion

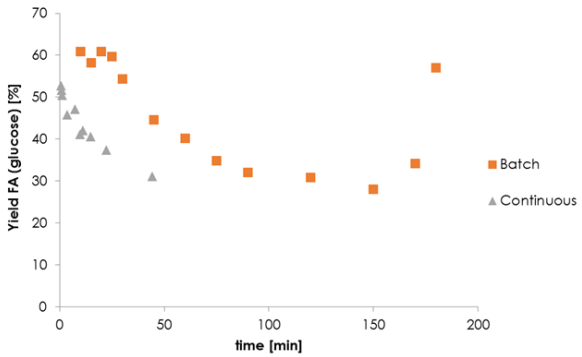

Figure 1. Yield to formic acid (referred to the initial amount of glucose) as a function of reaction time in batch and continuous reactions

As shown in Figure 1, despite the difference in the yield to formic acid achieved at the same reaction time in both reaction methods, there is a clear similitude in the trend that yield follows with reaction time. In batch reactions, yield to formic acid was higher at shorter reaction times, achieving up to 63% after 10 min in batch reactions. However, yield to formic acid decreased when reaction time, probably due to the decomposition of formic acid into CO_2 at high temperatures, achieving the minimum yield at 150 min. After this time, the yield to formic acid increased again, indicating a different mechanism for formic acid production. The same trend is addressed for results obtained in the continuous pilot plant. However, in the continuous facility it is possible to work with residence times as low as 1 minute where maximum yields in continuous are observed.

Higher yields in batch reactions can be explained by the different heating profiles in both reaction systems. While in the continuous systems the heating time for reaching 300ºC could take around 30 min, in the continuous system the heating till 300ºC is instantaneous. In both cases, byproducts obtained from glucose conversion in hydrothermal processes were acetic acid, lactic acid, glycolaldehyde and glyceraldehyde.

4. Conclusions

In this work, the hydrothermal reduction of $NaHCO_3$ using glucose (lignocellulosic derivative) as reductant achieved a yield to formic acid up to 63% after 10 min of reaction at 300ºC in a batch reactor. In continuous maximum yields are obtained at with residence times of 1 min, decreasing afterwards. Despite a lower yield to formic acid achieved in the continuous pilot plant, it opens the opportunity of implementing the process in those focus of CO_2 production.

Highlights

- Catalytic pyrolysis of biogas digestate.
- Optimization of operating parameters.
- The composition of pyrolysis oil is influence by catalysts presence.

1. Introduction

Biogas production by anaerobic fermentation is a promising method of producing an energy carrier from renewable resources [1].The digestate resulted from biogas production is widely used as a fertiliser in farm land[2,3]. However, there is a concern about land spreading of digestate due to the possible heavy metals and pathogen content if not controlled properly. Alternative uses of digestate such as incineration, pyrolysis and gasification of the biogas digestate have been investigated by several researchers[3]. The objective of this study was to investigate catalytic pyrolysis of biogas digestate in order to obtain liquid fractions with potential as fuels components.

2. Methods

The pyrolysis of the digestate was carried out in a continuous system, using a quartz tubular reactor positioned in the central area of a vertical furnace provided with temperature control system. To perform pyrolysis tests, the digestate was conditioned. The preliminary pyrolysis experimental program was performed at the following operating parameter values: I) atmospheric pressure; II) temperature in the isothermal reaction zone: 420°-550° C; III) bulk velocity: 0.1-1 h^{-1}.

3. Results and discussion

The tests of biogas digestate pyrolysis were carried out in presence or absence of catalysts, at different operating parameters. The catalytic pyrolysis was done over nanostructured metal catalysts, prepared by precipitation of copper and iron precursors in presence of various anti-agglomeration additives. The analysis of bio-oil resulted from catalytic pyrolysis of biogas digestate indicates a composition suitable as fuel components. The main compounds identified were linear and branched aliphatic hydrocarbon components, unsaturated compounds, alcohols, carbonyl compounds.

4. Conclusions

The results indicated superior performance for the pyrolysis process in the presence of nanostructured metal catalysts compared with the non-catalytic process.

Continuous In Situ Extraction of Volatile Fatty Acids in an Anaerobic Digestive System.

Gerard James[1], Robert Pott[1]

1 Department of Chemical Engineering, Stellenbosch University, Western Province, South Africa

**Corresponding author: rpott@sun.ac.za*

Highlights

- Liquid-liquid equilibrium studies were conducted using TOA and TBP in canola oil.
- Extraction efficiencies of VFAs differ between synthetic and AD solutions.
- Continuous extraction of VFAs allow for a pH control setup.

1. Introduction

The global demand for sustainable renewable energy has increased exponentially over the past decade. One of the approaches for renewable energy has been anaerobic digestion (AD) for the production of biogas [1]. However, AD is susceptible to acidification, which can cause the anaerobic digester to fail. Acidification is caused when there is an excessive accumulation of volatile fatty acids (VFAs) in the broth. This accumulation of VFAs reduces the pH of the broth, which can cause further methanogenic consortia decay [2]. Therefore, a more sustainable/preferred approach to AD would be to co-produce VFAs and biogas, which could be achieved by continuous *in situ* extraction of the VFAs from the AD process using liquid-liquid extraction (LLE). Laboratory-scaled experiments indicate a strong correlation between the degree of VFAs extracted and the pH of the solution. This implies that LLE can be applied to an AD system to control the pH of the system to prevent the accumulation of VFAs [3]. The successful implementation of an *in situ* pH control process can be used for the continuous removal of VFAs from an AD bioreactor. This energy efficient processing method will increase the productivity of AD and will bring additional revenue to the AD industry, through the sale of VFAs in addition to biogas.

2. Methods

LLE experiments were conducted in batch, using either a synthetic solution of VFAs or AD effluent obtained from a previous student's work. Equal volume of solvent (organic phase) was added to the aqueous phase and vortexed for 5 minutes. The samples were kept in a shaker incubator at 37°C and 150 rpm, and left for 24 hours to ensure equilibrium was reached. The samples were centrifuged and allowed to settle for 1 hour before determining the VFA concentration in the aqueous phase by HPLC. The VFA concentration for the organic phase was calculated by mass balance. The solvent consisted of 20 vol% of the extractant (either TBP or TOA) and canola oil (diluent). The synthetic aqueous solution contained approximately 14 g/l of VFAs in distilled water. The individual concentration for acetic acid, propionic acid, butyric acid and valeric acid are given as 65%, 15%, 14%, and 6% respectively. Experiments were done in triplicate at the centre point.

3. Results and discussion

Laboratory-scaled experiments suggest that there is a significant difference between the degree of extraction in the synthetic solution and the AD effluent (Figure 1A). This could be due to certain ions present in the AD effluent [4]. A strong correlation can also be seen (from Figure 1A) between the extractive efficiency of the solvent and the pH of the solution. This is largely due to the ability of the solvent to extract VFAs below their pKa value [5]. This suggests that there is a trade-off between the amount of VFAs that can be extracted and the amount of methane production. However, an alternative solution would be to design an *in situ* LLE unit to control the pH of the digester to prevent acidification, shown in Figure 1B. This would be achieved by continuously removing VFAs to prevent excessive accumulation. Therefore, the digester would be able to co-produce methane and VFAs, which could bring additional income to the AD system. Similar LLE results were achieved using TOA/TBP in lamp oil and oleyl alcohol.

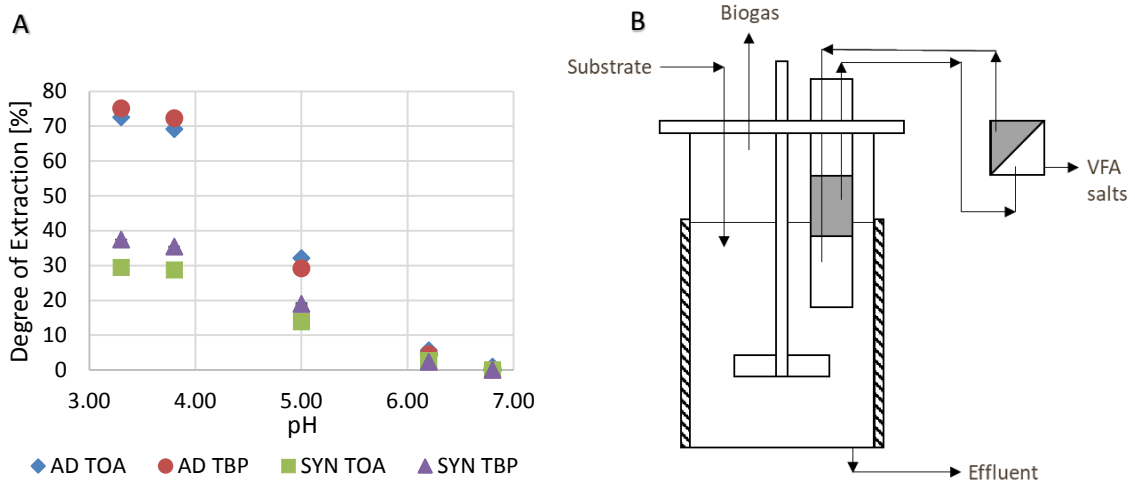

Figure 1: Liquid-liquid extraction of volatile fatty acids using 20% TOA/TBP in canola oil at various pH: (A) A degree of extraction comparison of synthetic solution and AD effluent, (B) Design of a continuous *in situ* extraction anaerobic digester to control pH with a back-extraction unit for solvent recovery.

4. Conclusions

Liquid-Liquid experiments were conducted using TOA/TBP in canola oil, at various pHs, to extract VFAs from a synthetic solution and AD effluent. These experiments indicate a difference between the extractability of the solvent in the synthetic solution and the AD effluent. However, this could be explained by certain ions present in the effluent. The results also indicates a strong correlation between the extractability of the solvent and the pH of the solution. As a result, a more sustainable approach would be to implement a continuous *in situ* extraction of VFAs using LLE to prevent product inhibition of the methanogens.

GASOLINE BLENDING and DISTRIBUTION SCHEDULING

Feleke Bayu, Debashish Panda, Munawar Shaik, Manojkumar Ramteke

Department of Chemical Engineering,

Indian Institute of Technology Delhi, India

E-mail: ramtekemanoj@gmail.com, mcramteke@chemical.iitd.ac.in

Tel No.: (91)-1126591026 (Office); Fax No: +91-1126581120

Highlights

- Graphical GA is used to minimize gasoline blending and distribution operating cost
- The efficacy of the proposed model is checked by solving an industrial problem
- It gives about 1.1-million-euro cost reduction compared to the benchmark reference

1. Introduction

Scheduling of gasoline blending and distribution scheduling (SGBD) is a process of allocating resources in the way the cost is minimized without compromising the quality and the demand of the products. Gasoline accounts about 43% of the total crude oil products. According to the 'International Energy Agency's (IEA) New Policies Scenario' [1] estimates, the total crude oil demand will increase from 95 Mb/d to 115 Mb/d between the year 2016 and 2040. Although the usage of renewable energy sources is significantly increasing, for the next two decades, Crude oil will remain the main energy source, particularly for transportation. Therefore, optimizing gasoline blending process enables to boost the profitability and productivity of crude oil refinery plants which intern reduces the environmental load.

Gasoline blending involves combining the refining intermediate products in a way that gasoline yield becomes maximized since gasoline has a high-profit margin compared to the other products. In the meantime, maintaining gasoline property indices such as octane number (ON), Reid vapour pressure (RVP), anti-nocking and stability specifications, sulphur content, ASTM distillation point and flash point come together.

2. Methods

A graphical genetic algorithm (GGA) which has a sparse representation compared to the conventional GA (CGA) is used to optimize gasoline blending and distribution process. GGA uses a graphical representation where the material flow is represented by the arrow (edge) and processing units or orders by the box. Here, a discrete time-based (period-wise) model is developed. For each period, unlike CGA, in the chromosome structure, GGA considers only the feasible edges which

leads to a tremendous chromosome size reduction. Moreover, it executes genetic operation (crossover and mutation) using a graphical method. During decoding as well as after a genetic operation, the correction will be performed whenever there is constraint violation. Other than the aforementioned differences it follows the same procedure with the conventional NSGA_II.

3. Results and discussion

Using the proposed model, an industrial problem is solved. The result is shown in the table 1. As shown in the table, compared to the CGA there is a significant variable and constraint size reduction for GGA which will enable it to solve complex industrial problems. At the same time, it has around 5 % of production cost reduction compared to the benchmark reference which is a mathematical programming-based model.

Table 1: Model statistics

Number of Variables	Number of			Costs (k€)	
% Reduction over CGA	Constraints for CGA	Penalty function for GGA	% Reduction	Cerda et al [2]	Proposed GGA
87	11541	309	97	18517.24	17413.85

4. Conclusions

The proposed model is more compact and has a better computational efficiency compared to the CGA and it also gives a better economic benefit relative to the benchmark reference[2].

Crosslinked Carboxymethyl Cellulose–Polyethylene Glycol Binder for the Improved Cycle Performance of Silicon Anodes in Li–Ion Batteries

Dongsoo Lee[1], Kangchun Lee[1], Seho Sun[1], Jeongheon Kim[1], Bonggu Kim[2], Junseong Kim[2], Yeongil Jung[2], and Ungyu Paik[1*]

[1]*Department of Energy Engineering, Hanyang University, Seoul, Republic of Korea, 133-791*

[2] *School of Materials Science and Engineering, Changwon National University, Changwon, Gyeongnam 641-773, Korea*

**Corresponding author: upaik@hanyang.ac.kr*

Highlights

- A facile in situ crosslinked binder system is proposed by a convenient, environmental-friendly and low-cost methodology for the practical use.
- The silicon anode prepared with the CMC-PEG binder shows stable cycling performances as lithium-ion batteries.

1. Introduction

Silicon has been widely studied due to its relative abundance and high theoretical specific capacity (~3572 mAh g^{-1}) as an anode material for lithium ion batteries (LIBs). However, the drastic volume changes up to 300% associated with Li still hinder the practical implementation of Si. Herein, we report an in situ cross-linked carboxymethyl cellulose-polyethylene glycol (CMC-PEG) binder and its application to the silicon anode for the long-term cycle life of LIBs. potential to be used for Si and other active materials experiencing volume expansion for LIBs.

2. Methods

For slurry preparation of the reference electrode with CMC, silicon , conducting carbon, CMC, and SBR were placed into deionized water in a weight ratio of 85 : 5 : 8 : 2. For slurry preparation of the electrode prepared with the crosslinked CMC-PEG binder, silicon, conducting carbon, CMC, PEGDE, and SBR were placed into deionized water in a weight ratio of 85 : 5 : 6.4 : 1.6 : 2.

3. Results and discussion

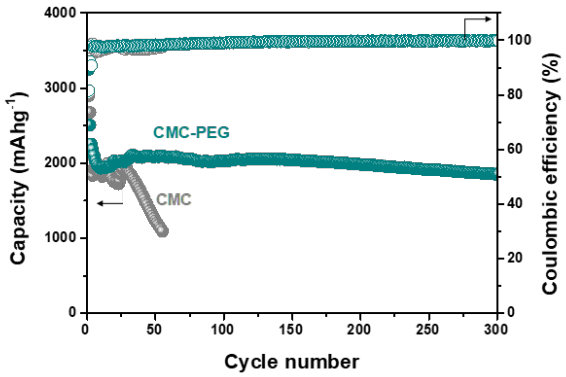

Figure 1. Cycling performance of the silicon electrodes prepared with CMC and crosslinked CMC-PEG binders at 0.5 C rate.

The crosslinked CMC-PEG binder is simply prepared during the electrode drying process without an additional process. In particular, the crosslinked CMC-PEG binder enables the improved and adhesion between active materials and a current collector, and cohesion between active materials. The silicon anode prepared with the crosslinked CMC-PEG binder exhibits stable cycling performance with a capacity of ~2000 mAh g−1 over 300 cycles.

4. Conclusions

Crosslinked CMC-PEG binder was prepared by a facile and low-cost approach. The silicon electrode prepared with the CMC-PEG binder exhibited outstanding cycle performance over 300 cycles at 0.5 C. In terms of the simplicity, in situ crosslinked CMC-PEG binder has a potential to be applied to the silicon anodes for stable cycle performance of LIBs.

Quantitative analysis of gasification of Botswana coal using a 5kg/h auger reactor

Mmoloki Makoba[1*], Paul Agachi[1]

1Department of Chemical, Materials and Metallurgical Engineering, Faculty of Engineering and Technology, Botswana International University of Science and Technology, Private Bag 0016, Palapye, Botswana

**Corresponding author: makobam@biust.ac.bw*

Highlights

- To perform gasification of three different coals in Botswana
- Comparison of the product gas in terms of the amount of gas produced.
- To determine which coal field produces most product gas

1. Introduction

Botswana has approximately 212 Billion tons of coal of which less than a quarter of a billion tons is mined annually forming a part of the Karoo supergroup. It is in the region of what is called the Karoo Supergroup which is the most widespread stratigraphic area in Africa south of the Sahara Desert [1]. These reserves have been found to have high ash, medium calorific value, and low-medium quality bituminous coal [2]. Despite these coal riches, Botswana has only one power plant that generates and supplies electricity to the whole country being able to meet only 30% of the demand in the country. Botswana is developing at a high rate with a lot of infrastructure being erected which calls for more power supply that can be done through the process of coal gasification.

Gasification is the thermochemical conversion of carbonaceous material into valuable synthetic gas. The process takes place in the presence of steam and oxygen. An auger type reactor is a mechanically forced reactor with a screw driven by a motor to control its residence time. This feature allows for agitation which allows for contact with metallic surface and therefore more efficient heat transfer rate.

The auger reactor housed in BIUST is specifically 400 mm long with capabilities of up to 1050 °C temperature, up to 5 kg/h feed rate and residence time of at least 5s.

2. Methods

The samples were first taken through a TGA to determine physical properties. The feeder was then set to run at the required feed rate and the reactor to the required residence time. Heater duty was put to 10 kW. Main parameters for this process were oxygen and steam at 1 atm pressure and temperatures up to 1323 K. All parameters and measurements were recorded during the test. The results were then analyzed and concluded.

3. Results and discussion

Minergy coal shows to be the highest quality coal with lowest ash content and highest volatile matter and fixed carbon as shown by Table 1 and Figure 1. This coal field also produced more gas due to the highest percentage of volatiles.

Coal Fields (Composites)	Characteristics of Composite Coal				Quantitative analysis (per kg)
	Moisture	Volatile Dry	Ash Dry	FC Dry	
Mabesekwa	7.55	23.91	43.66	32.43	115 litres
Minergy	8.49	27.34	33.34	39.32	135 litres
Morupule	8.78	19.2	52.94	28.23	95 litres

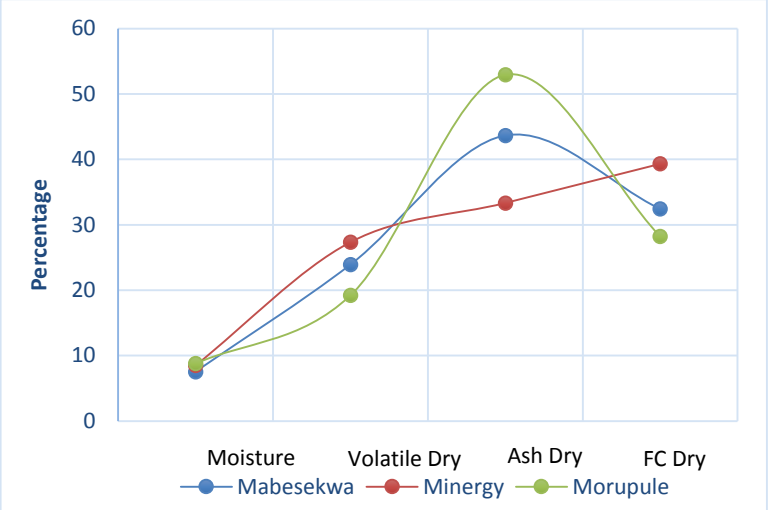

Figure 1. Proximate analysis of three coal fields in Botswana

4. Conclusions

Comparing coals from three different mines across the country, Minergy coal field shows to have the most valuable coal followed by Mabesekwa coal field and then Morupule coal field according to the amount of product gas collected compared under the similar conditions. Coal in Botswana differs across the belt.

Using the PC – SAFT model to estimate the speed of sound in synthetic and natural oil and gas mixtures

Samarov A.A.[1], Toikka A.M.[1], Prikhodko I.V.[1], Golikova A.D[1], Zvereva I.A.[1], Farzaneh-Gord M.[2]

**Corresponding author: samarov@yandex.ru*

Highlights

- Thermodynamic properties
- Sound speed
- PC – SAFT
- Natural gas

1. Introduction

The speed of sound is an important thermophysical quantity, which is used for practical purposes to assess the density of formation fluids in wells in a wide range of external conditions. Along with temperature and pressure, the speed of sound is one of the parameters easily determined in the experiment that can be used to find the molecular weight and density of the gas mixture, as well as to estimate the magnitude of natural gas consumption at gas distribution stations.

Among modern equations of state that are tested by different researchers to improve the quantitative description of the speed of sound in pure and mixed fluids of different nature, the equations of the SAFT (Statistical Associating Fluid Theory) family are distinguished [1]. One of such state equations, the state equation based on the statistical theory of an associated fluid with a perturbed chain (Perturbed Chain – SAFT), was proposed by Gross and Sadowski [2].

In this paper, we applied the version of the PC – SAFT model to estimate and predict the speed of sound for a number of multicomponent systems containing oil and gas fluids. The model calculations performed give good results, sufficient for practical assessments and control of the sound speed (and densities) in the fluid mixtures under consideration.

2. Results and discussion

In this paper, we used the CP – PC – SAFT state equation (Critical Point-based Perturbed Chain – Statistical Association Fluid Theory) and tested the performance of the proposed Polishuk and co-authors method [3] in estimating the sound speed for multicomponent systems containing components of natural gas with different methane content (74–97 mol%). For the calculations, synthetic gas mixtures and natural gas mixtures from different fields were selected, with known experimental sound speeds in a wide range of pressures for a range of temperatures. The average absolute error of the obtained sound speed values in all considered systems does not exceed 2.0%, which indicates high accuracy characterizing the properties of the studied gas mixtures.

According to literature data, the results of predicting the speed of sound and density for a synthetic gas mixture using the CP – PC – SAFT model are somewhat inferior in accuracy given by the GERG-2008 multiparameter correlation equation of state (0.1%), which is recommended and widely used in engineering calculations for oil and gas industry.

3. Conclusions

The results of sound speed and density determination in systems formed by oil and gas components indicate the promise of further use of the PC – SAFT model for evaluating the thermodynamic and thermophysical properties of natural gas for applied purposes.

The Contribution Of CO_2 Utilisation to GHG Emission Reduction: Some Results BasedoOn A European Supply Chain Optimisation.

Federico d'Amore, Victor Baldo, Fabrizio Bezzo*

CAPE-Lab - Computer-Aided Process Engineering Laboratory, Department of Industrial Engineering, University of Padova, via Marzolo 9, 35131 Padova PD (Italy).

Highlights

- Optimisation of a carbon capture, transport, storage and utilisation network.
- <0.6% of European CO_2 from coal/gas plants can be removed through utilisation.
- 5.5% cost reduction achievable thanks to revenues deriving from utilisation.

1. Introduction

In the last 50 years, CO_2 constituted nearly the 80% of overall anthropogenic greenhouse gases (GHGs) emissions; global actions are therefore needed to tackle the increase of carbon concentration in the atmosphere [1]. Carbon capture and storage (CCS) has been highlighted as one of the most promising options. Recently, also carbon utilisation pathways have been highlighted as potential options to reduce the costs that derive from the installation and operation of a more general CCS and utilisation (CCUS) infrastructure. Nevertheless, there is debate on the actual effectiveness of the chemical conversion of CO_2, indicating that only minor environmental benefits could be obtained [2]. In this work, the aim is to evaluate the effects of CCUS from an economic perspective and to assess what contribution may derive from CO_2 utilisation for conversion into chemical products at a European level.

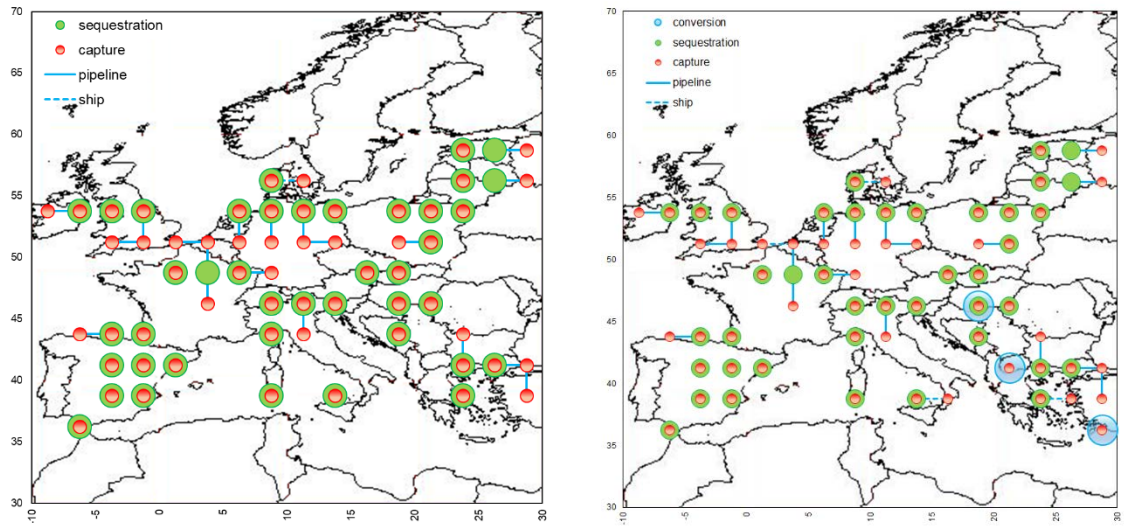
2. Methods

This contribution proposes a static mixed integer linear programming model for the economic optimisation of European CCUS supply chains (SCs). Building up from [3], the European territory is discretised by aim of set *g* of 124 squared cells and the SC takes into account the location of large stationary sources of CO_2, the techno-economic description of set *k* for carbon capture options, of set *l* of transport means, the location and size of storage basins, and the techno-economic features of the CO_2 utilisation stage via set *c* of chemical outputs. Given the numerous reaction mechanisms for CO_2 conversion [4], a restricted number of processes was selected according to the following principles: (*i*) minimum production threshold according to market demand (>1Mt/year of converted CO_2); (*ii*) techno-economic data availability (productivity and costs); (*iii*) environmentally promising (CO_2 emissions lower than consumption); (*iv*) current technology economically promising (the conversion process must generate a profit). As a result, set *c* = {PPP, MeOH}.

3. Results and discussion

The CCUS model was optimised using the GAMS CPLEX solver on a 16GB RAM pc in 27h (optimality gap <1%). As reference case, results from [3] of the optimal CCS network are reported (Scenario 0).

The CCUS system (Scenario A) is optimised according to the selection of a reduction target of 43% of European CO_2 emissions from large stationary sources (consistent with [5]), and imposing to satisfy the current European production of PPP and MeOH. As a result, the SC entails a total cost *TC* for installing and operating the CCUS network that is reduced by 5.5% with respect to Scenario 0, because the introduction of chemical conversion brings in some revenues (with a profit equal to 1.57€/t). Conversely, the chemical conversion of CO_2 allows just a slight reduction of 0.7% of total capture costs *TCC*, which decrease from 30.93€/t (Scenario 0) down to 30.72€/t (Scenario A). The total transport cost *TTC* slightly varies from 1.96€/t (Scenario 0) to 1.90€/t (Scenario A). Despite a small decrease in the exploitation of geological storage (i.e., -1.44%), total sequestration costs *TSC* are unchanged between Scenario 0 and Scenario A (0.47€/t and 0.46€/t, respectively). In terms of CO_2 emission reduction, the net impact of utilisation amounts to 0.58% of the overall captured amount (comparable with [2]). It can be observed that the SC configuration is nearly identical between Scenario 0 and A (Figure 1). Including utilisation, capture points do not change and the main driver to establish the transport system is still the location of the sequestration sites.



(a) (b)

Figure 1. Final SC configurations for (a) Scenario 0 and (b) Scenario A.

4. Conclusions

This work has assessed the potential impact of a European CCUS SC. Results show that the environmental impact of CO_2 utilisation is likely to be a minor one (<0.6% reduction in GHG emissions for the chemicals considered in this study). The main benefit is the reduction of the overall costs (decreasing by 5.5%), since conversion would provide for new revenues (differently from sequestration).

Investigation of Mass Transport and Crystallization Processes of Acoustically Levitated Droplets under Elevated Pressures

Danijel Boroša

BOROSA Acoustic Levitation GmbH, Universitätsstr. 142, Technologie-Zentrum Ruhr,

44799 Bochum/Germany, www.borosa.de, info@borosa.de

Highlights

- Acoustic Levitation
- Wall-Contact-Free Crystallization
- Gas Hydrates
- Physical Properties & Mass Transport

1. Introduction

Mass transport and crystallization experiments are among the most challenging measurements in the field of process engineering and chemistry. The results of these studies provide an important basis for many chemical engineering processes and other technical systems. Mass transport studies of liquids in the presence of dense gases are usually performed with the aid of the pendant-drop-method. Especially, in case of phase-conversion processes, which cause a solidification of the hanging droplet, the disadvantage is the contact between the droplet and the capillary, which is influencing the solidification process. Therefore, a non-contact method would be desirable to observe the mass transport and crystallization processes, e. g. hydrate formation. The acoustic levitation represents a possibility to examine samples without contact to any wall [1] [2].

The modification of a high-pressure-view-cell led to a successful implementation of an acoustic levitator into a pressure- and temperature resistant housing (pressure maximum = 20 MPa, temperature maximum = 453 K). The new measurement device allows the investigation of gas hydrate formation at a contact-free acoustically levitated droplet under elevated pressures.

In preliminary investigations it was possible to show the formation and controlled decomposition of carbon dioxide hydrates. The formation of carbon dioxide hydrates was observed for the first time at acoustically levitated water droplets.

2. Methods

The experiments were carried out with a high-pressure view-cell including an integrated acoustic levitation device. The compact laboratory device L800 is well-suited for accurate measurements of mass-transport mechanisms of small samples. The specifically developed software detects the acoustically levitated sample automatically and analyzes the contour of the droplet. With this information the volume of the rotationally symmetric sample can be measured and documented.

3. Results and discussion

Previous experiences according to gas hydrate formation measurements show that the exact determination of the transition time of larger test samples cannot be simply done. As a result, it is easier to observe one droplet in order to measure its phase change behaviour and the corresponding test parameters. Furthermore, the small sample has got an almost uniform temperature distribution during the measurement. The images illustrate an example of an experiment regarding the formation of a CO_2-hydrate (Fig. 1).

The continuous phase is CO_2 with a constant pressure of 2.9 MPa. The temperature of the continuous phase is about 281 K. Shortly after the injection of the water droplet, the cooling of the continuous phase is started. When a temperature of about 279 K is reached the bottom of the droplet begins to solidify. Then the crystal growth covers the entire droplet. The whole process from a liquid droplet to a gas hydrate was in this case about 8 minutes long. The diagram (Fig. 1) contains the measurement results compared with literature data. Each measurement point is a result of the arithmetic average of three measurement points.

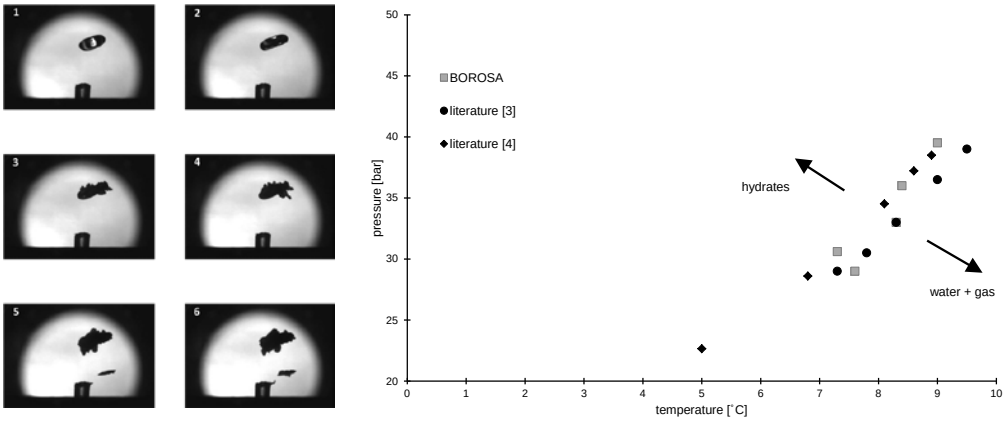

Figure 1: Contact-free CO2-hydrate formation, p= 2.9 MPa / T = ca. 281 K (start) – 279 K (end) [1] / pT-diagram [3] [4]

4. Conclusions

Through the successful combination of a high-pressure measurement cell and an acoustic levitator it was possible for the first time to observe the formation of CO_2 gas hydrates contact-free. It was necessary to develop a method for injecting liquid water droplets in the pressurized view-cell without an unwanted crystallization in the pipes. Finally, it was possible to acoustically levitate a water droplet and to observe its phase change from liquid to solid state. The acquired measurement data were compared with literature data. A good agreement with literature data can be confirmed. Consequently, the new apparatus L800 is suitable to measure gas hydrate formation regarding sample volume, composition and morphology at the same time.

Assessing different modelling approaches for secondary nucleation

Luca Bosetti, Marco Mazzotti*

Institute of Process Engineering, ETH Zurich, 8092 Zurich, Switzerland

**bosettil@ethz.ch*

Highlights

- Attrition considered as a breakage phenomenon and as the source of secondary nucleation
- Physical expression of breakage rate, daughter distribution and secondary nucleation rate
- Comparison of secondary nucleation and breakage by attrition
- Combination of numerical methods: finite volume, fixed pivot, fractional step

1. Introduction

The production of active pharmaceutical compounds relies upon continuous crystallisation, during which the crystals produced are formed via secondary nucleation. A precise physical and mathematical description of the phenomena occurring during secondary nucleation has been neither fully understood, nor fully described yet. One of the possible mechanisms for the formation of nuclei is attrition[1], which is a purely mechanical process that generates fragments that are removed from the crystal surface and then grow or dissolve in the bulk solution. In this study, the formation of secondary nuclei is considered to be a consequence of the detachment of small fragments from a mother crystal, because of impact with the stirrer, which is the most common phenomenon[1].

2. Methods

The scope of this work is to compare two approaches to include secondary nucleation in a mono-dimensional population balance equation model (PBE). The first approach is the one usually used in the literature [1], where a semi-empirical expression for secondary nucleation is included as a boundary condition of the PBE model, in analogy with primary nucleation. Such an expression is usually dependent on the energy input, e.g. stirring intensity, supersaturation and an integral property of the crystals' population, e.g. the total area or the total mass [2,3]. The second approach consists in considering secondary nucleation as a pure attrition mechanism, thus accounting for it through a source term in the PBE, namely an integral term.

In order to model attrition as a source term, we have defined a daughter distribution of fragments [2] and an attrition frequency to quantify the size distribution and occurrence of the attrition events, respectively. Moreover, not all the particles produced through attrition evolve in the same way. In fact, a particle will grow depending on its size according to a size-dependent growth expression. The entire process has been modelled at isothermal conditions, in a batch crystallizer.

The phenomena considered are growth, dissolution, breakage and secondary nucleation. The numerical methods used are hybrids between finite volume[4] for growth, dissolution, and secondary nucleation and fixed pivot[5] for breakage. In presence of source terms, a fractional-step method has been applied[4].

3. Results and discussion

The phenomenon of formation of nuclei (or fragments) has been successfully described by the two modelling approaches, even though they are conceptually very different, since one is active only in the presence of supersaturation, i.e. secondary nucleation, and the other is always active. The results show that we can achieve similar results regarding the production of fines, but the effect of supersaturation is obviously different. Thanks to this result, we are able to have an insight into the two phenomena, starting from physical properties of the system, and physical operative conditions. The study has been conducted in a fully parametric way, which make the model very flexible to change in operating conditions and in changes of the material to crystallize.

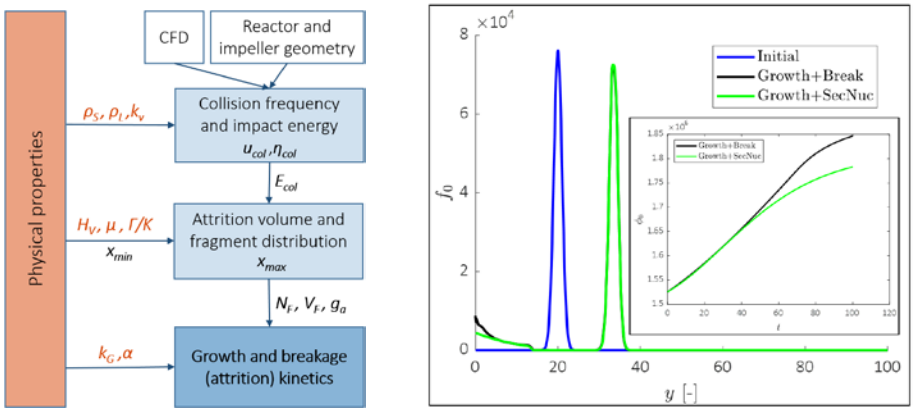

Figure 1. (a) Schema for the physical determination of the breakage rate and of the daughter distribution. (b) Comparison of the final populations obtained with the model with growth and breakage (black) and with the one with growth and secondary nucleation (green).

4. Conclusions

In this work, it has been shown how the two modelling approaches lead to similar conclusions, when the expressions for secondary nucleation and that for breakage by attrition have been derived from the physical properties of the system and its operative conditions. Experimental validation of the model will allow to clarify which approach is more suitable to describe continuous crystallization.

Highlights

- Kinetic assessment for continuous crystallization developed
- Population balance kinetic model (PBM) built for two solvent systems to evaluate solvent dependency
- MSMPR process parameters optimized and validated through PBM

1. Introduction

In the pharmaceutical industry, crystallization is a key unit operation utilised to produce particles with desired properties, such as the particle size distribution, as this has an influence on downstream processes such as filtration and drying. The acquisition of reliable kinetic correlations that describe how rates of nucleation and growth vary over the crystallization design space is necessary for enabling robust prediction of crystallizer performance. The aim of this study was to generate a standardised workflow approach for the generation of crystallization kinetics data using population balance modelling (PBM), and to assess the batch crystallization process for feasibility of continuous processing for an early development compound.

2. Methods

Initially, the crystallization growth kinetics were estimated by means of seeded isothermal desupersaturation experiments in a batch reactor. PAT tools such as Attenuated Total Reflectance-Fourier Infrared (ATR-FTIR) spectroscopy and Focused Beam Reflectance Measurement (FBRM) were utilised for *in situ* to track the desupersaturation profile and the progression of the seed distribution, respectively. The initial crystal size distributions (CSDs) and desupersaturation profiles were used to estimate the growth kinetics as a function of temperature and supersaturation. Two solvent systems were tested to extract growth kinetics and were used for comparison. Furthermore, activity coefficients as a function of temperature and composition were considered in the kinetic model, which enabled to directly evaluate the solvent dependency effect. Following satisfactory validation of crystal growth kinetics, a continuously operated single-stage mixed suspension mixed product removal (MSMPR) crystallizer was used to extract the secondary nucleation kinetics.

3. Results and discussion

Three seeded isothermal desupersaturation experiments were performed to estimate the crystal growth kinetics, which are outlined in Table 1. A conservative approach of using a high seed loading of 50% allowed for the estimation of growth kinetics in the absence of nucleation. Furthermore, the temperature and initial relative supersaturation range covered in the parameter estimation was between 0 to 30°C and 0.226 to 0.670, which ensured that the entire phase diagram was covered and that the estimated parameters could describe the growth over a wide range of operating conditions. One experiment (exp 4) was performed to validate whether the growth is size dependent or independent by using a larger seed fraction.

Table 1. Experimental conditions for parameter estimation for solvent system 1

Experiment	Temperature (°C)	Relative S0 (-)	Seed Loading (%)
1	0	0.670	50
2	15	0.474	50
3	30	0.226	50
4	30	0.226	50

During the continuous crystallization study, a recycling system was employed to significantly reduce the waste of raw materials during the MSMPR study prior to the onset of steady state, which can be very useful during the early stages of process development where limited amount of product is available. Furthermore, problems such as blocking of transfer line and feed inlet were eliminated, by applying a rapid intermittent withdrawal of slurry via dipped pipe[1], and by using a tube-in-tube configuration to insulate the feed inlet line. Finally, a novel 3D printed jacketed nozzle was attached at the end of the feed inlet line to avoid the saturated solution from crystallizing which can lead to blockage. Based on PBM and utilisation of the kinetic data[2], CSD was simulated and residence time distribution, operating temperature and productivity of the MSMPR were optimised and finally experimentally verified. Overall, a standardised workflow was developed for the kinetic assessment of an early development compound for continuous crystallization.

Highlights

- V(II), V(III) and V(V) supersaturated solutions were prepared by electrolytic dissolutions of commercial vanadium salt in sulphuric acid solutions.
- Pure crystals of hydrated V(II), V(III) and V(V) sulfates ($VSO_4 \cdot 7H_2O$, $V_2(SO_4)_3 \cdot 10H_2O$ and $V_2O_5 \cdot 1.5H_2O$) were isolated and identified as precipitating phases, in different conditions.

1. Introduction

The vanadium redox flow battery (VRFB) has been receiving considerable attention in recent years, as one of the most viable energy storage technologies for large-scale application. It eliminates the cross-contamination present in flow battery, enables long cycle life (>10000 cycles), high-energy efficiencies and relatively low-cost structure for large storage capacities [1]. As the concentration of vanadium species in the H_2O-H_2SO_4 electrolyte determines the VRFB energy density, high concentrations are required. Meanwhile, major precipitation of vanadium compounds must be avoided [2]. Despite current researches aiming at understanding the vanadium salts precipitation in a VRFB, very little has been done to identify the phases precipitated in the vanadium acidic solution used as VRFB electrolyte. This study has thus focused on (i) preparing V(II), V(III) and V(V) supersaturated solutions (ii) identifying the precipitation products in VRFB operating conditions, with an aim of improving the understanding of vanadate chemistry in a high concentrated sulphuric acid solution.

2. Methods

The vanadium supersaturated solutions are prepared by dissolution of commercial $VOSO_4$ powder suspension, and subsequent electrochemical oxidation (for V(V) preparation) or reduction (for V(II) and V(III) preparation) in one of the compartment of a two-compartment electrolytic cell separated by a Nafion cationic membrane. Thick carbon felts (5mm) were used as anode and cathode. Based on the solubility curves of the vanadium salts available in the literature [2], 60.63 grams of $VOSO_4$ powder (corresponding to 5 mol L^{-1}) were added in 50 mL of a 5 mol L^{-1} H_2SO_4 solution, and placed either into the negative half-cell to prepare V(II) and V(III) supersaturated sulfate solution, or into the positive half-cell to prepare V(V) sulfate solution. The galvanostatic electrolyzes were run at a constant current density (1 A) with a DC power supply. The vanadium species concentration was followed by UV-vis spectroscopy for V(II) and V(III) solution and by titration for V(V) solution. When the required vanadium conversion was achieved , the supersaturated solution was transferred to another vessel where they were aged at constant temperature (30 °C for V(II) or V(III) and 60 °C for

V(V)) and at constant agitation (400 rpm), while the vanadium species concentrations were monitored until precipitation occurred. The precipitated products were then filtrated, washed with ethanol, dried at 60 °C for 4 hours, and analyzed by X-ray diffraction (XRD), thermogravimetric analysis (TGA) and UV-Vis spectroscopy.

3. Results and discussion

The initial vanadium concentrations were measured before the aging process as 3.2, 3.5 and 4.0 mol L^{-1} for V(II), V(III) and V(V) solutions, respectively. Significant amounts of precipitated solids were obtained in V(II) and V(III) solutions, after 12 h (purple precipitate for V(II) and green precipitate for V(III)). For the V(V) solution, 11 days were required to produce enough solid (orange/brown precipitate) for further characterization. The obtained precipitated powders were then diluted in a sulphuric acid solution and analyzed by UV-Vis spectroscopy. They all showed their own specific absorption profile, confirming that each of the precipitates corresponds to a specific oxidation state, depending on the initial solution. Powder XRD analysis of each of the dried precipitates was performed (Figure 1). The precipitate obtained from the V(II) solution perfectly match the $VSO_4 \cdot 7H_2O$ phase, and the solid produced from V(III) and V(V) solutions fairly match $V_2(SO_4)_3 \cdot 10H_2O$ and $V_2O_5 \cdot 1.5H_2O$ phases, respectively. These phases were similar for different aging/precipitation durations. To confirm the V(III) and V(V) precipitates identification, the powders were heat-treated at 200 °C in air and analyzed again by XRD. This temperature (200 °C) was determined by TGA. It enables a complete removal of the water from the hydrates without any decomposition (to SO_3 for example) nor any phase transition (due to oxidation for instance). After the heat treatment, the V(III) and V(V) precipitates perfectly match the $V_2(SO_4)_3$ and V_2O_5 pattern respectively.

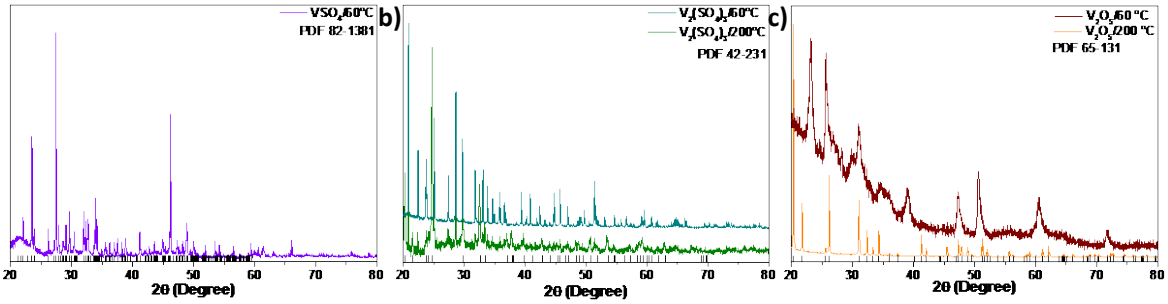

Figure 1. X-ray diffraction pattern of the precipitation product of the (a) V(II), (b) V(III) and (c) V(V) solution after aging.

4. Conclusions

In summary, we report a method to prepare V(II), V(III) and V(V) supersaturated solutions in an H_2SO_4-H_2O electrolyte, from the only vanadium sulfate compound commercially available ($VOSO_4$). We also identify the precipitation products which may form in a VRFB operated with such supersaturated solutions. The results showed that V(II), V(III) and V(V) sulfate solutions precipitate as VSO_4, $V_2(SO_4)_3$ and V_2O_5 hydrates and not in their anhydrous form. Taking into account this hydration degree might change the vanadium concentration limits of a VRFB and the occurrence of precipitation which are currently calculated in the literature with the anhydrous form [1].

Isothermal cold crystallization kinetics and properties of thermoformed poly(lactic acid) composite films

Anongnat Somwangthanaroj[1,2,*], Chutimar Deetuam[1], Chavakorn Samthong[1], Suphattra Choksriwichit[1]

1 Department of Chemical Engineering, Faculty of Engineering, Chulalongkorn University, Bangkok 10330, Thailand; 2 Special Task Force of Activating Research (STAR) in Novel Technology for Food Packaging and Control of Shelf Life, Chulalongkorn University, Bangkok 10330, Thailand
**Corresponding author: anongnat.s@chula.ac.th*

Highlights

- Effects of fillers and silane surface functionalization were investigated.
- Faster cold crystallization of PLA with the presence of fillers was observed.
- Talc is the most effective nucleating agent for PLA.

1. Introduction

Biodegradable polymers have gained great attention as eco-friendly alternatives to conventional plastics derived from fossil fuels. Poly(lactic acid) (PLA) is the most well-known biodegradable thermoplastic that has been extensively used for diverse applications, such as household appliances, automobile interiors, tissue engineering, drug delivery, and food packaging materials [1, 2] because of its unique properties including biodegradability, biocompatibility, high transparency, and high tensile strength (75 MPa) and modulus (3.2 GPa) [3, 4]. Nevertheless, PLA has some weaknesses including brittleness with elongation at break less than 4%, poor melt strength, poor thermal stability, and low gas barrier properties. Further, PLA is also known as a slow crystallizing polymer; this leads to a very long injection moulding cycle time during the cooling step, and the end-use products have low crystallinity, which strongly affects its optical, thermal, and mechanical properties [5]. Accordingly, slow crystallization behaviour of PLA should be improved for potentially being used in the industrial applications as it deserves. In this work, the effect of the addition of talc, $CaCO_3$, and cassava starch at various contents on the morphology, mechanical and thermal properties, and isothermal cold crystallization kinetics of PLA composites is examined.

2. Methods

The isothermal cold crystallization kinetics is investigated by fitting the experimental data from differential scanning calorimetry (DSC) with a theoretical Avrami model. The study on annealing effect under cold crystallization on the thermal and tensile properties is performed by comparing cast films with thermoforming films. Eventually, surface treatment of talc with vinyltriethoxysilane (VTES) and 3–aminopropyltriethoxysilane (APTES) is also performed to examine the silanization effect on the properties of PLA composites in comparison with the untreated system. Tensile properties including tensile strength, elongation at break, Young's modulus, and tensile toughness of cast films and thermoforming films of neat PLA and PLA composites were measured at room temperature using a universal testing machine (Intron model 5567, USA) in accordance with ASTM D882.

3. Results and discussion

The Avrami model was employed to study the isothermal cold crystallization kinetics by DSC. Dynamic DSC results revealed that incorporation of filler can facilitate the cold crystallization of PLA. The highest isothermal cold crystallization rate constant *k* and the shortest crystallization half time $t_{1/2}$ were achieved for the PLA/talc composites under isothermal temperature of 100 °C, implying that talc was the most effective nucleating agent for PLA in this study. After annealing the cast films under isothermal cold crystallization condition to induce the orientation of PLA chains, the thermoforming films had higher degree of crystallinity as well as improved tensile strength and Young's modulus. The successful grafting of silane coupling agent onto the talc surface was confirmed by FTIR measurement and it was noticed that films with the silanization of talc surface with APTES showed the fastest cold crystallization rate. Therefore, the strong interfacial adhesion in the PLA composites containing APTES treated talc resulted in less debonded talc particles from the cryofractured surfaces and an enhancement of tensile properties.

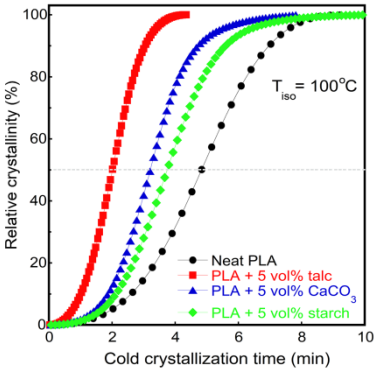

Figure 1. Relative degree of crystallinity X_c of neat PLA and its composite cast films containing 5 vol% untreated fillers at T_{iso} = 100 °C. Inserted horizontal line is X_c = 50%.

4. Conclusions

The effects of three different fillers and silane surface functionalization on morphology, thermal and tensile properties of the poly(lactic acid) (PLA) composites were comparatively examined. The surface functionalization of talc particles by silanization reveals higher tensile strength as well as faster cold crystallization rate, which is attributed to the enhanced interfacial interaction between PLA chains and talc particles. Therefore, it can be summarized from our work that cold crystallization behaviour of the polymer composites depends not only on inherent nucleating ability of filler, but also the surface functionality of the filler particles.

Highlights

- Novel antisolvent crystallization process for Indomethacin
- Increased productivity obtained from ternary solvent system
- Desired polymorph obtained via seeding

1. Introduction

Development of crystallization processes for manufacturing of active pharmaceutical ingredients (APIs) with the desired purity, solid form, particulate properties, as well as sufficiently high process yield is very crucial for pharmaceutical industry. Polymorphism, particle size distribution and crystal shape of APIs are a complex function of crystallization process parameters, whereas the productivity of a batch crystallization process strongly depends on the difference between the API concentration at the initial operating conditions and the final condition of the batch. A high process yield requires a solvent system that provides high API solubility at the initial batch conditions and a remarkable change of the API solubility with the changing operation parameter, i.e., decreasing of temperature and/or addition of antisolvent [1]. In this work, we show that the use of binary solvent mixture compared to the pure solvent can provide increased solubility leading to the increased productivity of APIs during crystallization. We also show that the altered solute-solvent interactions favoring the formation of desired polymorph can be obtained by using solvent mixtures instead of pure solvents. Indomethacin (IMC), a nonsteroidal anti-inflammatory drug, is used as the model compound. It has been reported that IMC can form five polymorphs and several solvates [2]. However, metastable α-IMC having needle like crystal shape and thermodynamically most stable γ-IMC having plate like crystal shape are most commonly observed. In this work, antisolvent crystallization of IMC from acetone-methanol-water system has been carried out with acetone-methanol (66.5-33.5 Wt%) as solvent and water as an antisolvent.

2. Methods

Binary solvent mixture acetone-methanol was selected based on the solubility of γ-IMC in single and binary solvent mixtures (Fig. 1) reported earlier [3,4]. Firstly, the solubility of γ-IMC in acetone-methanol-water with varying composition of water was measured at 25 °C. Based on the determined solubility data, seeded and unseeded antisolvent crystallization experiments of IMC from acetone-methanol-water were performed at 25 °C. The procedure included dissolution of IMC in 30 g of acetone-methanol solvent contained in a 100 ml reactor followed by stepwise addition of

water as an antisolvent. Each experiment was performed at two different initial concentrations of IMC as shown in Fig. 2. In experiments with high (C_i^1) and low (C_i^2) initial concentrations, 9 and 12 g water was added, respectively to obtain the respective solvent composition of 23 and 28.5 wt% water as shown in Fig. 2. In case of seeded experiments, seed load (γ-IMC, 71-125 µm) of 0.75, 1.5, 3, and 4% of Δ*C* were used. The experiments were monitored with ATR-FTIR probe and characterization of IMC crystals was carried out with XRPD, SEM and particle size analyzer.

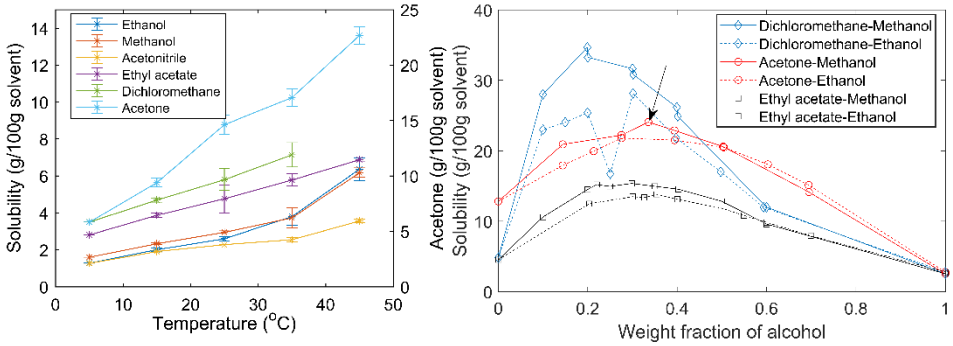

Figure 1. Solubility of γ-IMC in pure organic solvents (left) [4] and in binary solvent mixtures at 25 °C (right) [3].

3. Results and discussion

In comparison to the seeded cooling crystallization of IMC from ethanol reported earlier [4], significantly high productivity was obtained during antisolvent crystallization of IMC from acetone-methanol-water (Table 1). Increased crystal yield was obtained mainly due to the extended thermodynamic boundaries allowing much higher initial concentration of IMC in acetone-methanol binary mixture [5].

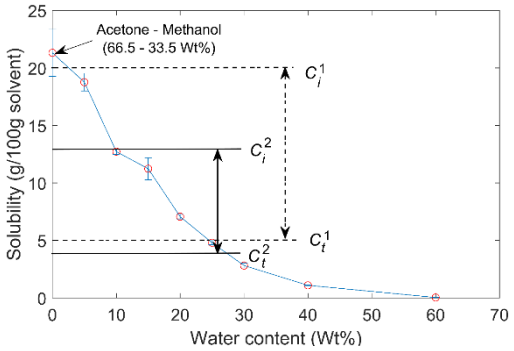

Figure 2. Measured solubility of γ-IMC in acetone-methanol-water at 25 °C.

Table 1. Results from antisolvent crystallization of IMC from acetone-methanol-water at 25 °C.

Properties	Unseeded		Seeded	
	C_i^1	C_i^2	C_i^1	C_i^2
Solid form	Solvate	Solvate	γ-IMC	γ-IMC
Productivity (mg/g/min)	-	-	0.75	0.38
			0.015*	

*Maximum productivity of IMC obtained during cooling crystallization from ethanol [4]. Productivity values for current work are for highest seed load.

4. Conclusions

In this work, we have shown that the desired γ-IMC can be produced consistently through seeded antisolvent crystallization from acetone-methanol-water with improved productivity.

Highlights

- Data-driven model for CLD-to-PSD prediction
- Model required limited data and showed good generalization properties
- Applicable to different crystal morphologies (rod, compact, platelets)
- Comparison with model variations using PCA and geometric models

1. Introduction

In pharmaceutical crystallization, Focused Beam Reflectance Measurement (FBRM) has become a standard tool for in situ particle monitoring due to its ease of process implementation and ability to operate at high solids concentrations. However, a major limitation of this technique is that its measurement signal, i.e., the chord length distribution (CLD), differs fundamentally from particle size distribution (PSD) data due to the FBRM measurement principle described in literature [1,2]. Thus, the measured CLD is not only a function of particle number and size, but is generally also affected by particle morphology and various process parameters, e.g., probe positioning, particle concentration, and optical effects of the continuous and dispersed phase. The combination of these factors produces the actual measurement signal, which differs from a theoretically calculated CLD. Thus, a data-driven modeling approach has been proposed recently which allowed the quantitative determination of 1D and 2D PSDs from measured CLDs, suggesting an effective solution to the above-mentioned limitations of the FBRM [1]

2. Methods

The data-driven model architecture is based on three sequential steps:

1. CLD data is compressed into a small set of CLD descriptors (low order moments).
2. The CLD descriptors are mapped into a small number of PSD moments using a regression model.
3. Finally, the PSD moments are expanded into a full particle size distribution using a 2-layer network model.

Fundamental for the final step are parameterized functions (herein called generating functions) which reduce the number of model parameters. It is noteworthy that this model architecture has undetermined parameters in step 2 and step 3 which need to be estimated using a training data set to fit these parameters for the system being monitored. The model training was performed with three compounds featuring different particle morphology as shown in Fig. 1.

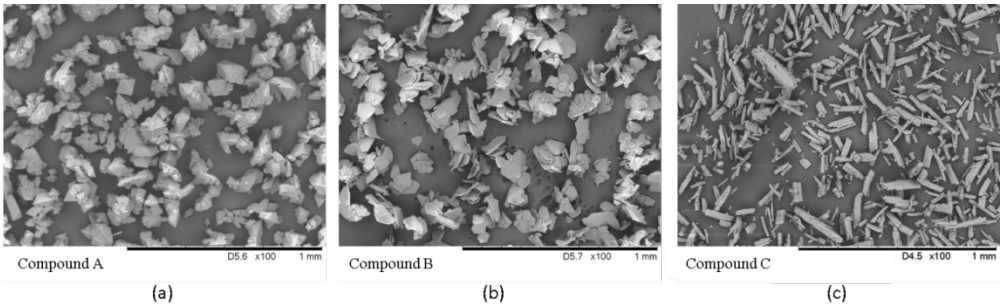

Figure 1. Three compounds featuring different crystal morphologies modeled with the data-driven model: (a) compact, (b) platelet, and (c) rod morphology.

3. Results and discussion

A limited training set of four different PSDs each at four different solid concentrations proved to be sufficient for all three morphologies. Fig. 2 shows as example the comparison of the measured PSD and the PSD estimated from CLD and solids concentration data for the platelet compound:

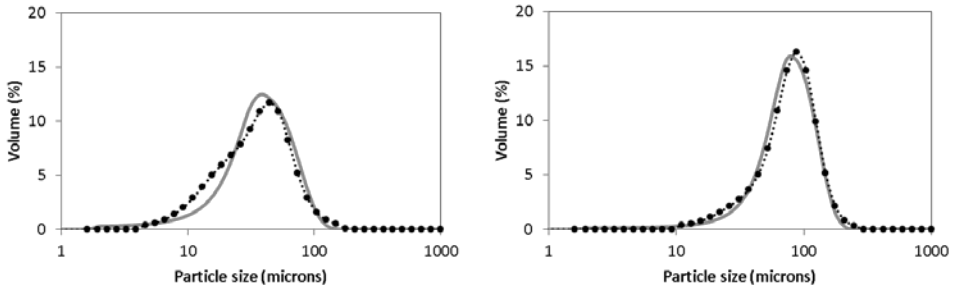

Figure 2. Experimental laser diffraction PSDs for the platelet morphology shown as dots (dotted lines are a guide for the eye) together with corresponding PSD predictions from CLD and solid concentration data.

Model accuracy was assessed using the root mean square deviation between measured and simulated PSDs. The RMSD values were similar not only for all three compounds but also for development batches monitored years before compiling the training data, indicating robust generalization.

4. Conclusions

A data-driven CLD-to-PSD model was applied to compounds with different morphologies at slurry concentrations typical for industrial crystallization processes. In all cases, a limited experimental data set which can be generated in less than two days was sufficient to obtain a model which is able to accurately predict particle size distributions from CLD and solids concentration measurements. While the approach has thus far only been tested on three systems, the breadth of morphologies which yielded positive results suggests that this framework has the potential to have a broad application.

Crystallization fundamentals and industrial processes

Deracemisation via temperature cycles: the effect of the initial and operating conditions

F. Breveglieri*, B. Bodák, and M. Mazzotti

Institute of Process Engineering, ETH Zurich, 8092 Zurich, Switzerland

**Corresponding author: fbrevegl@ethz.ch*

Highlights

- Effect of the initial and operating conditions on the deracemisation process.
- Qualitative comparison between experiments and PBE model.
- Experimental variability due to small variations of the experimental conditions.

1. Introduction

Solid-state deracemisation via temperature cycles is among the techniques used to attain chiral purity. By applying periodic temperature variations to a suspension of a conglomerate forming compound in the presence of a racemisation reaction occurring in solution, only one pure enantiomer is obtained[1].

Previous contributions have shown that by starting the process with asymmetric initial conditions, i.e. an excess of one enantiomer, this one will be isolated at the end of the process[1]. However, a thorough investigation of the conditions affecting the deracemisation outcome has been performed only for a similar isothermal deracemisation process[2]. In this work, we combine results obtained by performing experiments and by running simulations to investigate the effect of the initial and operating conditions on the process outcome. Particularly, we analyse how the initial enantiomeric excess (ee_0), the parameters describing the initial particle size distribution (PSD), and their combination affect the attained handedness and the deracemisation time, when performing temperature cycles. We also evaluate some additional parameters, such as the suspension density, to better explain the variability of the outcome observed in some deracemisation experiments.

Finally, we vary several operating conditions, especially the temperature profile, to investigate their effect on the process in terms of time and productivity.

2. Methods

The simulations of the process are performed with a PBE-based model, previously presented[3]. The experiments are carried out using chiral model compounds and a base as racemising agent. The temperature profile is monitored with thermocouples and the evolution of the enantiomeric excess over time with chiral HPLC[4].

3. Results and discussion

In the case of experiments as well as of simulations, when the process started with the same PSD for both enantiomers and an initial excess of the desired one, the deracemisation proceeded towards this handedness (Fig. 1) [4,3]. In the absence of ee_0, the asymmetry in the initial conditions

can be introduced by differentiating the PSD of the two enantiomeric populations. These differences would determine the outcome of the deracemisation process.

We also combined the parameters describing the PSD and the ee_0, looking at how they compete for the initial asymmetry. For example, when the process started with an excess of the D-enantiomer, we obtained the L-enantiomer, if the mean size of its population was large enough to counterbalance the ee_0.

The described sensitivity to the initial conditions, is used to better analyse the variations among experiments repeated at the same nominal conditions. Taken an experimental parameter, we exploited the process model to test the variation of the deracemisation outcome as a function of small realistic deviations from the nominal value of this parameter. We, hence, qualitatively compared experimental and simulation results and we verified the agreement among the trends, when small variations are introduced.

By investigating different operating conditions, i.e. the cooling rate and the temperature range, we have verified how the process time shortens when the cooling rate increases. Thanks to the combination of experimental and simulation results, we could verify the presence of optimal conditions.

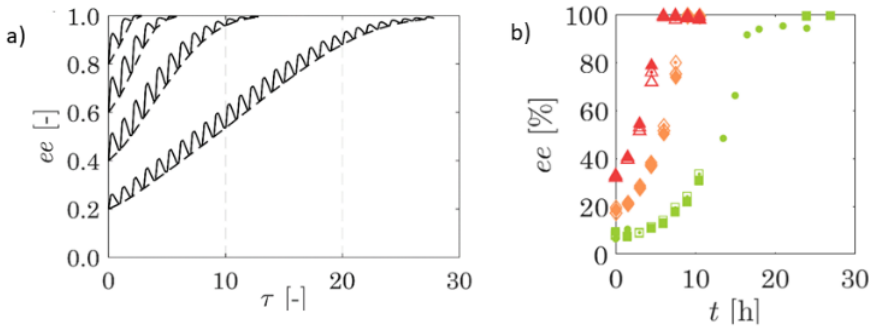

Figure 1. Effect of the initial enantiomeric excess. Evolution of the enantiomeric excess over time, obtained by running simulations at ee_0 = 0.2, 0.4, 0.6, 0.8 (a) and experiments at ee_0 = 7, 18, 32 % (b).

4. Conclusions

We have shown, experimentally and by running simulations, that the outcome of the deracemisation via temperature cycles is strongly influenced by the initial conditions, i.e. enantiomeric excess and particle size distribution. By further analysing the initial conditions, we have shown how the high sensitivity of the process to these parameters explains the variability observed during experiments. Finally, we investigated several operating conditions, and we identified the ones favourable for the process.

Modeling Batch Preferential Crystallization for Conglomerates Forming Systems using Shortcut Models

S. Bhandari[2*], T. Carneiro[1], E. Temmel[1], H. Lorenz[1,2], A. Seidel-Morgenstern[1,2]

1. Max Planck institute for Dynamics of complex technical Systems, Magdeburg, Germany
2. Otto von Guericke University, Chair of Chemical Process Engineering, Magdeburg, Germany

bhandari@mpi-magdeburg.mpg.de

Highlights

- Shortcut models are formulated and introduced for Preferential Crystallization
- Enantiomers of Monohydrate and anhydrate systems are studied
- Key performance indicators are evaluated

1. Introduction

Evaluating various kinetic mechanisms, Population Balance Models (PBMs) are a powerful tool to describe crystallization processes. Due to the consideration of many details, the resulting set of equations is difficult to solve and expensive in applying it for simulation and optimization. Preferential crystallization (PC) is a strong technique capable to resolve mixtures of enantiomers [1, 2]. In this study a shortcut model based on assuming uniform particles sizes and only one lumped kinetic mechanism is introduced. Correspondingly model parameters are calculated using the experimental data for batch preferential crystallization of conglomerate forming chiral systems. The analysis is based on the enantiomers of DL-threonine in water and DL-asparagine (DL-Asn) in water. The latter system forms a monohydrate. An evaluation of Key Performance Indicators (KPI) of the process (i.e. productivity and purity) is performed for the two systems using the shortcut models. The predictions are compared with the experimental results. A possible extension of the shortcut models to simulate preferential crystallization in racemic compound forming systems will be also shortly discussed.

2. Methods

The shortcut models are developed to describe batch preferential crystallization (PC) exploit the principle of “total mass transfer” that causes mass depletion of the liquid phase and mass build-up of the solid phase during the process. The following assumptions are made to derive the shortcut model for PC:

- Nucleation and growth rate are lumped and connected with a constant k_{GB}^{eff}. The two mechanism jointly cause liquid phase mass depletion and solid phase mass build up
- All crystals of one enantiomer are spheres of the same increasing size (no size distribution)
- A certain number of very small “crystals” of the counter-enantiomer are assumed to be initially present along with the seeds of the preferred enantiomer
- A production time t_{prod} is introduced as a function of supersaturation, which is the time at which the crystals of counter enantiomer is activated
- Driving forces respect metastable solubility limits in the 3-phase regions
- No aggregation or breakage occurs.

The basic equations of the model are:

Liquid phase mass balance:

$$\frac{dm_i}{dt} = -k_{GB}^{eff} 4\pi N_i R_i^2 (S_i - 1)^{n^{eff}} \quad i \in \{1,2\} \tag{1}$$

Solid phase mass balance:

$$\frac{dR_i}{dt} = \frac{k_{i,GB}^{eff}}{\rho_{Sol}} (S_i - 1)^{n_i^{eff}} \quad i \in \{1,2\} \tag{2}$$

3. Results and discussion

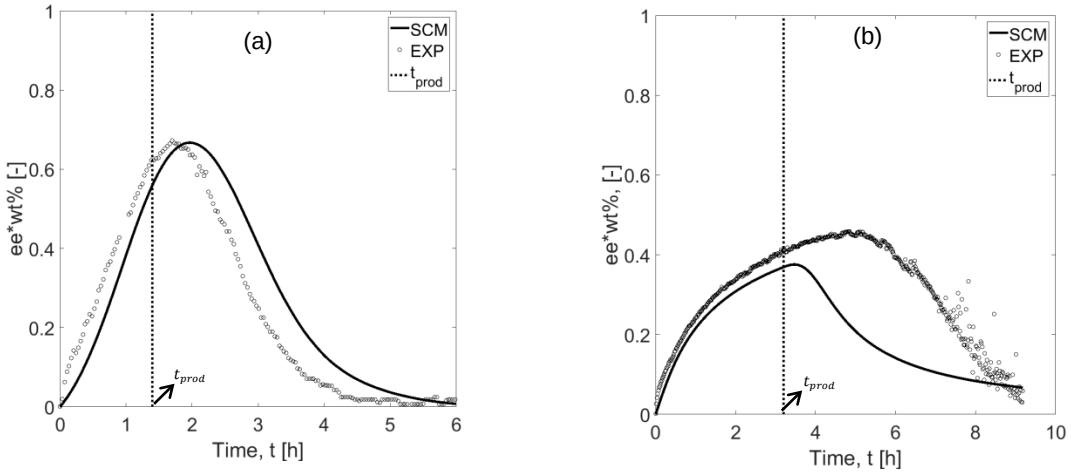

Figure 1. Comparison between shortcut model and experimental data of batch isothermal PC. Enantiomeric excess profiles of case (a) DL-threonine in water and (b) DL-asparagine monohydrate in water

Experimental results of case (a) threonine [3] and case (b) asparagine monohydrate were used to evaluate the potential of the shortcut model. As shown in Figure 1, both cases differ significantly in the initial rates and the process trajectories. The shortcut model is capable to capture these differences by using different effective order of crystallization kinetics (n^{eff} = 1 and n^{eff} = 6.6) respectively. The other two parameters required in shortcut model for PC is effective crystallization rate constant k_{GB}^{eff} and stop time t_{stop}. The parameter estimation in both the cases is performed using least square fitting method. Figure 1 clearly shows the performance of the model within the production time is satisfactory as compared with the experimental results.

4. Conclusions

The above results show that shortcut models can describe essential features of the PC process. The experimental results regarding enantiomeric excess compare well with predictions of the shortcut model. It is seen as a useful tool for preliminary estimations of KPI as productivity, yield, purity and identifying optimal operating parameters. Clear limitation of the shortcut model is the fact that it cannot predict the crystal size distribution and higher moments are not conserved.

Efficient assessment of combined crystallization, milling, and dissolution cycles for crystal size and shape manipulation

Pietro Binel[1]*, Fabio Salvatori[1], and Marco Mazzotti[1]

[1] Institute of Process Engineering, ETH Zurich, 8092 Zurich, Switzerland

*Corresponding author: binel@ipe.mavt.ethz.ch

Highlights

- Crystallization, dissolution, and milling selectively manipulate crystal shape
- The simulations identify general trends used for process characterization
- The interplay of critical operating variables and system parameters is elucidated

1. Introduction

The size and shape of crystals in a powder are important properties that significantly contribute to determining the quality of the final commercialized product and that affect several steps in the downstream process [1]. Different approaches have been proposed to modify the morphology of crystalline products. Here, we assess the effectiveness of a 3-stage process [2] consisting of cycles of crystallization, milling, and dissolution for products with different features, aiming at a robust and quick process design [3].

2. Methods

The 3-stage process is investigated through simulations and experimental work. A lab-scale setup is used to perform crystallization, wet milling, and dissolution while monitoring the solute concentration with the ATR-FTIR technology. The number of cycles performed and the rotor speed of the wet mill device are chosen as process variables. To measure the particle size and shape distribution (PSSD) of the population after each step of the process, the optical imaging device µDISCO [4] is employed. The simulations are based on two-dimensional morphological PBEs tailored to best describe every step of the process.

3. Results and discussion

Two model compounds featuring a needle-like crystal habit, namely β L-Glutamic acid and γ D-Mannitol, are used to map the design space spanned by the process variables onto the space plane, i.e. the plane where average length L_1 and width L_2 of the crystal population are plotted. For this purpose, a factorial design approach is adopted to minimize the experimental effort. It is observed that, although with β L-Glutamic acid a broad range of sizes and aspect ratios can be reached, γ D-Mannitol exhibits a very narrow attainable region for the same combination of operating variables. Simulations allow us to demonstrate that the different behavior or β L-Glutamic acid and γ D-Mannitol, which affects the shape of the attainable region (Fig. 1), is due to a major difference in the kinetics of growth and dissolution, then validated through direct experimental measurements or by comparison with values reported in literature.

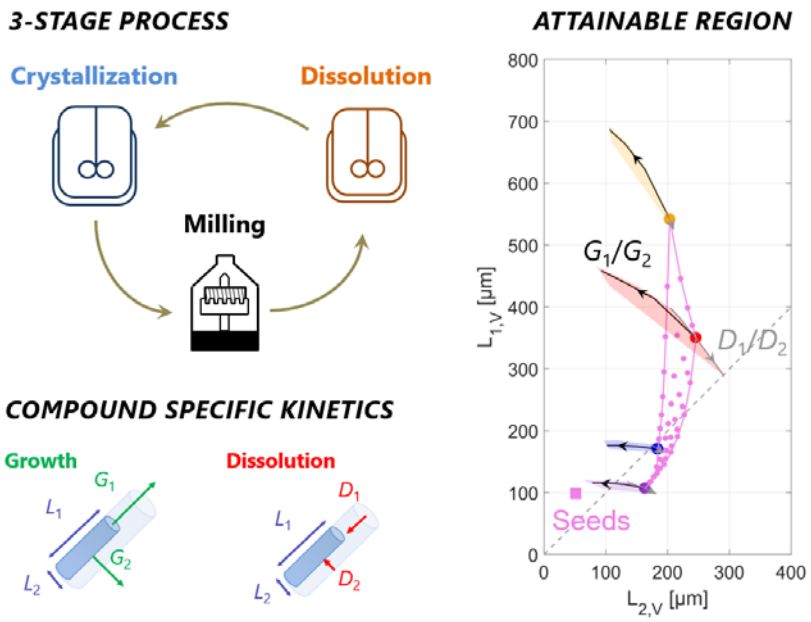

Figure 1. The 3-stage process consists of cycles of crystallization, milling, and dissolution. The attainable region in shape and size of the final population heavily depends on the kinetics of growth and dissolution of the product.

4. Conclusions

The outcome of the 3-stage process and its effectiveness in manipulating the shape and size of the crystals are related to both operating variables and system parameters, namely the growth and dissolution rate ratios. Simulations allowed determining generally valid compound-dependent features which relate the type of attainable region to the magnitude of the aforementioned ratios. The observation resulting from the in-silico work is demonstrated by running an experimental campaign.

Highlights

- Crystal nucleation and growth of NaCl in membrane-assisted crystallization were investigated
- PVDF with graphene speeded up crystal nucleation *in comparison to.* pristine PVDF

1. Introduction

Membrane-assisted crystallization is an emerging membrane process with the capability to extract simultaneously fresh water and valuable components from various streams: crystal nucleation and growth are carried out in a well-controlled pathway by using a porous hydrophobic membrane. Successful application of crystallization for produced water treatment, seawater desalination and salt recovery has been demonstrated [1–2]. Nano-composite membranes enriched with two-dimensional (2D) materials are becoming promising in membrane technology because they can assist mass transfer through membranes under specific conditions [3]. The understanding of crystal nucleation is far from complete [4]. This is because the molecular details of the process appear in a very small length scale of the order of nanometers, and they are, by definition, unstable and therefore form only transiently, so they are quite challenging to probe even in real time. However, today, with state-of-the-art measurements, nucleation has also been observed at the molecular scale [5]. Computational modelling and in particular molecular dynamics (MD) provide exciting insights into the mechanisms of such phenomena and enable kinetic and thermodynamic quantities to be estimated [6]. Here, we present the results from molecular dynamics simulations of the crystal nucleation and growth of a sodium chloride solution in contact with hydrophobic polymer surfaces of polyvinylidene fluoride (PVDF) containing also graphene at 5% wt and at 10% wt. In parallel, membrane crystallization experiments were performed utilizing the same kind of polymeric membranes in order to compare the experimental findings with the computational data.

2. Methods

Unbiased molecular dynamics simulations using all atom were performed for the investigation of the feasibility of growing NaCl crystals. The initial amorphous PVDF model (density of 1.9 g/cc) was constructed using the amorphous cell module in the commercial software, Material Studio package (version 7.0) of BIOVIA Dassault Systemes [7] and the COMPASS force field [8]. All MD simulations were then performed using the GROMACS software package, version 5.1.4 [9]. After equilibration, production runs of 200 ns were carried out.

3. Results and discussion

Crystals obtained from crystallization experiments and simulations showed the characteristic cubic block-like form in accordance with the expected geometry of the NaCl crystals.

Lower nucleation time and crystal growth rate were observed for PVDF with Graphene at 5% and 10% wt systems in comparison with the pristine PVDF indicating that the aggregation of Na^+ and Cl^- in crystals was faster for membrane systems containing Graphene that native PVDF (Figure 1).

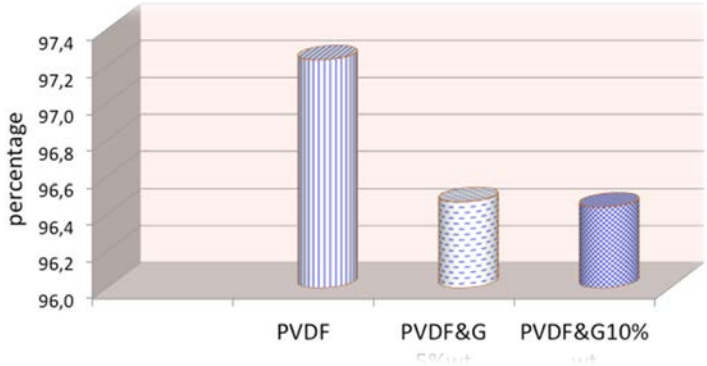

Figure 1. Percentages of ion in crystals after 200 ns of simulations.

4. Conclusions

Both experimental tests and MD simulations demonstrate that the chemical composition of the membrane surface affect the crystallization of salts in nucleation grow rate, crystal size and shape: the nanomaterials influence kinetics of crystal formation, reducing the nucleation times.

Highlights

- An *in silico* tool was developed for a pharmaceutical crystallization process.
- Developed tool was used for process risk assessment.
- A comprehensive uncertainty and sensitivity analyses were performed to explore operation design space.

1. Introduction

Crystallization is still predominant separation and purification method during the recovery of solids from solutions especially in pharmaceutical industries [1]. The operating condition of a crystallization process is of critical importance because properties of a crystal product such as purity, size, shape distribution and polymorphic form depend strongly on the condition under which the crystallizer is operated [2, 3]. Moreover, these product properties affect the performance of the following downstream operations such as filtration and drying, and eventually efficacy of the product formulation. Traditionally, crystallization processes have been operated recipe-based in the pharmaceutical manufacture and the quality of the product has been determined by testing at the end of the process. Quality-by-testing (QbT) has often resulted in failed batches, which in return led to loss of profit, while the pressure of producing faster, cheaper and more efficiently has been increasing day by day [2, 4]. Process systems engineering methods and tools possess significant advantages over traditional methods; improving process understanding, speeding up process development and providing better control over process variables. Additionally, the FDA has promoted the usage of quality-by-design (QbD) approaches, integration of process analytical technology (PAT) tools into the process design and manufacturing as well as identification of uncertainties and quantification of process risk assessment [5, 6]. Therefore, the objective of this work is to develop an *in silico* tool for a pharmaceutical crystallization process to support design, optimization, control and uncertainty/sensitivity analysis for process risk assessment. The developed tool was used to explore an operational design space in order to guide the design using comprehensive sensitivity and uncertainty analysis. Additionally, we performed experiments to verify predicted results.

2. Methods

An *in silico* tool was developed for a batch cooling crystallization system. Crystallization of paracetamol from ethanol was chosen as a case study. The solubility and crystallization kinetic data

of the mentioned solute-solvent system were taken from the literature [7, 8]. Related mass, energy and population balance equations are implemented and solved in MATLAB/Simulink environment. Several sources of uncertainties in process are identified and the effect of uncertain process parameters on the process output variability are quantified through uncertainty analysis. Sensitivity analysis is performed to investigate the design space of initial concentration, seed specification (mass, mean, sigma), cooling time and cooling profile. Additionally, experimental data are used to verify model predictions in terms of solute concentration and final crystal size distribution.

3. Results and discussion

A risk based approach requires understanding of how process factors affect the quality and performance of the product/process, which process variabilities have critical importance to achieve consistent product within desired quality requirements and therefore to quantify the risk of producing poor quality product. To this end, several uncertainties in the crystallization design space were identified. Using the developed tool, a study on the quantification of process risks was performed. The effect of the initial concentration, seed specification, cooling time and cooling profile on the process output in terms of process yield and nucleation was investigated though sensitivity analysis. Simulation results showed that cooling time, seed mass and cooling rate were the most significant factors that affected strongly the product yield and nucleation. Therefore, more effort should be given to optimize these parameters to get higher yield and avoid nucleation. Additionally, after performing experiments to compare simulation outcomes, we observed that model predictions were in good agreement with the experimental data.

4. Conclusions

In this study, we presented an *in silico* tool for a pharmaceutical crystallization process. We used uncertainty and sensitivity analysis to identify process variables and to quantify their effect on the process outcome for process risk assessment. As a case study, an application on the exploration of the operational design space was shown. We compared also experimental data with model predictions. In conclusion, *in silico* tools provide an effective and cost-efficient platform to develop processes, investigate design spaces, to explore feasibility of different operation and control strategies and to quantify the process risks. Pharmaceutical industries can benefit from model based approaches through reduction of process failures, consistent batch-to-batch products and gaining acceleration to compete with challenging market driving forces.

PET Recycling – Contributions Of Crystallization to Sustainability.

Claudia Pudack[1], Manfred Stepanski[1]

1 Sulzer Chemtech Ltd, Neuwiesenstrasse 15, 8401 Winterthur, Switzerland

**Corresponding author: Claudia.Pudack@sulzer.com*

Highlights

- Chemical PET recycling allows to upcycle all types of waste PET plastic.
- The de-polymerization process breaks down the waste PET into its monomers, MEG and DMT.
- The monomers can be purified and re-polymerized into high purity, food-grade PET.
- Solvent-free melt crystallization of DMT removes all coloring and critical impurities.

1. Introduction

Polyethylene terephthalate (PET) is the most common thermoplastic polymer of the polyester family. It is a naturally transparent and semi-crystalline plastic widely used as a fiber for clothing, as an effective moisture barrier with wide applicability in bottling and packaging, and as an engineering plastic when it is combined with other materials. Some of the most important characteristics of PET include its resistance to water, its high strength to weight ratio, and its wide availability as an economic and recyclable plastic. PET was first polymerized in the 1940s by DuPont chemists looking to develop polymer materials for use as textile fibers. It is produced from the synthesis of mono ethylene glycol (MEG) and dimethyl terephthalate (DMT) or purified terephthalic acid (PTA). The former is a transesterification reaction that produces methanol as a by-product, whereas the latter is an esterification reaction that releases water.

Once the polymer is formed, it is very difficult to purify and for this reason, the purity of the starting materials is of high importance. Vacuum distillation processes are used to purify ethylene glycol, whilst DMT and terephthalic acid are conventionally purified by suspension crystallization. For DMT, the suspension crystallization plant and associated solvent recovery section typically account for 45% of the total investment costs [1]. Therefore, an improved DMT process has been developed, which replaces the suspension crystallization with solvent-free melt crystallization technology. This reduces both, investment and operating costs, and improves the operability and flexibility of the process. The resulting high-purity DMT has an excellent quality and color stability and is suitable for the manufacture of high molecular weight PET.

According to some reports, the current global polyester production is around 56 million tons, mainly for synthetic fibers (more than 60%). However, the demand for PET in the bottling and packaging industry, particularly for food and beverages, is growing and already accounts for roughly 30% [2]. In general, polymers are increasingly used in a variety of applications and have become a major concern in the marine environment because of their persistence at sea. Scientists estimate that more than eight million tons of plastic are being washed into the oceans every year [3]. Moreover,

the cumulative quantity of plastic waste available to enter the ocean from land is predicted to increase even further. Finding solutions for the plastic debris problem is complex and requires a combination of recycling, closing the source and cleaning up what has already accumulated in the oceans. The current study will focus on the recycling routes of PET, with special emphasis on the chemical recycling of PET bottles by means of methanolysis.

This chemical recycling process degrades PET into two main reaction products, DMT and MEG, the starting materials for the transesterification process. The main advantage of this method is that the methanolysis can be installed in the existing polymer production line, since the DMT obtained has a product quality identical to virgin DMT [4]. In addition, MEG and methanol can be easily recovered and recycled. Moreover, purification of the DMT by melt crystallization will reliably remove critical impurities (e.g., water, glycols, alcohols and phthalate derivatives) that will have a negative impact on its conversion rate to PTA.

Highlights

- Chiral Separation at the eutectic using serial crystallization works resulting in high enantiopurity
- In situ monitoring of the enantiomeric excess with Raman is possible.

1. Introduction

As the majority of new pharmaceutical substances are chiral, pharmaceutical industry seeks access to a broad range of chiral resolution methods to separate enantiomers of such chiral compounds. While new resolution methods such as attrition enhanced deracemization are developed, preferential crystallization (PC) has been proven to be an efficient and selective method to separate enantiomers in a conglomerate system. Interestingly, if the crystallization feed is sufficiently enriched using another separation technology, PC of the preferred enantiomer can also be applied to racemic compound forming systems [1]. Here we present a simple PC process to efficiently and robustly produce enantiopure crystals, starting with a suspension of both enantiopure and racemic compound crystals in a solution of eutectic composition.

2. Methods

In the feed vessel, an enriched suspension with both racemic and enantiopure mandelic acid crystals in water was equilibrated at temperature T_1 so that the feed solution composition was equal to that of the eutectic point at the same temperature (Figure 1). A filtered solution was continuously pumped from the feed vessel into the first crystallizer (racemic compound DL crystallizer) and from that into the second crystallizer (enantiopure product D crystallizer), continuing as a recycle for the feed vessel. The crystallizer suspensions were held at a slightly lower temperature $T_2<T_1$ and were monitored by in situ Raman spectroscopy. The crystallizers initially contain solution at the eutectic composition and respectively racemic and enantiopure seed crystals.

3. Results and discussion

Due to the small temperature difference between feed flow and crystallizer suspension a small supersaturation is created which induces the seed crystals to grow while preventing nucleation. Therefore, DL-Mandelic acid is crystallized in the first DL crystallizer while D-Mandelic acid is

crystallized in the second D crystallizer increasing suspension densities in both crystallizers. The differences in the pure D- and DL-mandelic acid solid Raman spectra allow to monitor in situ the solid composition while the intensity changes of these differences allow to estimate their suspension density changes. This thus enables detection of contamination of the undesired DL mandelic acid in the D crystallizer due to primary nucleation events.

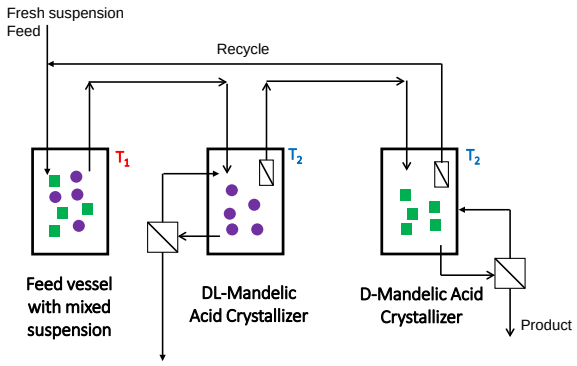

Figure 1. Sequential Cascade Crystallizer set up for the separation of conglomerate and racemic compound forming systems at eutectic composition.

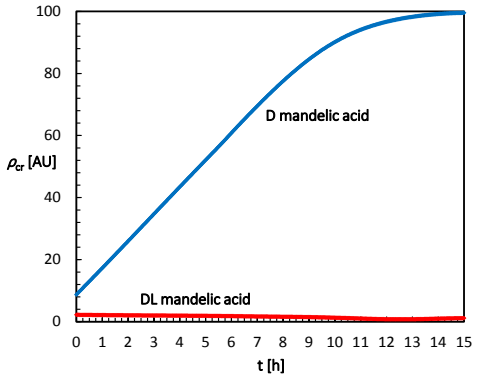

Figure 2. Estimated suspension densities ρ_{cr}(D) and ρ_{cr}(DL) (in arbitrary units) of D and DL mandelic acid in the D-Mandelic acid crystallizer during the separation process determined from in situ Raman spectroscopy.

Typical results in figure 2 show an increase in the suspension density of D-Mandelic acid (blue line figure 2). The presence of DL-mandelic acid crystals was not detected in the D crystallizer throughout the entire experiment (red line figure 2) indicating that the supersaturation towards this compound in the D acid crystallizer was sufficiently lowered by the crystallization of DL-Mandelic acid in the DL crystallizer. Eventually, nucleation of D-Mandelic acid in the DL crystallizer occurred and the D concentration in the Feed to the D crystallizer decreased, lowering the increase of the D-Mandelic acid suspension density in the D crystallizer.

4. Conclusions

The sequential crystallization of DL- and D-Mandelic acid allows for a robust process that results in a fast and stable chiral separation of mandelic acid at the eutectic. In addition, we show that Raman spectroscopy can be used to monitor the purity and suspension densities of the desired and undesired products. This process will also be applied to conglomerate forming systems with and without racemizing agents.

Highlights

- Precipitation processes to separate lithium as carbonate were investigated
- Temperature and mixing intensity affected mainly precipitation
- lithium will be a key element for modern electric vehicles and devices
- Efficient recovery of lithium from secondary materials will be crucial in future

1. Introduction

The demand of lithium is expected to increase significantly within next ten years mainly due to the need to increase battery production capacities for electric vehicles. It is reported that batteries consume 39 % of total lithium [1]. This is because lithium is the lightest metal and the most energy dense of battery materials [2]. It is essential to recover and recycle lithium more efficiently from different sources to avoid the shortage of this critical metal. Xu et al [3] investigated the usage of saline lake waters as feedstock for lithium recovery. The review published by Swain [4] introduced the lithium recovery processes from brines. In our previous work, Han et al. [5], we investigated the recovery of lithium carbonate by precipitation from aqueous multicomponent solution simulating battery waste leachate. Precipitation results of lithium carbonate (Li_2CO_3) via homogeneous reactions with sodium carbonate as the reactant are reported by [5-7]. A few studies [8, 9] reported the application of CO_2 to precipitate Li_2CO_3. However, there has not been a study to compare the homogeneous reaction and heterogeneous reaction for the Li_2CO_3 precipitation. The aim of the present work was to compare precipitation and reaction kinetics of lithium with reactant of Na_2CO_3 solution and reactant CO_2 gas in alkaline solution at various operational conditions in terms of residence time, mixing intensity and precipitation temperature.

2. Methods

In the present work semi-batch precipitation of lithium carbonate was investigated by homogeneous and heterogeneous reactions in a stirred jacketed crystallizer. For homogeneous reaction study, sodium carbonate was used as the reactant. Na_2CO_3 solution was pumped to Li_2SO_4 solution to precipitate Li_2CO_3. In heterogeneous reaction study, CO_2 gas was used as a carbonate source to feed into the Li_2SO_4 solution to precipitate Li_2CO_3. NaOH solution was added to adjust the solution pH at the beginning. Different variables including temperature, stirring rate and feeding rate (residence time) were studied. Conductivity and pH was monitored with a Consort Multi-parameter analyzer (C3050). A thermostat (Lauda ECO RE630) with an external temperature sensor that immersed into the solution was used to control the temperature of the solution. An inline probe (Particle track G400, Mettler Toledo) was placed into the reactor and used to monitor the whole precipitation process in order to obtain kinetics data. After precipitation, the solid sample was separated by vacuum filtration with a Büchner funnel. The crystals were characterized by X-ray powder diffraction (XRD, X'Pert PRO), and Raman spectroscopy (PicoRaman, Timegate Instrument

Oy) to determine crystal composition and crystal morphology. The crystal yield was determined with the mass of precipitates.

3. Results and discussion

Generally, high temperature can accelerate reaction, and enhance the nucleation and crystal growth. Figure 1 shows conductivity and pH changes in heterogeneous reaction with temperature of 25 and 50 °C. It can be clearly seen that the pH reduced slightly at the beginning, then dropped suddenly at some point, and kept decreasing gently for both temperatures. The conductivity reduced gently for a certain period and then kept constant at the end for both cases. The clear differences within two studied temperatures can be found: residence time is shorter at higher temperature. This means that the chemical reactions and precipitation are faster at higher temperature. The crystal yield obtained from precipitation process at 50 °C was even doubled at higher temperature. Another reason is also due to the lower solubility of Li_2CO_3 at higher temperature [10]. Stirring rate enhanced the reaction, which can accelerate the occurrence of precipitation.

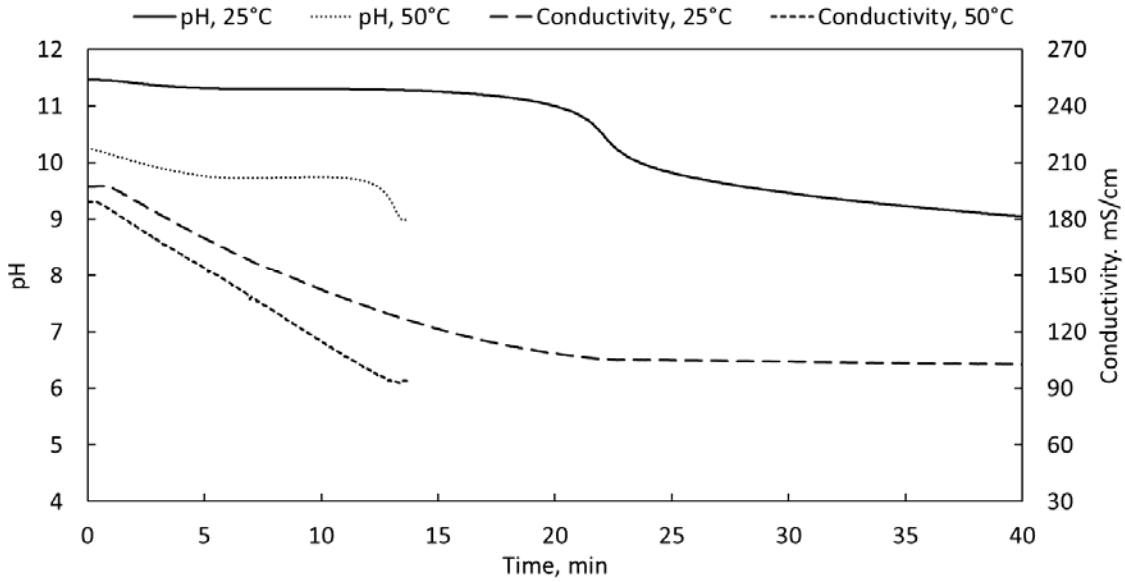

Figure 1. Trends of pH and conductivity changes at 25 and 50 °C in heterogeneous reaction.

4. Conclusions

The precipitation of Lithium carbonate from homogeneous and heterogeneous reactions were compared. Higher crystal yield can be obtained at higher temperature. Precipitation was enhanced by the increase of stirring rate.

Reactive crystallization of dolomite by CO_2 fine bubble injection from concentrated brine and conversion to inorganic phosphor

Taichi Kimura[1], Yoshinari Wada[1], Shinnosuke Kamei[1], Koji Masaoka[1, 2], Toshihiko Hiaki[1], Masakazu Matsumoto[1*]

1 College of Industrial Technology, Nihon University, 1-2-1 Izumi-cho Narashino, Japan;
2 Research Institute of Salt and Sea Water Science, The salt Industry Center, 4-13-20 Sakawa, Odawara, Japan

Highlights

- Minimizing bubble size increased produced weight and Mg/Ca ratio of $CaMg(CO_3)_2$.
- Mg/Ca ratio of $CaMg(CO_3)_2$ increased with an increase in crystallization time.
- Emission intensity of $CaMg(CO_3)_2$ phosphor increased with increasing the immerse time.

1. Introduction During the salt manufacturing process in Japan, NaCl is manufactured by evaporative crystallization after concentrating seawater through electric dialysis membranes, and the concentrated brine which contains ions such as K^+, Ca^{2+} and Mg^{2+} with high concentration is discharged. To build a utilization system for seawater resources based on the salt production process, a recovery and upgrading method for Ca^{2+} and Mg^{2+} from the concentrated brine is demanded. From the viewpoint of solubility of salts, the synthesis of carbonate by reactive crystallization between the dissolved Ca^{2+} and Mg^{2+} in the concentrated brine and CO_2 can be considered an effective separation/recovery method, as the solubility of carbonate of Ca^{2+} and Mg^{2+} is lower than the solubility of hydroxide in the solution at a pH range below 8.0. In particular, dolomite ($CaMg(CO_3)_2$), which is the double salt derived from the structure of calcite by the ordered replacement of Ca^{2+} and Mg^{2+}, is used in various industrial fields. To improve the functionality of $CaMg(CO_3)$, it is essential to gain access to the Mg/Ca ratio of 1.0. Generally, high concentrations of Ca^{2+}, Mg^{2+} and CO_3^{2-} are necessary for synthesis of $CaMg(CO_3)_2$ with a high Mg/Ca ratio [1]. In this study, the fine bubble formation technique that enables the generation of regions with a higher ion concentration near the gas-liquid interfaces was applied to the reactive crystallization of $CaMg(CO_3)_2$ from the concentrated brine. Furthermore, $CaMg(CO_3)_2$ with a high Mg/Ca ratio can be converted to phosphor which is superior to emission intensity and quantum efficiency, because Mg^{2+} ions in crystal structure of $CaMg(CO_3)_2$ are arrayed more regularly than solid solution. In this paper, we report the effects of CO_2 fine bubble injection on the produced weight of $CaMg(CO_3)_2$ ($W_{dolomite}$) and the Mg/Ca ratio during reactive crystallization of $CaMg(CO_3)_2$ from concentrated brine, and the effects of immerse time on emission intensity of phosphor converted from the obtained $CaMg(CO_3)_2$.

2. Experimental

2.1 Reactive crystallization of $CaMg(CO_3)_2$ from the concentrated brine by fine bubble injection

The concentrated brine that is removed K^+ by cooling crystallization of KCl after NaCl production in salt manufacturing process was used. The major components of the concentrated brine are $MgCl_2$, NaCl and $CaCl_2$ which have the concentrations of 2.1, 0.8 and 0.7 mol/L, respectively. Fine bubbles with an average bubble diameter (d_{bbl}) of 40 µm were generated using a self-supporting bubble generator by shear of impeller and a negative pressure owing to high-rotation, with the rotation rate maintained at 1500 min^{-1} and the CO_2 flow rate controlled at 11.9 mmol/(L·min). For comparison, the bubbles with d_{bbl} of 2000 µm were obtained using a dispersing-type generator. At 298 K, CO_2 bubbles were continuously supplied to 300 mL of concentrated brine, and $CaMg(CO_3)_2$ was crystallized within a crystallization time (t_c) of 60 min. The solution pH during crystallization was maintained constant at 6.8 by adding 8.0 mol/L-NaOH aqueous solution. The Mg/Ca ratio of $CaMg(CO_3)_2$ was estimated from the amount of peak shift from calcite $CaCO_3$ to $CaMg(CO_3)_2$ [2].

2.2 Conversion to phosphor from the $CaMg(CO_3)_2$ obtained by CO_2 fine bubble injection

10.0 g/L of the obtained $CaMg(CO_3)_2$ at t_c of 60 min were immersed into mixed solution of 0.1 mol/L $TbCl_3$ and 0.1 mol/L $CeCl_3$ at 298 K. The immerse time (t_i) is controlled in the range of 0 – 24 h. Fluorescence spectra of the $CaMg(CO_3)_2$ phosphor were measured by fluorescence spectrometer.

3. Results and discussion

3.1 Effects of CO_2 fine bubble formation on the reactive crystallization of $CaMg(CO_3)_2$

The reactive crystallization of $CaMg(CO_3)_2$ from the concentrated brine was performed at d_{bbl} of 40 or 2000 µm. $W_{dolomite}$ and the Mg/Ca ratio at d_{bbl} of 40 µm was obviously higher than the 2000 µm at all values of t_c, and the Mg/Ca ratio at d_{bbl} of 40 µm reached 0.86 with 60 min crystallization. The results indicate that generation high concentration of Ca^{2+}, Mg^{2+} and CO_3^{2-} probably because of the acceleration of CO_2 absorption and the electrification of the fine bubble surface caused by minimization of the bubble diameter.

3.2 Conversion to phosphor from obtained $CaMg(CO_3)_2$

The obtained $CaMg(CO_3)_2$ with a Mg/Ca ratio of 0.86 crystallized by fine bubble injection at d_{bbl} of 40 µm was converted to phosphor. The fluorescence spectra of the $CaMg(CO_2)_3$ phosphor are shown in **Figure 1**. Under light irradiation at wavelength of 254 nm, the green emission was observed in visual at all t_i values and the emission peak intensities at 489, 544, 548 and 621 nm increased with an increase in t_i. This is caused that the replacement of Mg^{2+} in $CaMg(CO_3)_2$ to Tb^{3+} acting as an emission center and Ce^{3+} acting as a sensitizer proceeded with increasing t_i.

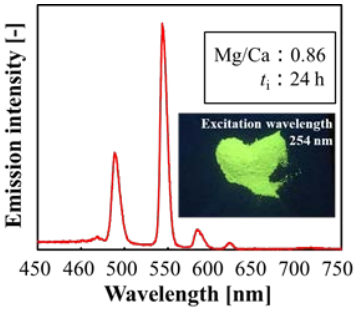

Figure 1. Fluorescence spectra of phosphor

4. Conclusions Using the CO_2 bubbles with different d_{bbl} values, the reactive crystallization of $CaMg(CO_3)_2$ from the concentrated brine was carried out. The results indicate that the minimization of d_{bbl} led to the increase in $W_{dolomite}$ and Mg/Ca ratio. Additionally, when the obtained $CaMg(CO_3)_2$ with Mg/Ca ratio of 0.86 converted to phosphor by immersing into 0.1 mol/L $TbCl_3$ and $CeCl_3$ solution, the emission intensity of $CaMg(CO_3)_2$ phosphor increased with increasing t_i.

Highlights

- Separation of stereoisomers by crystallization.
- SLE for two selected solid solution forming systems.
- Crystallization kinetics for the two systems.

1. Introduction

A significant number of the drugs currently in use contain chiral substances as active pharmaceutical ingredients (API). Therefore, a considerable interest has arisen in pharmaceutical companies in chiral separations in order to eliminate the unwanted isomer. The most frequently used method for chiral separations is the so-called classical resolution method, which involves formation of diastereoisomeric salts. The diastereoisomers are then separated by conventional crystallization. The efficiency of the operation is determined by the solid phase behavior of chiral systems. The separation is the most challenging when solid solutions are formed, which occurs for components with miscibility in the solid phase.[1]

2. Methods

Two different model systems were analysed, which consisted of pharmaceutically active stereoisomers that showed miscibility in the solid phase: System I, which was a mixture of diastereoisomeric salts of citalopram with (+)-O,O'-di-p-toluoyl-D-tartaric acid, ((+)DTT)), and System II, which was a mixture of stereoisomeric salts of nafronyl with oxalic acid. The nafronyl molecule possesses two stereogenic centers.

3. Results and discussion

The solid-liquid equilibrium (SLE) data acquired for System I are presented in Fig. 1A. It is evident that the solubility of S-citalopram·(+)DTT is higher compared to R-citalopram·(+)DTT, therefore, the former can be enriched in the mother liquor. The SLE data indicate the formation of solid solutions in the crystalline phase. The equilibrium relationship for the mixture of nafronyl oxalate stereoisomers in System II is much more complex (Fig. 1B), particularly in case of the dependency $x^{L}_{eq,1,3} = f_p(x^{S}_{2,4})$, for which the equilibrium curve consists of the upward and downward sloping parts. The composition region, in which the same liquid concentration can be matched with more than one equilibrium concentration in the solid phase indicates the possibility of establishing multiple equilibrium states.[2]

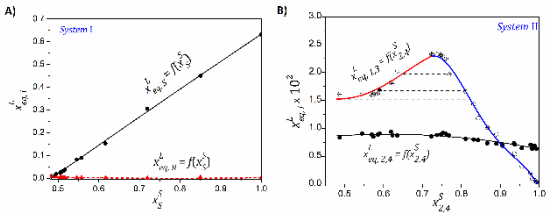

Figure 1. Characterization of SLE for *System* I (A), *System* II (B). Symbols – exp. data, lines - polynomial approx.

This phenomenon can be most probably attributed to polymorphic behaviour of one component showing also miscibility at the solid state.

The crystallization kinetics for System I were measured for different compositions diastereoisomeric mixtures of S- and R-citalopram·(+)DTT. The experiments were performed for the seeded and unseeded solutions. From Fig. 2. A it can be observed that the process can be accelerated by seeding the solutions. In case of the seeded crystallization, the concentration drop in the mother liquor is almost instantaneous, while it is delayed for the unseeded one. This indicates that nucleation is the rate limiting step of the operation.

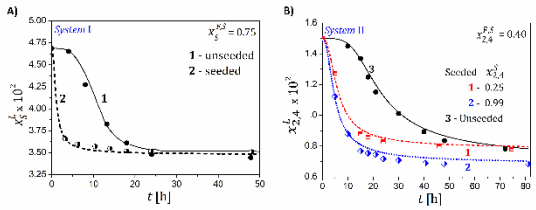

Figure 2. Course of the crystallization for seeded and unseeded solutions in: A) *System* I, B) *System* II [3]

The crystallization kinetics for System II were measured for the mixtures of two racemates 2,4 and 1,3. To determine the impact of seeding on both the process kinetics and the phase behavior, the seeded and unseeded crystallizations were performed in parallel for solid mixtures with the feed composition in the range corresponding to the occurrence of dual equilibrium states (hatched area in Fig. 1B). The seeded crystallization was markedly faster than the unseeded one (Fig. 2B), and the composition of seeds determined the course of the process and the equilibrium state (curves 1,2,3 in Fig. 2B), therefore, the course of the crystallization and the occurrence of the desired state could be imposed by addition of seeds with appropriate composition. When no seeds were added, the equilibrium states corresponding to the left-hand side or right hand-side of the equilibrium curve for racemate 1,3 (Fig. 1B) were established randomly (Fig. 2B). This behavior could be attributed to the co-existence of different polymorphs, which both formed solid solutions but with different solid phase compositions.

To describe the crystallization kinetics, a mathematical model was developed based on the moment method. The model accounted for cooperative nucleation and crystal growth in the solid solution forming system. The model was efficient in reproducing the kinetic profiles in the seeded as well as unseeded crystallization in both systems. Typical results of the model simulations are compared to the experimental data in Fig. 2.

4. Conclusions

Both Systems I and II differed in phase behavior; in the former the target compound was enriched in the mother liquor, whereas in the latter one in the crystalline phase. In System I the equilibrium states were established reproducibly regardless of the composition of the mixture, whereas in System II multiple equilibrium states were established, which most probably was caused by the formation of polymorphs. The mathematical model developed can potentially be used for description of crystallization kinetics in other solid solution forming systems.

Bulk Density Control in the Cooling Crystallization of L-Methionine with pH Control

Wang-Soo Kim, Kee-Kahb Koo

Department of Chemical and Biomolecular Engineering, Sogang University, Seoul 04107, Korea

**Corresponding author: koo@sogang.ac.kr*

Highlights

- Explosive primary nucleation of L-methionine (L-Met) was induced by pH control.
- Agglomeration was observed with particle counts measured by FBRM.
- Larger and thicker L-Met agglomerates with high bulk density could be obtained by cooling L-methionine slurry made by pH increase.

1. Introduction

L-Methionine (L-Met), which is one of hydrophobic amino acids, has been used for a dietary source due to the role as a donor of an active methyl group [1]. Generally, it is difficult to obtain single crystals of L-Met due to strong tendency for agglomeration and final L-Met agglomerates obtained by cooling from aqueous solution has very low bulk density due to their hollow structures [2]. In the present work, to improve the bulk density, L-Met was crystallized by pH increase with one-pot injection of an electrolyte aqueous solution into saturated acidic solution of L-Met and then large-sized agglomerates with high bulk density could be obtained by slow cooling the suspension made by the one-pot injection.

2. Methods

L-Met was crystallized with pH increase of acidic L-Met solution (saturated state of 60 °C from 300 g water with addition of 2 wt % sulfuric acid) by the injection of sodium acetate aqueous solution (1 mole dissolved in 20 g water). After the injection was completed, the slurry was stirred for about 2 h to agglomerate L-Met crystals and then cooled to 30 °C with a slow cooling rate of -6 °C/h. During crystallization by pH increase, particle counts were in-situ monitored by focused beam reflectance measurement (FBRM) and hydrogen ion concentration was observed with real time by measuring pH values using the relation, $pH = -\log[H^+]$. Size and morphology of L-Met agglomerates were confirmed by images of scanning electron microscopy (SEM).

3. Results and discussion

Figure 1 shows the history of particle counts and pH values when sodium acetate aqueous solution was injected with one-pot using a syringe. As soon as the injection was carried out, the pH increased instantaneously from 2.6 to 4.0 and particle counts were observed to drastically rise. Thereafter, the pH remained constant, but the particle counts began to decrease monotonically. This result indicates that the great number of tiny L-Met crystals generated by explosive primary nucleation tend to agglomerate continuously. The total number of particle counts measured by FBRM (Figure 1a) is the sum of the number of chord length (Figure 1b; the range of 1 – 1000 μm) that is the

distance of laser light from FBRM probe traveling over each particle surface [3]. When the suspension in which agglomeration occurs is monitored by FBRM, particle counts are generally decreased due to high possibility of measuring the largest chords of agglomerates. Therefore, it can be expected that the decreases in both particle counts and chord length distribution area are caused by agglomeration.

Figures 2a and 2b show that L-Met agglomerates obtained by pH increase were found to be denser and thicker than those by just cooling. As shown in Figure 2c, much larger and denser L-Met agglomerates was found to be obtained with crystallization by pH increase followed by the cooling process. It can be concluded that supersaturation generated by cooling was predominantly consumed to enlarge L-Met agglomerates.

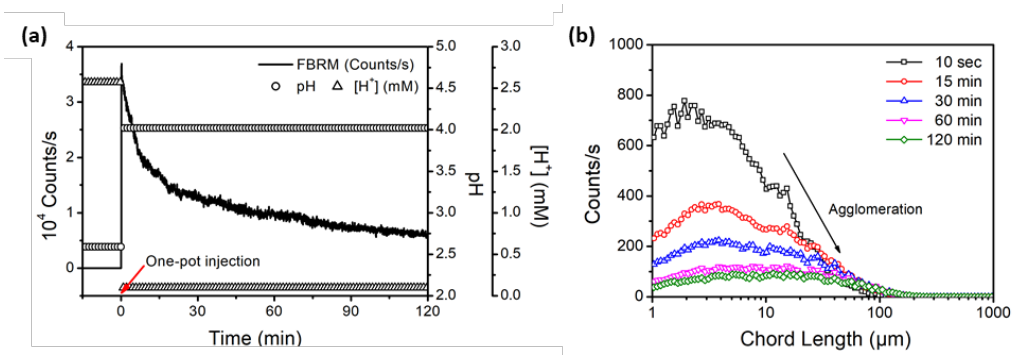

Figure 1. (a) Total counts and pH values in case of one-pot injection, (b) chord length distribution varying with time.

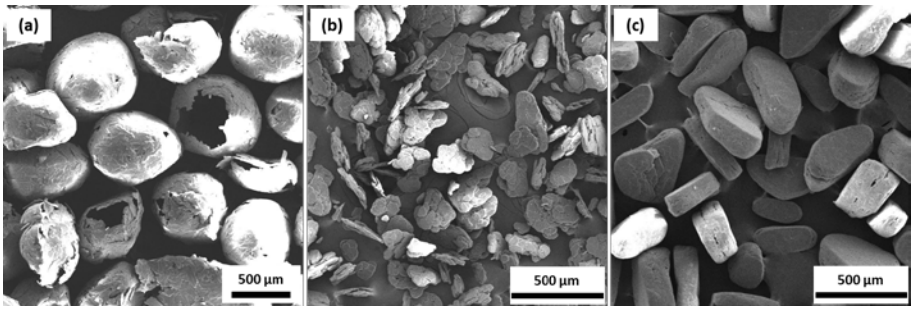

Figure 2. SEM images of L-Met agglomerates obtained by (a) cooling from 60 to 30 °C, (b) pH increase from 2.6 to 4.0, (c) pH increase followed by cooling.

4. Conclusions

Explosive nucleation was generated by instantaneous pH increase, resulting in production of L-Met agglomerates with the bulk density of 500 g/L. Furthermore, as a result of additional cooling, large and dense agglomerates with 760 g/L could be successfully obtained. On the other hand, the bulk density of L-Met agglomerates with the hollow structure obtained from just cooling was 200 g/L.

Multiphase CFD Simulation of Small-Scale Crystallization Reactors

Ramona Achermann[1], Pawel M. Orlewski[1], Marco Mazzotti[1*]

1 ETH Zurich, Institute of Process Engineering, Sonneggstrasse 3, CH-8092 Zurich, Switzerland;

**Corresponding author: marco.mazzotti@ipe.mavt.ethz.ch*

Highlights

- Multiphase CFD simulation of small-scale crystallization reactors
- Qualitative and quantitative information on flow and mixing behavior
- Better design of high-throughput crystallization experiments

1. Introduction

Crystallization is a widely used purification step in the fine chemical and the pharmaceutical industry. Reducing the reactor volume to study crystallization processes is especially beneficial at an early stage of research since it saves valuable compounds, reduces costs and allows for high-throughput screening[1]. Thus, in recent years small-scale crystallization reactors have gained increasing popularity within the crystallization community[1,2]. However, compared to large-scale crystallizers, different hydrodynamic properties of these miniaturized reactors have not yet been thoroughly studied. Therefore, to close the gap, by performing a multi-phase modelling using CFD (Computational Fluid Dynamics), a better understanding of the effect of operating conditions on the flow properties in such small reactors could be obtained. In this work, two commercially available micro reactors using different stirrers, namely the overhead stirrer and the stirrer bar, have been modelled with and without the addition of solid particles. Knowing the hydrodynamics of such small stirred vials will improve the overall understanding of the occurring crystallization phenomena such as nucleation, growth or breakage since shear forces or mixing can have a significant influence on them[3,4].

2. Methods

The commercial CFD code ANSYS Fluent 18.2 was used to conduct the simulations. To model the turbulence, the Reynold's stress model (RSM) was applied and standard multiphase models were used to model the effects of solids on the flow field. An enhanced wall treatment model was added to better capture the behavior near the wall and the grid was refined until mesh-independent results were obtained. For both stirrers, a single reference frame (SRF) was used and the simulations were run at steady state.

3. Results and discussion

A complete qualitative and quantitative comparison of the two investigated stirrers was performed with and without solids for a wide range of operating conditions. This gave information on the

distributions in the reactor of the velocity, of the turbulent energy dissipation rate, as well as of the solids together with their exposure to shear forces and the homogeneity of the system. Figure 1 shows the velocity distribution for the two configurations investigated.

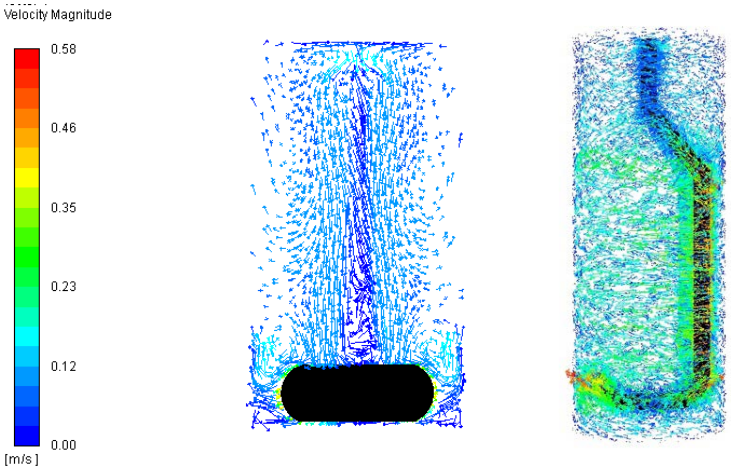

Figure 1. Comparison of the velocity distribution in the stirrer bar (left) and overhead stirrer (right).

4. Conclusions

In this work, the mixing and flow behavior of the overhead stirrer as well as the stirrer bar used in commercially available micro reactors were studied with and without solid addition using CFD modelling. Obtained results allowed for a better understanding of the hydrodynamics in the system and of their dependence on the operating conditions, which could then allow for an improved overall understanding of the phenomena occurring in the crystallization processes studied in those systems.

Crystallization fundamentals and industrial processes

High-throughput droplet-based platform for studying nucleation

Elena C. dos Santos, Giovanni M. Maggioni and Marco Mazzotti
Institute of Process Engineering, ETH Zurich, 8092 Zurich, Switzerland
edossantos@ipe.mavt.ethz.ch

Highlights

- Droplet-based microfluidics
- Stochasticity of primary nucleation
- Effect of shear rate on nucleation
- Nucleation rates estimation and uncertainty propagation.

1. Introduction

Nucleation, the very early stage of crystallization processes, is of fundamental importance on defining crystal properties such as purity, size distribution and polymorphism [1]. It is well established that nucleation is a stochastic phenomenon [2-3], which imposes challenges to obtaining reproducible experimental data. Thus, numerous identical experiments are essential to correctly estimating primary nucleation kinetics. In this context, droplet-based microfluidics offers, not only good control of transport phenomena (enhanced mass and heat transfer), little or no gravity effect, and few impurities, but also, the ability of generating thousands of nanodroplets in a nearly monodisperse fashion. Such a high-throughput technique enables to probe a considerable number of identical discrete crystallizers, necessary to build representative statistics. Nevertheless, the error committed by not sampling the entire population (finite sampling) will invariably exist. The magnitude of this stochastic uncertainty depends solely on the number of samples and on the chosen confidence interval. Such an uncertainty needs to be quantified, firstly, as a criterium for guaranteeing randomness of the process and secondly to be properly propagated to the parameters to be estimated, e.g., nucleation rate. The nucleation rate is the number of nuclei formed per unit time and volume at a given supersaturation. The latter can be regarded as the difference in chemical potential between the supersaturated and equilibrium states of the compound in solution, i.e., the driving force of the nucleation process. However recently, a few studies have discussed that shear promotes the aggregation of meso-scale clusters into stable clusters, so that nucleation proceeds via a two-step mechanism [4-5]. Despite the number of studies, the exact mechanism controlling nucleation under fluid dynamic conditions is still unclear.

2. Methods

We used PEEK T-junctions followed by translucent FEP tubes to study crystallization in droplets under flow conditions at different droplet velocities. The experimental set-up consists of three main parts. Firstly, in the generation zone (GZ), immiscible fluids were fed with syringe pumps into a PEEK T-junction, where droplets were formed. These components were placed inside a temperature-controlled incubator to maintain solutions at the desired dissolved state. After been formed, droplets flow to the crystallization zone (CZ), which consists of a certain length of FEP tube placed in a cold-water bath. Due to the supersaturation created by reducing the system temperature, a number of droplets crystallizes while travelling along the tube depending on the tube length, which

was varied in order to probe different nucleation residence times. Finally, droplets moved to the observation zone (OZ), where the FEP tube was placed under a light microscope, to monitor through image acquisition whether droplets have crystallized, thus enabling building nucleation statistics.

3. Results and discussion

For each single experiment, we have assessed its internal consistency via statistical analysis based on slicing the population of droplets, e.g., comprising of about 3000 droplets, in smaller subgroups. In Fig. 1, we show this procedure and plot both the experimental probability values as a function of the number of droplets, and the uncertainty band. The spread in probability values towards lower number of droplets shows repeatedly strong consistency, and hence, this variability is entirely due to stochasticity. In Fig. 2, values of nucleation rates estimated via the linearized form of the cumulative exponential distribution function are plotted with their corresponding confidence intervals obtained through the propagation of the uncertainties in nucleation probability. In this figure, we observe an increase in nucleation rate of about 3 orders of magnitude in respect to the stagnant situation. Such a high difference can be associated with the recirculation flow patterns, generated inside the droplets at flowing conditions. The latter may favor nucleation via aggregation of pre-clusters by enhancing particle collision, but at the same time may hinder nucleation by reducing contact and bridging time.

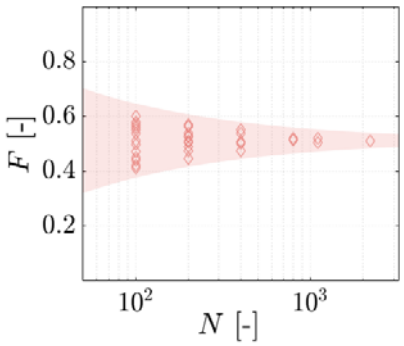

Figure 1. Probability points of single experiments sliced in smaller number of droplets.

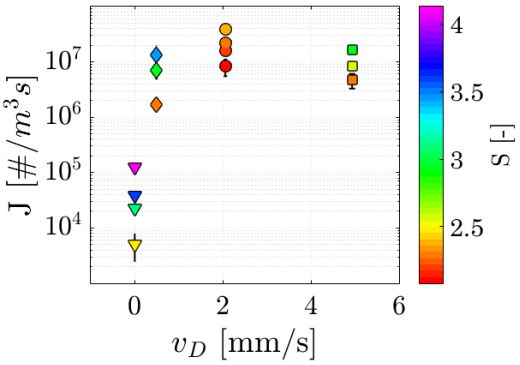

Figure 2. Probability points of single experiments sliced in smaller number of droplets.

4. Conclusions

We estimated primary nucleation kinetics from large number of nanodroplets in varying fluid dynamic conditions. Making use of statistical tools, we were able to assess the statistical representability of the experimental data and to estimate their inherent uncertainty. Finally, we showed that nucleation rates increase non-monotonically with droplet velocity, possibly because there exists an interplay among the effects of energy dissipation due to mixing on clusters' agglomeration.

Highlights

- Protein crystallization kinetics was determined using a modified SAXS technique.
- Results obtained were comparable to those measured in a seeded tank crystallizer.
- The modified SAXS setup can support development stage of bulk crystallization.

1. Introduction

Determination of the process kinetics and development of adequate kinetic rate equations for design of bulk crystallization is based on measurements of time-dependent concentration profiles. Typical experimental setups for acquisition of kinetic data consist of a small-volume tank, in which the supersaturated solution is stirred. Samples of the solution are collected at different time intervals and subjected to the concentration analysis. This procedure is laborious and consumes a large amount of often valuable protein solution. Therefore, in this work we propose another approach for the characterization of crystallization kinetics of proteins in situ, which is based on a modification of small-angle X-ray scattering (SAXS) technique. The kinetic data acquired in the SAXS setup were compared to those taken from a stirred-tank crystallizer (STC) setup, in which unseeded (uSTC) and seeded (sSTC) crystallization was analyzed [1].

2. Methods

The model protein for the study was lysozyme (LYZ), which was crystallized from supersaturated aqueous solutions of ammonium sulfate. The kinetic measurements were performed in SAXS, uSTC and sSTC for the supersaturated protein solutions with the same compositions.

In the SAXS system a small amount of the protein solution (1.5 mL) was forced to recirculate within the setup. The SAXS intensity curves were measured at different time intervals and converted into kinetic profiles using a calibration factor. The diffraction images of the sample taken at the end of the kinetic experiments were recorded to confirm the presence of the crystalline phase (Fig. 1).

In the STC setup the crystallization kinetics of LYZ was measured in a 10 mL tank. In the uSTC setup the protein solutions were stirred with a magnetic stirrer at 400 rpm. In the sSTC setup, the experiments were repeated under the same conditions, but the solutions were seeded with 1.6 mg of the seed crystals.

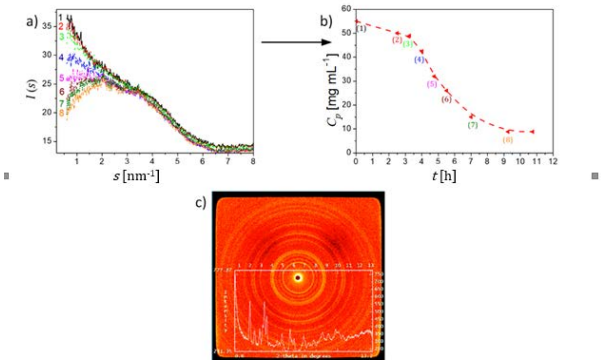

Figure 1. Course of the crystallization in SAXS. (a) Time evolution of the scattering intensity curves plotted against the modulus of the momentum transfer, *s*; (b) the corresponding kinetic curve; dashed line - guide to the eye; (c) typical diffraction image recorded at the end of the experiment

3. Results and discussion

The analysis of the experimental data indicated that the kinetic rate accelerates with increasing the supersaturation degree, and decelerates with increasing ammonium sulfate concentration (C_{salt}) in both systems (Figs 2a, 2b). The seeded crystallization is accomplished significantly faster than the unseeded one (Fig. 2a). Moreover, the hydrodynamic conditions in the SAXS setup could be adjusted for which a quantitative agreement between the kinetic data acquired from both systems was achieved (Fig. 2b).

To predict the time evolution of concentration profiles of the protein in the liquid phase and quantify the crystallization kinetics, a population balance model was used, which consisted of kinetic rate equations of nucleation and crystal growth [1]. The same kinetic equations could be used to describe the course of crystallization in both systems. The results of the measurements and numerical simulations were compared (Figs 2a, 2b).

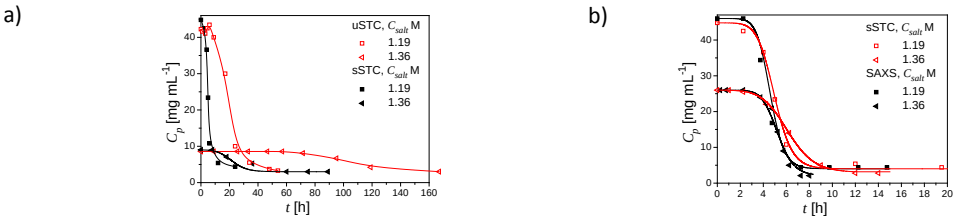

Figure 2. Comparison of the kinetic curves measured in the (a) sSTC and uSTC; (b) sSTC and SAXS setups

4. Conclusions

The modified SAXS setup can be applied to support kinetic measurements for bulk crystallization. The implementation of flow motion in the SAXS setup enhances the rate of crystallization kinetics and reduces the time of measurements. The method allows online monitoring the presence of the crystalline phase as well as acquiring kinetic profiles using very small volumes of valuable protein solutions.

Crystallization fundamentals and industrial processes

Determination of nucleation kinetics from metastable zone width and induction time data for sonocrystallization of pyrazinamide.

Abhishek Maharana[1], Debasis Sarkar[2]

[1,2] Dept of Chemical Engg, IIT Kharagpur, West Bengal, India

Highlights

- Nucleation kinetics is estimated from MSZW and induction time data.
- Sangwal's nucleation theory is used for estimating nucleation parameters.
- Induction time showed a sharp decrease with increase in ultrasound amplitude.

1. Introduction

Crystallization is an important separation and purification technique in many chemical and pharmaceutical industries. Most industries use simple batch crystallization for generating crystals of definite crystal size distribution (CSD) and purity. However, it is very difficult to control primary nucleation to obtain crystals of definite properties because it occurs in a thermodynamically unstable region [1]. Primary nucleation requires very high levels of supersaturation which brings difficulty in controlling the crystallization process. To overcome this situation sonocrystallization can be used. Cavitation induced during ultrasound can create high supersaturation even at a lower superstation ratio which can induce nucleation to achieve target CSD and create nuclei of desired polymorph [2]. MSZW denotes region between solubility curve and onset of nucleation. Information about MSZW helps in avoiding excessive nucleation, ensures required CSD and also helps in determining nucleation kinetics. Induction time is the measure of ability of a supersaturated solution to remain in state of metastability. It has been related to size of nuclei and thus it is important for evaluation of nucleation kinetics.

Pyrazinamide is an important API drug for treatment of *Mycobacterium tuberculosis.* The effect of continuous sonication with different amplitude on nucleation kinetics for cooling crystallization of pyrazinamide from its solution in acetone is studied. Nucleation parameters are calculated from metastable zone width (MSZW) and induction time experimental data. To the best our knowledge, a study on effect of continuous sonication on nucleation kinetics of pyrazinamide has not been reported in open literature.

2. Methods

Solubility of pyrazinamide in acetone is computed gravimetrically in the temperature range of 283.15 K to 323.15 K. A 500 ml jacketed crystallizer with a temperature controller having a precision of ±0.05 K is used. Probe sonicator is installed to introduce ultrasound of different amplitude. The ultrasound probe is dipped 1 cm from the solution surface. The onset of nucleation is observed by visual inspection. Polythermal method is used to determine MSZW and isothermal method is used to determine induction time. Next classical nucleation theory is used to estimate the nucleation rate:

$$J = A\exp\left[-\frac{B}{\ln S_{\max}^2}\right], \text{ where } B = \frac{16\pi}{3}\left(\frac{\gamma\Omega^{\frac{2}{3}}}{T_{nuc}k_B}\right)$$

3. Results and discussion

Figure 1 represents MSZW in presence and absence of ultrasound. It is evident from the figure that in presence of ultrasound, the MSZW decreases significantly. The Sangwal's classical three dimensional nucleation theory approach is used for estimation of nucleation parameters as follows:

$$\left(\frac{T_0}{\Delta T_{\max}}\right)^2 = F - F_1 \ln R, \text{ where } F = F_1\left(X + \ln T_0\right),\ F_1 = \frac{1}{B}\left(\frac{\Delta H_g}{RT_{nuc}}\right)^2,\ X = \ln\left(\frac{A}{f}\frac{RT_{nuc}}{\Delta H_g}\right)$$

The value of $\Delta H_g/R$ can be obtained from the plot of mole fraction of solubility versus $1/T_0$. The value of f is inverse of molecular volume of pyrazinamide. The parameters A and B is estimated from the plot of $(T_0/\Delta T_{max})^2$ versus lnR. Figure 2 represents effect of supersaturation on induction time. The decrease in induction time with increase in ultrasound amplitude is shown in Figure 3.

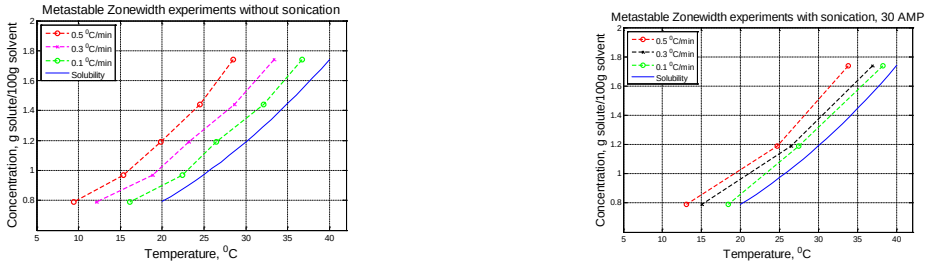

Figure 1. MSZW experiments in presence and absence of ultrasound.

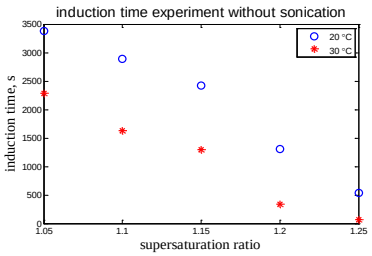

Figure 2. Plot of induction time vs. supersaturation

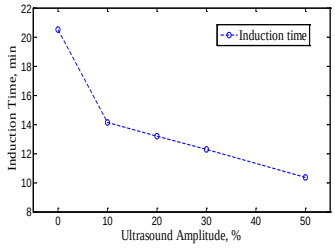

Figure 3. Induction time at different ultrasound amplitude

4. Conclusions

The metastable zone width was measured for different cooling rates and different ultrasound amplitudes. It was observed that the MSZW increases with increase in cooling rate and decreases with increase in ultrasound amplitudes. The nucleation parameters (A and B) were calculated from Sangwal's classical three dimensional approach. Induction time decreases with increase in supersaturation ratio. It also showed a sharp decrease with increase in ultrasound amplitude at constant supersaturation.

Highlights

- Dolomite is selectively crystallized at pH of 5.3–6.8 and temperature of 273–298 K.
- Aragonite with high selectivity is obtained in range over 333 K at pH of 5.3 and 6.0.
- $Mg(OH)_2$ as by-product is produced besides carbonates in pH range over 7.8 at 298 K.

1. Introduction

So as to build up a utilization system of seawater resources based on the salt production process, a recovery and upgrading method for calcium (Ca) and magnesium (Mg) from the discharge concentrated brine of salt manufactory in Japan was studied. From the viewpoint of solubility of salts, the synthesis of carbonate by reactive crystallization between the dissolved Ca^{2+} and Mg^{2+} in concentrated brine and CO_2 can be considered as an effective separation/recovery method. In this study, the production regions of Ca and Mg carbonates from the concentrated brine were classified for operational parameters during the reactive crystallization using the minute gas-liquid interfaces around CO_2 fine bubbles as novel reaction fields where the crystal nucleation proceeds predominantly. In the regions near the gas-liquid interfaces of CO_2 fine bubbles, the local increase in the concentrations of Ca^{2+}, Mg^{2+}, and CO_3^{2-} caused by the electric charge on fine bubble surface and the acceleration of CO_2 mass transfer owing to minimizing the bubble diameter [1]. In this paper, we report that the effects of the solution pH and reaction temperature (T_r) on the selectivity of Ca and Mg carbonates during reactive crystallization from the concentrated brine with CO_2 fine bubble injection.

2. Experimental

2.1 Concentrated brine The concentrated brine discharged from salt manufacture was used. In Japan, NaCl is manufactured by evaporative crystallization after concentrating seawater through an electric dialysis membrane, and the concentrated brine that removed K^+ by cooling crystallization is obtained concurrently with KCl. The major components of the above concentrated brine are $MgCl_2$, NaCl and $CaCl_2$, which have the concentrations of 2.1, 0.8, and 0.7 mol/L, respectively.

2.2 Experimental apparatus CO_2 fine bubbles were continuously supplied to 300 mL of the concentrated brine, and $CaMg(CO_3)_2$ was crystallized in a crystallization vessel. CO_2 fine bubbles

with an average bubble diameter (d_{bbl}) of 40 μm were generated using a self-supporting bubble generator by increasing the impeller shear rate under reduced pressure [1], with the rotation rate maintained at 1500 min^{-1} and the CO_2 flow rate controlled at 11.9 mmol/(*l*·min).

2.3 Experimental procedure The initial solution pH in concentrated brine was adjusted at a specified value of 4.3–8.3 by adding 4.0 mol/*l*–NaOH or 1.0 mol/*l*–HCl solution, and the solution pH during reactive crystallization was maintained constant at a set value by adding 4.0 mol/*l*–NaOH solution. T_r varied in the range between 278 and 348 K using a thermostat bath, and the reaction time (t_r) was controlled within 60 min. After the crystallization progressed for a specified length of time, the suspension was filtered and the reaction products were washed with deionized water and then dried at 373 K in a dryer. The selectivity of solid products was identified by the peak area ratio from X-ray diffraction.

3. Results and discussion

The selectivity of solid products at a t_r of 60 min plotted against solution pH and T_S is shown in **Figure 1**. At a pH of 5.3–6.8 and T_S of 278–298 K, the dolomite ($CaMg(CO_3)_2$) crystallization proceeded dominantly. When T_S increased to 333 K at pH of 5.3 and 6.0, aragonite $CaCO_3$ as the dominant product was obtained. At a constant T_S of 298 K, aragonite $CaCO_3$, $CaMg(CO_3)_2$, and $Mg(OH)_2$ were simultaneously obtained in the pH range over 7.8, and the selectivity of $Mg(OH)_2$ became high at a pH of 8.3.

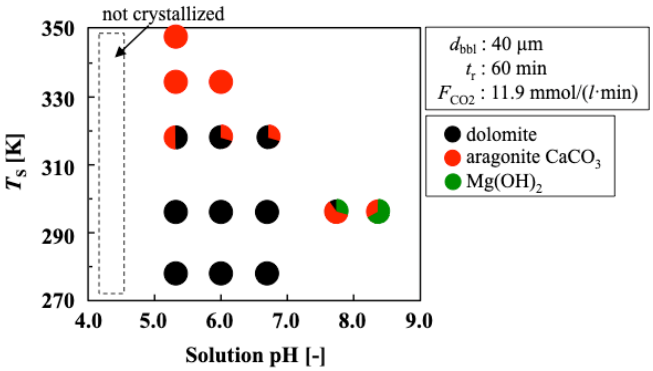

Figure 1. Effects of solution pH and T_S on the selectivity of solid products.

4. Conclusions

The production regions of Ca and Mg carbonates from the concentrated brine by fine bubble injection were classified by the solution pH and T_S. Consequently, the production of $CaMg(CO_3)_2$ with high selectivity was confirmed at a pH of 5.3–6.8 and T_S of 278–298 K. The aragonite $CaCO_3$ was preferentially produced in the T_S range over 333 K at pH of 5.3 and 6.0. When the solution pH was greater than 7.8 at a constant T_S of 298 K, not only $CaMg(CO_3)_2$ and aragonite $CaCO_3$ but also $Mg(OH)_2$ as a by-product was precipitated.

ADREM: Benchmarking new modular reactor technologies

Emmanouela Korkakaki[1], Koos Overwater[1], Marco van Goethem[1], Stéphane Walspurger[1]

1 TechnipFMC B.V., Afrikaweg 30, 2700 AB, Zoetermeer, the Netherlands

**Corresponding author: emma.korkakaki@technipfmc.com*

Highlights

- Methane conversion to liquid chemicals in one-step process has been benchmarked.
- Microwave technology replaces thermal methods for benzene with energy savings of 40%.
- C2 mixtures are produced with plasma technology with the minimum environmental impact. (a significant decrease of GHG emissions)
- OCM in gas solid vortex reactor is scalable and outperforms fixed bed reactors.

1. Introduction

The aim of the ADREM project is to develop new modular and flexible reactor technologies, that can accommodate different methane-rich sources, such as flared gas, associated gas from oil extraction, or biogas, and valorize it directly to chemicals. Some examples of key candidates that could be used on that concept are flared gas (which for 2017 was approximately 141 bcm), and the biogas that has reached 50 bcm in 2017. The impact of the flared gas to the environment is huge, since only for 2017, approximately 140 bcm were flared, equivalent to approximately 400Mt CO_2 and enough to provide the annual gas consumption of Germany and France.

In this work we focused on the integration of new reactor concepts, developed during the ADREM project, in the overall process design and on the evaluation of the feasibility for the technology upscale from an engineering point of view. The aim was modular, flexible units, that can be easily transported to remote locations, or to methane sources with small gas production.

2. Methods

Lab-scale results from the ADREM partners were used for the reactor performance evaluation, while for the pretreatment and downstream of the products state-of-the-art was used. Two cases of throughput were considered for the process design: i) associated gas and, ii) biogas. Liquid products (e.g. mixture or low purity products) that are easily transportable to a centralized purification unit were defined as process output. For each chemistry a flow scheme was developed, based on the product and on the reactor's requirements. The mini-methanol plant (commercially available) was used as a benchmark. The ADREM novel reactor concepts that were evaluated were: i) microwave assisted non-oxidative methane coupling, ii) plasma non-oxidative methane coupling, iii) oxidative coupling of methane (OCM) in gas solid vortex reactor with and, iv) plasma dry reforming. The performance indicators of each concept were the productivity, the total energy consumption and the specific energy consumption of each scenario, the CO_2 emissions and the

carbon formation rates. Based on these numbers, the two “most promising” reactor concepts were selected for TRL5 demonstration.

3. Results and discussion

The process design revealed interesting results for the four different reactor concepts, when considering that electricity is decarbonized. The microwave non-oxidative methane coupling for benzene production showed low energy consumption. Compared to the benchmark case, the energy demand decreased by 40% in the case of associated gas. With respect to the CO_2 emissions, there is up to 50% reduction compared to flaring, depending on the throughput. Plasma coupling of methane to C2 mixtures showed operational flexibility, reducing significantly the CO_2 emissions. However, the energy requirements when the plasma technology was implemented, were increased two-fold in the best-case scenario (with associated gas as the feedstock) compared to the benchmark case. This reactor concept resulted in a decrease of CO_2 emissions by 50-80% compared to direct flaring. Plasma technology in the dry reforming for syngas (and subsequently methanol) production had a similar performance; the energy requirements of the plasma technology were on the high side, with a four-fold increase compared to the benchmark case, while the CO_2 emissions had a tremendous reduction of 70%. Finally, the gas solid vortex reactor had quite a unique setup, easily scalable, compact and yet able to handle large throughput, with relatively low energy consumption. In this concept, the energy requirements of the entire process were comparable to the benchmark case, with a 10% energy savings when associated gas was used. In this reactor concept, CO_2 emissions were reduced between 20-40% compared to direct flaring. Based on the comparison of the performance indicators, the microwave assisted methane coupling and the plasma coupling were selected for TRL5 demonstration.

4. Conclusions

The present work shows the potential of the ADREM new reactor technologies on the integrated overall process scheme. This work gives more insights on the modular and flexible reactor technology that can accommodate methane-rich sources and convert them to a liquid product. For all the evaluated reactor technologies, the CO_2 emission profile was low compared to flaring, while some of them showed competitive energy requirements compared to the conventional thermal methods.

This project has received funding from the European Union’s Horizon 2020 research and innovation programme under grant agreement No 636820.

Highlights

- RWGS was performed with 4 different catalysts (10% Cu / Al_2O_3, TiO_2, SiO_2, ZrO_2)
- Data was compared with modelling results for different reactor types – CSTR, PFR and PB
- Bulk-gas diffusion plays an important mass-transfer role at our operating conditions
- DFT-derived RWGS kinetic model from literature was improved for higher predictive power

1. Introduction

Over the last decades, there is an increasing need to capture and convert CO_2 to help reduce the effect of global warming. One of such routes is to convert CO_2 to syngas via reverse water-gas shift reaction (RWGS), and then further synthesize useful products such as liquid fuels and chemicals.[1] In order to produce efficient catalysts for this process, a thorough understanding of the surface reaction mechanisms is needed. Microkinetic modelling, with the help of experimental data and reaction parameters obtained by ab-initio methods such as DFT,[2] is a useful tool that can be used both for understanding the process and process optimization. In this work, different reactor models are developed and used with experimental data from activity[3] and analytics to fine-tune the reaction parameters and obtain good model predictive power.

2. Methods

For the experimental part, four different copper-based catalysts (10 wt. % Cu on Al_2O_3, TiO_2, SiO_2 and ZrO_2) were synthesized using the deposition-precipitation method. The synthesized catalysts were analyzed with different experimental techniques, such as XRD, BET, SEM, EDX and various chemisorption techniques such as H_2 TPR, H_2 and CO TPD and pulsed N_2O oxidation. The latter was used to determine the concentration of surface active sites that was later used as an input to the model and varied with the supporting material used.

A one-dimensional packed bed reactor model was developed for system simulation. The model accounted for both convective and diffusive mass transport, as well as the full microkinetic chemistry consisting of surface reactions, and adsorption/desorption processes obtained from [2]. The model was solved using the CVODE solver written in C,[4] and the numerical regression with

the experimental data using the model was performed using the COBYLA method from the SciPy library written in Python.[5]

3. Results and discussion

The microkinetic model from the literature was used to calculate the conversions and product selectivity at the experimental conditions used, and compared to experimental data. The type of the reactor used in the model (CSTR, PFR or PB) was given additional attention.

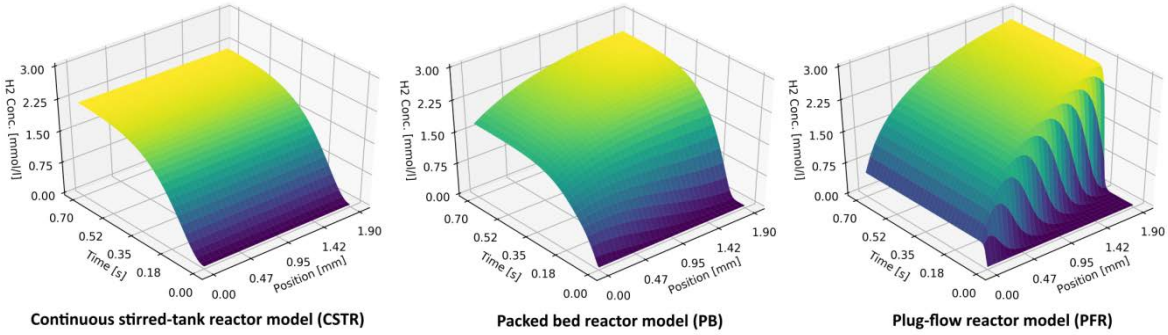

Figure 1. Comparison of different reactor models for the microkinetic RWGS reaction system. Depicted is the dependence of hydrogen concentration on the position of the reactor and the time in the simulation.

As seen in Figure 1, significant differences can be obtained when different models are used at the conditions in this study. This is due to the diffusion playing and important role at the gas flows and packed bed heights used. It can be seen that the packed bed reactor falls between the CSTR and PFR approaches with the degree of the reaction.

All of the models were used in numerical regression and the PB model gave the best fit to the experimental data. It was shown that with the improved model, it is possible to correctly predict the activity of copper based supported catalysts only from N_2O oxidation data, regardless of the supporting material used.

4. Conclusions

In this work, we show that for most experimental setups, gas diffusion plays an important role in mass transfer and has to be taken into account when modelling such systems. In addition, using the data obtained by experiments performed on different copper based catalysts, we explored various DFT-derived RWGS models from the literature and adjusted the best-fitting one to further improve its predictive power. It was shown that using N_2O oxidation data and our updated model, it's possible to correctly predict RWGS experimental activity of copper catalysts using different supporting materials.

Methane conversion to ethylene in nanosecond-pulsed discharge reactors

Evangelos Delikonstantis, Marco Scapinello, Georgios D. Stefanidis*

Process Engineering for Sustainable Systems, Department of Chemical Engineering, KU Leuven, Belgium

**Corresponding author: georgios.stefanidis@kuleuven.be*

Highlights

- Methane can be directly converted to ethylene at 20% yield and 2020 kJ/mol$_{C2H4}$ energy consumption in nanosecond pulse discharges at >3 bar without use of catalyst.
- 25.7% ethylene yield at 1642 kJ/mol$_{C2H4}$ can be attained from a two-step non-oxidative methane coupling process in a hybrid plasma-catalytic reactor.

1. Introduction

Ethylene, one of the most important commodity chemicals, is mainly produced by thermal cracking of long hydrocarbons but can also be formed from methane via non-oxidative coupling (NOMC). In view of crude oil depletion and abundant reach-in-methane gas reservoirs discovery, NOMC becomes an appealing route for ethylene formation. Processes, other than thermocatalytic ones, operating at lower temperatures and utilizing low-CO_2 electricity instead of heat are currently investigated for methane-to-ethylene conversion. Among them, non-thermal plasma can activate methane coupling reactions at lower temperatures, overcoming thermal losses in gas heating, while green electricity can be utilized for plasma ignition thereby avoiding fuel burning [1]. However, plasma is usually (i.e., at most common operating conditions) not very selective to ethylene since the energetic thresholds of the electron impact reactions of CH_3, CH_2 and CH (precursors of C_2H_6, C_2H_4 and C_2H_2, respectively) are comparable.

The present work focuses on ethylene production via NOMC in a nanosecond pulsed spark discharge. In this context, two process alternatives are developed and optimized: 1) a single-step selective conversion of methane to ethylene in plasma without use of catalyst; 2) a two-step process in which mainly acetylene is produced in the plasma zone and, subsequently, undergoes selective hydrogenation to ethylene in a catalyst zone downstream of the discharge, in a single reactor volume, using heat and H_2 produced in the discharge itself.

2. Methods

Plasma-assisted NOMC experiments were carried out in a tubular reactor comprising an inner, axial (2.2 mm diameter) copper-made wire (high voltage electrode) and an outer, co-axial (7 and 10 mm internal and external diameter, respectively) stainless-steel tube (ground electrode). The discharge gap was 2.4 mm wide while the coaxial plasma reactor length was 25 cm. The plasma reactor was powered by a nanosecond pulsed power supply (NPG-24/3000, Megaimpulse Ltd.,) triggered by a

waveform generator (33220A, Keysight Technology) at 3 kHz pulse frequency. A commercial Pd-based catalyst supplied by Johnson Matthey was used in the two-step process.

3. Results and discussion

High ethylene yield in a single step without catalyst use is attained in the discharge. At moderately elevated pressures (5 bar) and H_2 cofeeding (CH_4:H_2=1:1), acetylene formation is suppressed, and ethylene is produced at ~20% yield [2] per pass (Figure 1-left), consuming 2020 kJ/mol$_{C2H4}$. A reaction mechanism that explains the C_2 product distribution in this case has been suggested in Ref. [3]. Ethylene production at lower energy cost can be attained in a hybrid plasma-catalytic reactor system in which methane is first converted to acetylene in a nanosecond pulsed spark discharge, reaching up to 23.5% yield per pass, and, subsequently, acetylene is hydrogenated to ethylene by a Pd-based catalyst, which is placed in the post-plasma zone. Overall, ethylene is formed as major product at 25.7% yield per pass (Figure 1-right), consuming 1642 kJ/mol$_{C2H4}$. The two-step process is carried out in a single reactor volume that aside from the discharge energy does not require any additional heat or H_2 input since both are provided by methane cracking in the plasma zone itself.

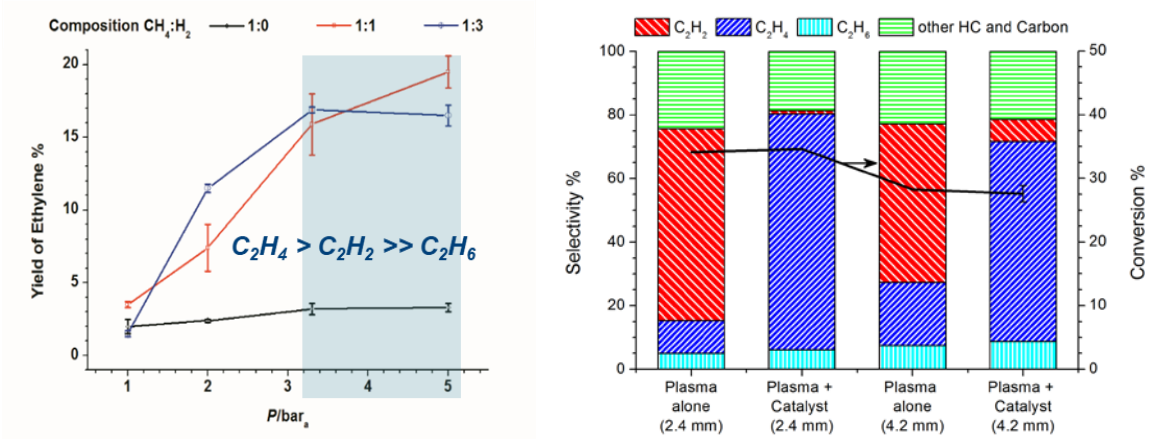

Figure 1. Ethylene formation as major product from methane in nanosecond pulsed discharges: *left*: single-step process operating at overpressure; *right*: two-step process operating at atmospheric pressure.

4. Conclusions

Ethylene can be produced as major product in nanosecond pulsed spark discharges via NOMC either in a single-step process at elevated pressures (>3 bar) without using catalyst, or in a two-step plasma-catalytic process operated at ambient pressure. 25.7% ethylene yield was attained in the two-step process at an energy consumption of 1642 kJ/mol$_{C2H4}$. This performance is relatively close to the recently published state-of-the-art using conventional thermal catalysis (23.4% ethylene yield at 1363 K) [4]. Compared to the latter work though, the advantages of the plasma process reported herein are that the exit bulk gas temperature is relatively low (650–750 K) and the technology is directly compatible with the emerging concept of powering chemical reactors with renewable electricity.

Traveling Microwave Reactor

Alberto Martínez González, Farnaz Eghbal Sarabi, Andrzej Stankiewicz, Hakan Nigar*

Process & Energy Department, Delft University of Technology, Leegwaterstraat 39, 2628CB, Delft, The Netherlands

**Corresponding author: H.Nigar@tudelft.nl*

Highlights

- Traveling Microwave Reactor (TMR) enables the process scale-up.
- Traveling-wave concept prevents the formation of a standing wave.
- It is suitable for high-energy demanding reactions, e.g., catalytic methane coupling
- TMR enables the temperature homogenization along the reactor.

1. Introduction

With the growing influence of renewable electricity as a primary energy source on Earth, the significance of the electricity-based technologies in process industries is likewise expected to increase. Microwave (MW) heating is a well-established electricity-based industrial technology employed on the commercial scale in various operations, such as drying, thawing, pasteurization, sintering, and ceramic processing. MW-assisted chemical reactions have been investigated for more than three decades, starting with liquid-phase homogenous systems then also in the heterogeneous solid gas-phase catalytic processes. Although there are many encouraging results of various laboratory-scale studies, commercial implementations of MWs in heterogeneous catalysis are non-existent. This is essentially due to the complexity of the interaction between MWs and solid catalysts, as well as to several important design factors influencing the performance of a continuously operated MW-assisted flow reactor [1]. The current study examines the above interactions and factors in a novel reactor concept, the so-called Traveling Microwave Reactor (TMR) [2]. The TMR concept will be validated on a high-energy demanding process, i.e., non-oxidative methane coupling.

2. Methods

The TMR has been designed based on the coaxial cable configuration. To do this, a three-dimensional finite element model, which couples electromagnetic waves and heat transfer, has been developed using the COMSOL MULTIPHYSICS® simulation environment. Figure 1 shows a cross-sectional schematic view of the modeled TMR along the axial direction. The TMR has been constructed with the stainless-steel inner and outer conductors, which form the coaxial structure having a reaction zone in between, see Figure 1. The reaction zone is an annular space between two concentric quartz cylinders. The heating tests have been conducted with different geometry (e.g., foams and extrudes) of silicon carbide (SiC) material in the packed-bed configuration. The temperature measurement has been performed with four thermocouples introduced inside the reactor through a hole in the inner conductor.

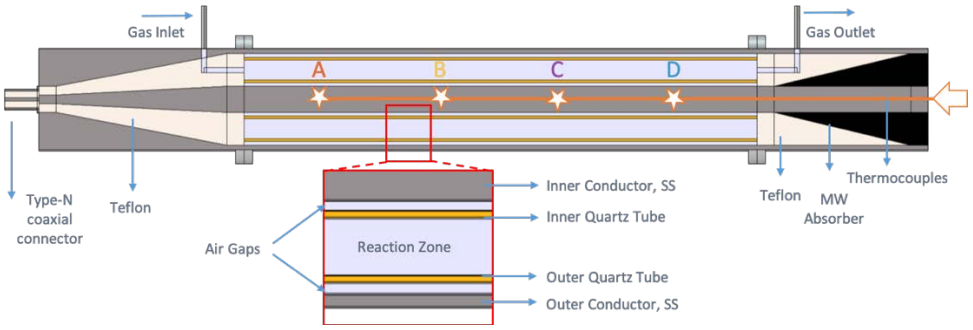

Figure 1. A cross-sectional schematic view of the TMR.

3. Results and discussion

Simulation results show that the MW energy is transported in the fundamental transverse electric and magnetic (TEM) mode, where the electric field lines run radially, while the magnetic field lines run in circles around the inner conductor. The good matching of spectral response and impedance characteristics shows that the behavior of the microwave model agrees well with the experimental setup which allows the validation of the model from the electromagnetic point of view. The transient temperature profile in the TMR fully loaded with a SiC packing is presented in Figure 2. The results reveal that the front part of the reactor has a temperature range 475-550ºC (thermocouples A, B, and C) and the final part has a range of 250-300ºC (thermocouple D). Since SiC is a good MW absorbent, most of the MW energy has been consumed in the front part of the reactor. Different packed-bed length and diameter are going to be further studied to improve the homogenous temperature distribution.

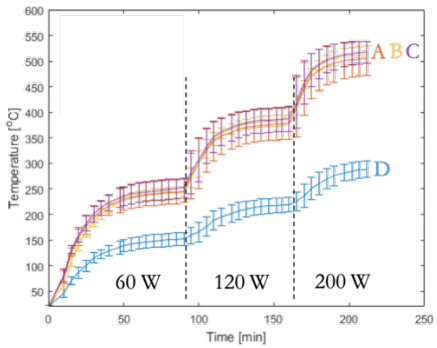

Figure 2. Transient temperature profiles with different MW power input.

4. Conclusions

A novel coaxial traveling microwave reactor is proposed to optimize the heat generation by avoiding the resonance. Simulation results prove that standing wave is not formed along the reactor and microwave energy travels ahead. Consequently, the heating uniformity in the TMR is expected to improve. To validate that expectation, heating characteristic of different catalysts in the designed reactor are under investigation. It is envisaged that this particular reactor concept may enable process scale-up beyond the intrinsic restrictions of cavity systems.

Highlights

- Synthesis of a thermally and mechanically stable catalyst for OCM in a GSVR.
- First demonstration of oxidative coupling of methane in GSVR.
- Process intensification of OCM

1. Introduction

Oxidative coupling of methane (OCM) is a promising pathway for the direct synthesis of C_2 hydrocarbons from methane according to the following global chemical reactions.[1]

$$2CH_4 + O_2 \rightarrow C_2H_4 + 2H_2O \qquad \Delta H_r^0 = -282 \text{ kJ mol}^{-1} \qquad (1)$$

$$2CH_4 + 0.5O_2 \rightarrow C_2H_6 + H_2O \qquad \Delta H_r^0 = -177 \text{ kJ mol}^{-1} \qquad (2)$$

The presence of oxygen and the high reaction temperature can facilitate the overoxidation of reactants and products to CO and CO_2, typically limiting the C_2 hydrocarbon yields to below 30%.[2]

$$CH_4 + 2O_2 \rightarrow CO_2 + 2H_2O \qquad \Delta H_r^0 = -801 \text{ kJ mol}^{-1} \qquad (3)$$

The high reaction exothermicity moreover dictates the need for a suitable heat management strategy.

In a gas-solid vortex reactor (GSVR), a rotating fluidized bed of solids is obtained by the tangential injection of gas at high velocities (Figure 1). [3] In the bed, the centrifugal forces on the catalyst particles balance the drag forces, leading to a dense and uniform bed. The very high gas-solid slip velocities intensify interfacial transfer of mass, energy and momentum, allowing a reduction in gas phase residence time. Using extensive computational fluid dynamics (CFD) simulations, a gas-solid vortex reactor has been designed and commissioned at Ghent University[3]. The diameter of the reaction chamber is 80 mm, containing 8 inlet slots with a width of 1 mm (Figure 1).[3]

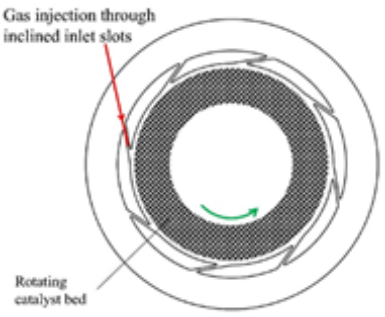

Figure 1 . Top view and operation of a gas solid vortex reactor in static geometry

Using bifurcation analysis incorporating detailed microkinetic models, Vandewalle et al. [4] showed that the good thermal back mixing combined with limited species back mixing in the GSVR can potentially improve C_2 yields when the reactor is operated on an ignited branch close to the extinction state. [5]

The high reaction temperature, the high solid velocities, and the low space times in the GSVR at those conditions require the development of a novel catalyst with high attrition resistance, high thermal stability, high activity, and proper size distribution. In this presentation, we report the

development of such a supported catalyst, and compare its performance in a fixed bed reactor with that in the GSVR.

2. Results and Discussion

Cold flow experiments were performed in the GSVR with inlet gas flow rates in the range of 15-30 $Nm^3\ hr^{-1}$, and slot velocities exceeding 100 m s^{-1} to test the stability of the catalyst bed and its attrition resistance. Under these conditions, a stable bed of 10 g of catalyst material with a thickness of about 10 mm could be retained in the GSVR at room temperature for a duration of 1 hour (Figure 2a). Over the 1 hour experiment, less than 1% of the material was entrained. Similar experiments with conventional Sr/La_2O_3 OCM catalyst pellets and with inert α-Al_2O_3 pellets resulted in rapid attrition and entrainment of the pulverised pellets with the gas stream. The gas flow rates and the catalyst material holdup in the GSVR correspond to very low space times of 0.1 $kg_{cat}\ s\ mol^{-1}_{CH4,0}$. For these space times, the synthesized catalyst material was tested in a quasi-isothermal fixed bed reactor at 800 °C and for a O_2:CH_4 inlet ratio of 4. A reasonable C_2 selectivity of 40-50% and a CH_4 conversion of 5-10 % were obtained for this high activity catalyst (Figure 2b). Typical OCM catalysts like Li/MgO and $NaMnWO_4/SiO_2$ show essentially no CH_4 conversion for space times below 5.0 $kg_{cat}\ s\ mol^{-1}_{CH4,0}$. [6] Next, the synthesized catalyst will be tested under reactive conditions in the GSVR. Based on detailed microkinetic simulations based on the fixed-bed experiments, a methane conversion of 4% and a C_2 selectivity of 45% are expected.

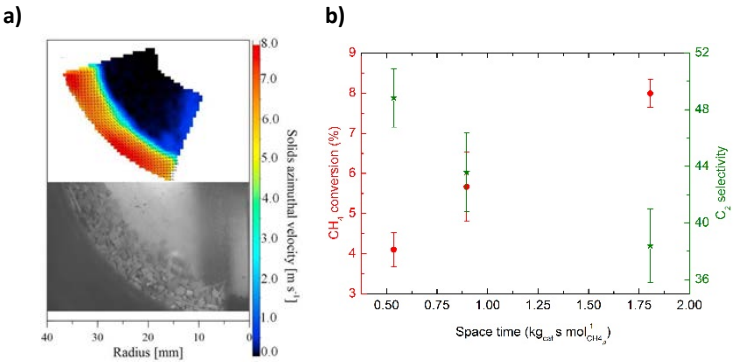

Figure 2 a) Azimuthal velocity of solids in the GSVR [3] and b) CH_4 conversion and C_2 selectivity vs. space time for synthesized catalyst at 800 °C

3. Conclusions

A thermally and mechanically stable OCM catalyst material was synthesized, which forms a stable catalyst bed under the harsh conditions in the GSVR reactor. At the conditions and at low space times, the synthesized catalyst material displayed a methane conversion between 5 and 10 % and a C_2 selectivity around 50%. Detailed simulations indicate that a similar performance can be expected in the GSVR. These proof-of-concept experiments are currently scheduled and will be reported at the conference.

Highlights

- Supercritical-solvothermal Mo/ZSM-5 synthesis boosts Mo dispersion and MDA stability
- The use of small polyoxometalates as Mo precursors of Mo/MCM-22 improves MDA performance
- Selective MW-assisted catalyst heating inhibits undesired gas-phase MDA reactions

1. Introduction

Non-oxidative methane coupling (MNOC) is a promising route to directly convert natural gas into more valuable hydrocarbons in one-step catalytic process. However, its industrial implementation is still hindered due to the relative low methane conversion and selectivity towards the products of interest as well as due to the low process stability derived from catalyst coking.

In the frame of the H2020 European Project ADREM (Adaptable Reactors for Resource- and Energy-efficient Methane Valorization), this works reports a multipurpose approach to enhance MNOC performance on the basis of the development of more stable and active catalysts and on the use of alternative heating sources to provide energy-efficient selective heating of the catalysts. The following topics were covered: 1) the development of a novel supercritical solvothermal synthesis for the benchmarking catalyst Mo/ZSM-5 in order to enhance metal dispersion and boost catalyst stability along the time on stream; 2) the use of small polyoxometalates as Mo precursors for the synthesis of Mo/MCM-22 in order to reduce the size of the initial Mo clusters and enhance metal dispersion in comparison to that obtained using the conventional Mo salts; 3) the use of microwave-assisted heating to improve the energy efficiency of the MNOC process while inhibiting the formation of heavy polyaromatics (i.e. hard coke precursors) as it is described by Julian et al. [1].

2. Methods

The supercritical solvothermal synthesis (SC-STS) of 5%Mo/ZSM-5, Si/Al = 23, was carried out using a self-built reactor set-up described elsewhere [2] in which a cold precursor solution

containing Mo with added support material (H-ZSM-5) is mixed with a hot solvent inside the reactor. Upon mixing at supercritical conditions, a super-fast precipitation of atomized metal precursor occurs within the zeolite pores.

A selection of polyoxomolybdate anions were employed as Mo precursors of Mo/MCM-22 catalysts under the assumption that the different structural arrangement of their Mo atoms within the polyoxometalate molecules would help to generate repulsion between discrete Mo centres, thereby avoiding the formation of Mo agglomerates on the zeolite surface and enhancing metal dispersion. MCM-22 (Si/Al = 20) was synthesized following the procedure of Corma et al. [3] and employed as support whereas the polyoxometallates were incorporated via incipient wetness impregnation.

All catalytic tests under conventional heating were carried out under benchmarking operational conditions: 700°C, 1500 mL/g_{cat}h, CH_4:N_2 = 80:20 and fixed bed configuration. Experiments performed under MW-heating were carried out at the same catalyst temperature and methane concentration but different space velocity (3000 mL/g_{cat}h).

3. Results and discussion

Comparing TEM micrographs (Figure 1.a) and MNOC catalytic performance of 5%Mo/ZSM-5 samples prepared by SC-STS and impregnation (Figure 1.b), it is found that both metal dispersion and hydrocarbon productivity are drastically improved using the proposed SC-STS method.

The Mo/MCM-22 catalysts prepared with the precursor $[(n\text{-}C_4H_9)_4N]_2[Mo_6O_{19}]$, especially the 5% Mo6/MCM-22 (Si/Al = 20), showed an excellent stability along 22 hours on stream keeping a nearly constant 5.8% benzene yield (>80% selectivity) without apparent catalyst deactivation, which is among the best reported long-term yields in literature for the MNOC process.

The use of MW-heating allowed inhibiting MNOC gas-phase reactions, i.e. polyaromatics production from the pool of methyl radicals and benzene molecules, thus, reducing hard coke deposition on the catalyst and enhancing catalyst stability.

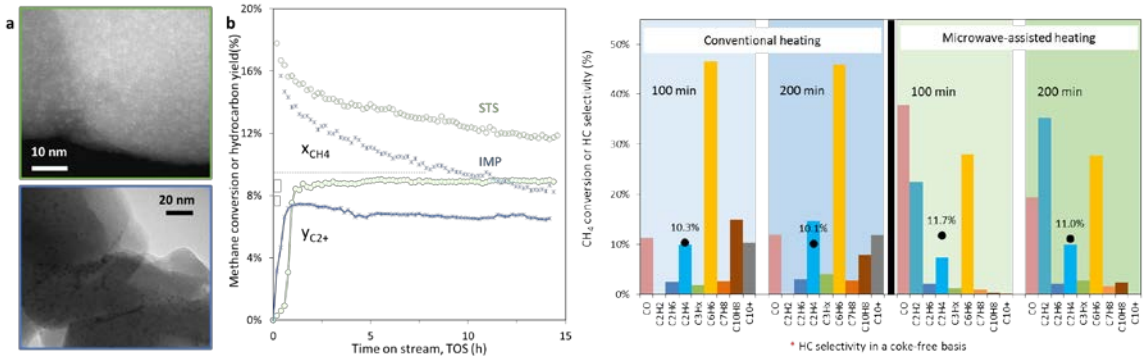

Figure 1. a) TEM micrographs illustrating metal dispersion provided by SC-STS and impregnation methods, b) experimental MNOC performance of 5%Mo/ZSM-5 catalysts prepared by SC-STS and IMP working at 700°C, 1500 mL/g_{cat}h and 0.5 g_{cat}, c) methane conversion and hydrocarbon products selectivity (coke-free basis) after 100 and 200 min on stream for MNOC on 4%Mo/ZSM-5@SiC operating at 700°C and 6000 mL/g_{cat}h under CH and MW heating

4. Conclusions

The three proposed approaches helped to enhance both catalyst stability and C_{2+} productivity with respect to conventional procedures, i.e. electrical heating and catalyst synthesis based on impregnation.

Highlights

- Optimal short-term scheduling of a real-life food industrial facility

1. Introduction

Current market trends and business globalization have steered industries towards large production volumes, complex alternative recipes and a larger product portfolio, thus leading to processes of increased complexity. Optimal production scheduling has a direct impact on the overall efficiency of processing facilities and can lead to increased productivity and minimal costs. Although a plethora of works study the optimal production scheduling problem [1], academic developments have been mostly tested on generic but small problem instances. This is mainly due to the computational complexity of real industrial problems, which easily become intractable. This gap between theory and industrial practice has been identified by the scientific community [2] and some recent works have successfully investigated medium to large problem instances [3]. In this work different solution strategies are proposed for a large real-life food industry.

2. Methods

The case of a canned fish production facility for a large-scale Spanish industry (Frinsa del Noroeste, S.A.) is considered. The first main goal is to develop an optimized weekly schedule, in order to minimize an objective metric (makespan, total production costs). Since no clear production bottlenecks exist, all three processing stages (filling and sealing, sterilization, packaging) of the facility need to be considered. The proposed methodology consists of three main pillars: a) a batching algorithm which translates the incoming product-orders to batches and lot-sizes; b) an MILP-model based on the general precedence framework; and c) a two-step (temporal and order-based) decomposition strategy. In order to extract a valid schedule, the MILP-model, which constitutes the core of the suggested solution strategy, consists of all the necessary timing, sequencing and allocation constraints. Additionally, plant-specific operational constraints are imposed by adding tight integer cuts in the model.

Furthermore, mathematical models are derived in order to describe the specific features of the sterilization process including product quality and safety, energy consumption and processing times. Quality is related to the surface colour of the canned tuna after the sterilization whereas safety refers to thermal destruction of harmful microorganisms. Such models are used in an optimal schedule of the sterilization processes based on the feasible scheduling solution obtained on the first step. Consumption of shared resources is also considered in order to prevent an overlapping in the demands that, for example, could make the previous solution unfeasible in the real implementations. This new optimization problem can focus on the features previously calculated with the realistic models, such as minimizing colour lost if the plant requires a special production, or increasing production by minimizing the sterilization process duration keeping the microorganism lethality over the security limit. The optimization focus on providing a real-time tool that helps the operator, which makes the horizon required to solve short, but increase the resolution speed requirements.

3. Results and discussion

The MILP model was implemented in GAMS 25.1 and solved using CPLEX 12.0. Optimality is reached for all iterations of the suggested solution strategy. Moreover, the problem is solved in a time acceptable by the company (1 hour). Compared to the real weekly schedule proposed by Frinsa, no overtime production during weekends was required.

Mathematical models for the sterilization process were developed. Order reduction techniques were implemented to increase simulation efficiency.

The sterilization optimal schedule is solved in a few minutes, which makes the solution suitable for launching the resolution each half an hour and obtaining a two hours prediction.

4. Conclusions

This work presents the optimization-based production scheduling and operation of a real-life food industry of high complexity. It was shown that the proposed strategy can schedule the plant under study and eliminate unnecessary overtime production.

Optimal Site-Wide Planning of A NH_3 Network – A Study on Uncertain Logistic Constraints –

Simon Wenzel[1,*], Yannik-Noel Misz[1], Keivan Rahimi-Adli[1,2], Benedikt Beisheim[1,2], and Sebastian Engell[1]

Highlights

- Optimal scheduling for physically coupled production plants.
- Application to an NH_3 network at an integrated petrochemical production site.
- Investigation of uncertain logistics in the supply chain on the optimal schedule.

1. Introduction

Many companies in the process industries operate in a highly competitive market environment and are thus obliged to improve continuously their production in terms of energy and material efficiency and to become greener [1]. In general, the value chain of chemical production consists of several, sometimes many production steps and complex interactions between these production steps exist, which lead to highly integrated and physically coupled systems of systems [2]. In large (petro-) chemical production sites, complex networks of flows of material and carriers of energy link the production plants. For an optimal operation of the overall system, mathematical modeling of the constituent systems and a joint optimization has to be employed to find site-wide optimal and feasible operating conditions according to different objectives such as material efficiency, reduction of carbon footprint, or economic performance indicators. The scope of such an optimization can, however, not be limited to the units and buffers of the production site, but it also has to consider exogenous influences such as fluctuating market prices for energy and raw materials and the logistics of their provision and distribution. Recently, there has been an increased interest in expanding the domain of optimization and thus enlarging the scope of the formulated optimization problems to include these aspects [3].

2. Method and case study

In [4], a mixed-integer linear program (MILP) optimization model with an expanded scope that includes demand side management (DSM), network optimization, plant optimization, and logistic constraints has been proposed for site-wide scheduling of integrated petrochemical production sites. It has been parametrized to generate a one month optimal schedule for the NH_3 network of INEOS in Köln, a large petrochemical production site in Germany. The logistic constraints cover the

deliveries to and the shipping of raw materials and base chemicals from the site via barges on the river Rhine and via train vessels. The nature of the solution of MILP is that the resulting schedule operates at the bounds, e. g., a tank is emptied just before a barge arrives. In practice, however, many exogenous influences and thus also the logistic constraints are not known precisely ahead of time. For instance, in Germany in the summer of 2018, the river Rhine was at such a low water levels that barges could only carry a fraction of their usual load or were even not able to deliver at all. Many chemical companies that are dependent on barge deliveries had to reduce their capacities or even had to shut down complete plants or production complexes.

3. Investigated scenario

In this contribution, we investigate the sensitivity of the optimal schedule for the operation of the INEOS in Köln production site with respect to this kind of events. We analyze the situation of a delayed barge, which is a common situation in daily operation. With the help of the formulated optimization model, we identify which measures should be taken in a critical situation. We investigate which process or plant has to reduce its load first or which production capacities can be shifted in order to ensure a seamless operation of the coupled production plants.

4. Conclusions

The analysis of the sensitivity of the optimal schedule for the operation of the NH_3 network at INEOS in Köln reveals important insights into where the site runs into critical limitations in a situation of unforeseen uncertain events such as delayed ships. The analysis is applicable to answer similar what-if scenarios for structurally related questions such as unforeseen equipment failures or plants shutdowns. The proposed optimization model offers a powerful tool to guide the planners' decisions at large (petro-) chemical production sites in the process industries.

Optimal Production Scheduling in the Packaged Consumer Goods Industry

Highlights

- Real-life large-scale consumer goods industrial case study
- MILP-based decomposition algorithm
- Plant reconfiguration
- Flexible production layout

1. Introduction

The ever-increasing competitiveness of large-scale industries necessitates the increase of productivity and minimization of production costs. Production scheduling has a direct impact on the overall efficiency of industrial facilities by minimizing, among others, changeover times which cause production downtimes, waste and energy consumption/use of resources. Potential plant reconfigurations also provide significant room for improvements of the overall productivity. Although production scheduling problems have received significant attention [1], the majority of the work is focused on relatively small to medium size problem instances. A few recent contributions have studied the application of scheduling techniques in medium- and large-scale industries [3]. In this work two MILP-based approaches are proposed for the optimization-based scheduling of a real-life large-scale consumer goods production plant. The first approach focuses on the optimal scheduling of the current plant layout while the second one is applied to a reconfigured flexible layout allowing the decoupling of the formulation and packing stages.

2. Methods

2.1 Current Layout

An MILP-based decomposition algorithm is proposed for the optimal production scheduling of the current plant layout focusing on the packing stage. The proposed MILP model optimizes the production sequence while considering constraints related to the allocation of the final products as well as the timing of processing steps [2]. Products' due dates, as well as appropriate constraints referring to the production/formulation stage of the plant, are taken into account to ensure near-optimal production schedules. The algorithm operates on an iterative fashion and a subset of the involved product orders is scheduled at each iteration.

2.2 Reconfigured flexible layout

In order to avoid varying bottlenecks in the process due to the product dependent maximum production rate of the formulation and the packing stage, the two stages can be decoupled. In the current layout the stages are closely coupled in each line, whereas the flexible layout relaxes these connections and includes an additional shared buffer between the two stages. The solution approach is again based on an MILP model and a decomposition algorithm, the main difference being the inclusion of material balances due to the limited capacity of the buffer.

3. Results and discussion

3.1 Current layout

A number of different case studies with varying numbers of products have been examined using the aforementioned scheduling algorithm and detailed near-optimal production schedules have been generated. Results indicate that a significant reduction in the changeover time can be achieved even for problems with more than 120 products.

3.2 Reconfigured flexible layout

A number of different case studies were examined for the flexible layout as well, again employing an optimization-based decomposition scheduling algorithm. The results demonstrate potential improvements, should this layout be adopted. Good schedules were obtain within very short computation time, which poses a major benefit, as computational efficiency is a key priority in an industrial setting.

4. Conclusions

In this work two mathematical frameworks, relying on MILP-based decomposition algorithms, were proposed for the optimization-based production scheduling of a packaged consumer-goods plant. The first approach considers the plant in its current layout, while the second examines a potential flexible layout. A case study with real-life data is used to illustrate the applicability and efficiency of the proposed approaches leading to a noticeable reduction of the changeover times.

Highlights

- Improved control and real-time process optimization leads to substantial savings.
- Monitoring and modelling the performance degradation in equipment is key.
- Integrating control, optimization and maintenance scheduling is the future path.

1. Introduction

Lenzing AG in Austria is the world's largest viscose fiber production plant. Lenzing's fibers are made from wood: They are botanic products derived from renewable sources and processed with resource conserving technologies. The production of these high-quality viscose fibers is a multi-step chemical technological process. The key role in terms of resource efficiency within the viscose-fiber production belongs to the spinbath recovery cycle. The recovery cycle itself (see Figure 1) is a sequence of basic operations carried out in several multi-unit networks. Due to its high-energy demand, the LENZING use case within the SPIRE project CoPro is particularly focused on the evaporation stage and the heat-recovery network.

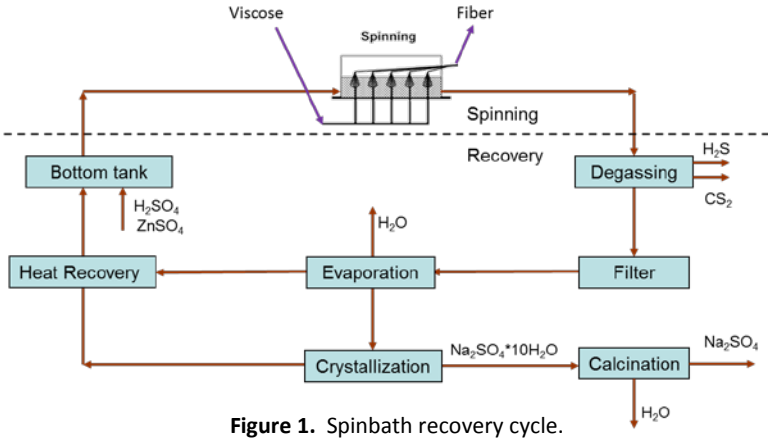

Figure 1. Spinbath recovery cycle.

2. Challenges

The first challenge concerns with the evaporation stage, where about 30 plants of different capacities and performances need to be allocated to recover the spinbath of around 10 lines of fibers production. Furthermore, in addition to fulfill continuous production demands, operational constraints such as possibility of physical connection or plants temporal availability need to be enforced. And, of course, this load allocation from spinbaths to plants needs to be done in the most energy-efficient way, i.e. with minimum specific-steam consumption (SSC).

Additionally to the above allocation problem, the evaporation plants suffer from performance degradation due to fouling inside the heat exchangers. Various cleaning operations can be chosen to

get rid of the fouling effects, but the personnel for maintenance is limited, so only a single plant can be cleaned per day. Hence, a *feasible* (must) and *optimal* (desired) scheduling of the maintenance operations over time is to be found. However, this is not independent from load allocation, and it is also affected by uncertainty in future predictions of production demands and weather. Therefore, an integral real-time scheduling optimization is a desirable outcome of the CoPro project.
Some of the plants are equipped with surface condensers as cooling systems. These condensers are fed with river water and the issue is: the more water is directed to the condensers, the more efficient the plants are. However, water is shared in a network with other parts of the factory, and its usage is subject to environmental regulation. Thus, an additional problem is to find the optimal water distribution to the evaporation network. But, this task is coupled with the plants allocation, as varying performance of the cooling systems may enable different decisions in the load allocation. Therefore, a tradeoff between plants efficiency and water usage is to be set up for optimization.

3. Results so far and outlook

In order to address the above challenges, a physics-based grey-box model for an evaporator was initially built to find the optimal control policy (lowest SSC) and to study the fouling effects [1]. Then, based on this work, simplified surrogate models for each plant operating with the new control were built. These models (updated periodically) serve in a mixed-integer quadratic optimization which suggests the best plant allocation to spinbaths in near-real time [2]. Savings of around 250 k€/year (1.8% more efficient operation) were gathered with the new decision support system (DSS). In parallel to this, models to predict the performance loss over time due to fouling were identified from experimental tests so that, by balancing the operation and cleaning costs, nonlinear optimization problems predict the best future day for cleaning in each plant, as well as the optimal cleaning task [1],[2]. Preliminary tests onsite with 5 plants show a potential benefit of 25 k€/year. The implementation to the whole evaporation network and heat-recovery one as well is ongoing.
Regression models for the surface condensers have been also identified from experiments, measuring the SSC variations at different water flows and temperatures. With these, a nonlinear optimization suggests the best water distribution to plants by balancing the savings in SSC with the water costs (subject to usage constraints) [3]. This setup can be integrated with the load-allocation optimization in a centralized fashion, and solved in near-real time using BONMIN. Tests in simulation show additional savings about 200 k€/year, but these may be too optimistic, as the effects of limiting the water usage in other parts of the factory is not considered yet in the optimization.
Finally, the integration of the plants load allocation and maintenance scheduling is already set up and tested in simulation with reasonable computational demands [4]. However, including uncertainty via scenarios in a two-stage optimization approach increases considerably the problem complexity (hence, resolution time) so alternatives for problem decomposition are under study.

Workshop on Crystallization Science and Engineering

Continuous crystallization to separate enantiomers exploiting two coupled fluidized bed crystallizers

Andreas Seidel-Morgenstern
Max-Planck-Institut für Dynamik komplexer technischer Systeme, Magdeburg, Germany

**Corresponding author:* seidel-morgenstern@mpi-magdeburg,mpg.de

Crystallization is one of the most effective ways to separate mixtures of enantiomers. Preferential Crystallization (PC) has proven to be applicable to provide selectively pure enantiomers from racemic mixtures of conglomerate forming systems [1]. Primarily batch processes are used so far. However, there are intensive efforts to develop continuous enantioselective crystallization processes [e.g. 2,3].
This contribution presents results of applying a fluidized bed crystallizer configuration for the continuous provision of enantiomers from a racemic feed solution. Objective is the supply of pure crystals with a defined narrow size distribution. To crystallize both enantiomers simultaneously two tubular fluidized bed crystallizers are coupled via their liquid phases. Saturated racemic solution is supplied at the bottom of the double jacketed crystallizers. To initiate the separation process seed crystals of both enantiomers are added. The growth of these crystals reduces the supersaturation of the processed liquid phases. The depleted mother liquors of both crystallizers are recycled via heated tubes into the feed tank. Thus, a racemic composition of the feed solution is maintained. A special feature of the process is the fact that the lower sections of both crystallizers are conical to offer the opportunity of classified product removal at certain heights [4]. This allows adjusting the mean product crystal sizes via the feed flowrate and provides narrow size distributions [5]. To ensure that the process operates continuously, larger particles and formed agglomerates are crushed in a mill. The fragments are returned as continuous seed streams. Undesired nuclei of the counter enantiomer and small particles leave the crystallizers with the fluid phases and are dissolved on the way back to the feed reservoir.

We will describe results of an interdisciplinary project devoted to solve three tasks. At first, the impact of important operating conditions (e.g. crystallization temperature and the various flowrates) is studied experimentally for two chiral systems. Secondly, the hydrodynamics of the two-phase flow are evaluated using Computational Fluid Dynamics (CFD) and the Discrete Element Method (DEM) [6, 7]. Further, in order to be able to optimize the crystallizer geometry and the operating conditions, a reduced process model based on population balances is developed exploiting Proper Orthogonal Decomposition (POD) [8,9].

Workshop on Crystallization Science and Engineering

Model-based analysis of continuous crystallization-milling processes with respect to productivity, particle size and polymorphic purity

Thomas Vetter

Department of Chemical Engineering and Analytical Science, University of Manchester, Oxford Road, M13 9 PL, Manchester, United Kingdom

thomas.vetter@manchester.ac.uk

Highlights

- Continuous crystallization processes of varying complexity are analyzed using population balance equation models.
- Attainable regions of particle sizes are identified for various continuous crystallization processes.
- For polymorphic systems, regions where phase pure material can be generated are identified and rationalized in terms of the required operating conditions.

Manufacturing pure material at a reasonable productivity and with good robustness is the goal of any industrial crystallization process. In this contribution, a few case studies will be presented where continuous crystallization processes have been analyzed using population balance equation models. The case studies will include works that elucidate the envelope of feasible product particle sizes from a given continuous crystallization process[1,2], as well as works where innovative milling/crystallization processes coupled with ancillary unit operations have been used to generate polymorphically[3,4] pure products. Across both sets of works, feasible operating conditions were identified and the process performance (with respect to yield, mean particle size, and phase purity) within this feasible region was investigated. While using the devised models quantitatively for this purpose relies on suitable kinetic parameters, it will be shown that even the qualitative (and quite general!) trends obtained from the models are of great use from a process design perspective.

- Application of model-free feedback control will be presented
- Monitoring and control of batch and continuous crystallization systems

1. Introduction

In the absence of a dedicated monitoring and control system, industrial crystallizers often perform sub-optimally, which is mostly reflected in a low-quality product with a wide or multimodal size distribution, undesirable mean crystal size, a sub optimal crystal shape or an unwanted crystal structure. Recent developments in in situ monitoring, modeling as well as in both model-free and model-based control strategies, however enable new opportunities in the design and application of control strategies for practical applications (Nagy and Braatz, 2012; Nagy et al., 2013). **2.**

2. Results and discussion

This lecture provides an overview of the state-of-the-art in the monitoring and model-free control of industrial crystallization processes and through a series of case studies illustrates how these recent developments can contribute to better product quality and improved performance of industrial crystallization systems. The advantages of using integrated in situ and in line monitoring systems as a composite sensor array in conjunction with a crystallization process informatics system will be illustrated, which enables robust data reconciliation, automated calibration and sensor fault detection as well as an intelligent, rapid design and of robust crystallization processes with precise control of critical quality attributes (Fig. 1). The key process analytical tools (PATs) that can be used for in situ monitoring of crystal size, shape, polymorphic form and purity will be described. Model-free control approaches, such as supersaturation control (SSC) and direct nucleation control (DNC) will be described and illustrated with industrial case studies. The control of batch, continuous stirred tank and tubular crystallization systems will be corroborated. The final part of the lecture will introduce the application of monitoring and control systems for novel integrated systems to achieve high degree of control of various crystal properties, including integrated crystallization and wet mill process and continuous plug flow crystallization platforms with spatially distributed control strategy and controlled spherical crystallization that enable the simultaneous control of the trade-off between bioavailability and manufacturability of the final product.

Highlights

- Thermodynamics and kinetics
- Diastereomeric and enantiomeric separations
- PAT applications

1. Introduction

A challenge in the translation of academic research into industrial applications is achieving alignment between the requirements for academic rigor and originality and the industrial demands for minimizing cost and time while maximizing quality.

In this presentation, examples of efforts to streamline the implementation of complex crystallization methods in addressing industrial crystallization challenges will be presented.

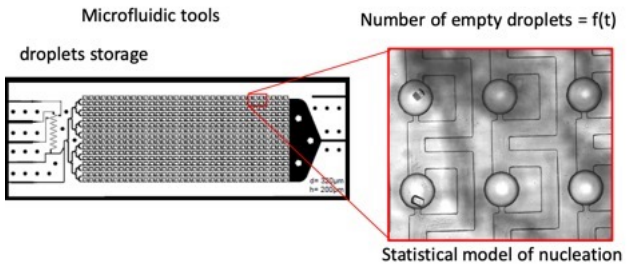
Crystallization science and engineering workshop organized by EFCE Working Party on Crystallization

Crystallization is a separation and purification process used in the production of a wide range of materials. Many aspects of industrial crystallization have been developed in the past years and have a good scientific basis. Recent developments are in progress such as isolation of polymorphs and resolution of enantiomeric systems, molecular modelling, effect of added impurities on the crystal growth process, use of computed aided fluid dynamic modelling or new methods for crystal characterization. However, new challenges arise from new industrial needs. These developments create research on complicated substances such as drugs or proteins in complicated or new solvents or multi-phase systems and lead to consider what is called “complex media”.

This presentation gives some examples of crystallization in complex media. Different reactor scales are used as generic tools studying crystal nucleation and growth.

Scale 1: an original microfluidic device was developed for investigating nucleation rate, growth kinetics, and phase transition of organic crystals in organic solvents (1,2) . This set-up allows to store up to 2000 small crystallization containers (20 to 100nL) and to control precisely their temperature and supersaturation. The case of eflucimibe showing two polymorphs and ibuprofen,in different organic solvents are studied. We believe that this microfluidic system gives new opportunies to study nucleation and phase transition of complex materials.



Scale 2: in a batch reactor the effect of additives on crystal growth is difficult to study because of the supersaturation evolution. We propose to adapt the constant composition (constant supersaturation) method in a semi-batch reactor, to compare the effect of several additives (3).

This study provides insights on the mechanisms governing the inhibition $CaCO_3$ crystallization at local scale, and enable to benchmark several additives.

Scale 3: transposition of the kinetics laws obtained are made at industrial scale with respect to changes in operating conditions. Observations at lab-scale allows to propose laws for governing mechanisms and explains the trends observed at pilot-plant scale.

Highlights

- Multiscale modelling is applied to the simulation of crystallization processes
- Multiscale modelling is augmented by artificial intelligence and deep learning tools
- Experimental data is used for model validation
- Two examples are discussed: flash nanoprecipitation and reactive crystallization

1. Introduction

Crystallization and precipitation are very important in chemical engineering as numerous particulate products are manufactured by relying on these processes. Examples span from the pharmaceutical industry to the materials industry, including catalysis and batteries. The final products properties are characterized in terms of distributions, notably the size distribution. In turn the particle size distribution (PSD), or crystal size distribution (CSD), is strongly affected by the operating conditions under which the process is carried out and in order to design, scale up and down and optimize the process, computational models are extremely useful. In fact, they can answer the complex question: under what operating conditions a specific PSD or CSD can be obtained? In this contribution the main computational modelling techniques are presented and discussed.

2. Methods

As the main emphasis is on the prediction of the PSD/CSD the most popular computational models are based on the solution of the population balance equations (PBE), that dictates the evolution of the PSD/CSD. However, since the PBE is strongly connected with the fluid dynamics of the crystallizer, very often the PBE is tightly coupled with a computational fluid dynamics (CFD) model. The coupling is often realized with quadrature-based moments methods (QBMM) such as the quadrature method of moments (QMOM) or the conditional quadrature method of moments (CQMOM) [1].

Moreover, as the rates with which particles and crystals are formed are governed by molecular processes, very often these models are coupled also with atomistic and molecular models. Among

the different modelling choices full atom molecular dynamics (MD) and coarse-grained molecular dynamics (CGMD) are mostly employed.

A plethora of codes is used to run these simulations, to couple the different models and to orchestrate the workflows, ranging from Ansys Fluent, OpenFOAM, code_saturne, LAMMPS, GROMACS, Salome, etc.

All the above-mentioned models, being based on first principles and physical laws are labelled as physics-based models. However, recently the simulation of these processes also relies on the use of artificial intelligence and deep learning tools to build data-driven models, which is contrast to the previous ones, are not based on first principles. An interesting idea is that since very often the amount of experimental data is often not enough to build a data-driven model, validated physics-based models can be used to augment and enrich a limited experimental data set and to build the data-driven model, following the digital twin concept.

3. Results and discussion

Two examples will be discussed in this presentation. The first one focuses on flash-nanoprecipitation via solvent-displacement for the production of amorphous polymer nanoparticles for controlled drug delivery applications, whereas the second focuses on the precipitation of inorganic crystals via reactive crystallization or precipitation. In the first example it will be shown how multiscale modelling can be used to simulate the polymer particle formation process, starting from molecules up to the actual crystallizer and to successfully predict the effect of the choice of the good solvent, of paramount important in these processes [2,3]. In the second example the use of these computational tools will be discussed for a different application process involving inorganic crystals.

**Corresponding author: kfjensen@mit.edu*

Highlights

- Continuous flow synthesis of nanocrystalline materials.
- Effect of reaction conditions on growth and crystal structure.
- Sequential growth of core-shell and modified nanoparticles.

Abstract

Continuous flow systems are shown to have advantages in synthesis and assembly of nanomaterials, including faceted metal nanoparticles, quantum dots, and nanodendrites. Synthesis in flow leads to sharper size distribution and faster growth than typically achieved in batch processes. The choice of reactor configuration, solvents, reagents, and exposure environment has significant impact on the resulting nanostructures. Chaining multiple flow systems provides control of nucleation, growth, ageing, and over-coating of core-shell nanoparticles, as exemplified with the synthesis of InP quantum dots. Sequential flow synthesis steps also enable synthesis of hierarchically structured nano and meso scale structures.

Highlights

- Resolution Control in a Continuous Preferential Crystallization Process
- Continuous Antisolvent Deracemization
- Semi-continuous Deracemization via Racemic Crystal Transformation monitored by in-situ Raman Spectroscopy

The biological activity of a chiral compound often depends on its handedness. However, the physical properties of left- and right handed molecules are the same. The manufacture of just one of the two chiral forms, therefore, is a challenge. Crystallization is an extremely powerful technology to enable the manufacture of enantiopure crystalline products: Enantiopure crystals are highly selective towards incorporation of enantiomer solutes with the same handedness. Therefore, chiral separation of the enantiomers through crystallization can lead to high enantiopurities, for instance through preferential crystallization. The extension of the crystallization process with a racemization reaction in the solution (deracemization) has additional benefits for yield as well as process stability: the counter enantiomer is racemized towards the preferred one (higher yield) so that the supersaturation for the counter enantiomer remains low (no crystal nucleation of the counter enantiomer crystals). In addition, for continuous manufacturing of enantiopure compounds these crystallization processes can be beneficial due to steady state operation and continuous control opportunities.

I will discuss a number of process configurations in which controlled crystallization is used to obtain an enantiopure product from complex multicomponent racemic systems.
