PREFACE

The Event is organized by AIDIC, the Italian Association of Chemical Engineering, under the auspices of the European Federation of Chemical Engineering (EFCE), as well as of the European Society of Biochemical Engineering Science (ESBES).

EFCE scientific congresses and symposia are the heart of its activities. The first EFCE European Congress was held in 1997 in Florence, organized also at that time by AIDIC; and it marked the start of a grand journey of growth. The European Congress of Chemical Engineering has now become a biennial and world-famous event, attended by scientists, researchers, teachers, students, industry professionals, owners, contractors and suppliers from all the continents, who can interact, share, debate, collaborate and inspire one another, bringing chemical engineering expertise on an unprecedented scale to a single location.

A few years ago ESBES joined EFCE for the organization of the European Congress, thereby widening their scope and their field of application. ESBES contribution to the topics of the Florence 2019 Congress is particularly relevant, due to the importance that biotechnology is taking and will take in research, society and industry.

The joint Congresses ECCE12 (the 12th European Congress of Chemical Engineering) and ECAB 5 (the 5th European Congress of Applied Biotechnology) and the associated events stand under the common theme of

Bridging Science with Technology : a Renaissance in Science

The scientific content of both the congresses ECCE12 and ECAB 5 is set under the governance of EFCE and ESBES Working Parties and Sections.
The conferences cover a wide range of research themes under the umbrella of Chemical Engineering and Applied Biotechnology. The topics treated by WPs and Sections are all those ones typical of Chemical Engineering and Applied Biotechnologies, from the classical ones, like process simulation and reactor design, to the most current ones, like nanotechnologies, bio-fuels, bio-catalysts, food and water, that represent the challenges of the future and are of interest to everybody.

MAIN TOPICS

ECCE12

1 SUSTAINABLE PROCESSES
2 PARTICLE TECHNOLOGY
3 PRODUCTION , PROPERTIES AND TECHNOLOGY OF NEW MATERIALS
4 NANOTECHNOLOGY
5 SEPARATION TECHNOLOGY AND HEAT & MASS TRANSFER
6 THERMODYNAMICS AND INTERFACIAL PHENOMENA
7 FLUID MECHANICS AND TRANSPORT PHENOMENA
8 MULTIPHASE SYSTEMS
9 MEMBRANE ENGINEERING : Energy from salinity gradients, Hybrid artificial organs
10 INDUSTRIAL ELECTROCHEMISTRY
11 PROCESS SYSTEM ENGINEERING
12 CHEMICAL REACTION ENGINEERING
13 BIOMASS
14 FOOD ENGINEERING
15 ENERGY AND CHEMICAL ENGINEERING
16 ENVIRONMENT, SAFETY & QUALITY
17 QUALITY ASSURANCE, CONTROL & MANAGEMENT SYSTEMS
18 KNOWLEDGE, EDUCATION & TRAINING

ECAB5

ADVANCED AND INNOVATIVE TECHNOLOGY IN INDUSTRIAL
19 BIO-PRODUCTION, BIO-SEPARATION, AND BIO-DETECTION (BIOSENSORS)
BIOENERGY, BIOFUELS&RENEWABLES, BIORESOURCES,
20 BIOREFINERY AND BIOMATERIALS (BIO-ACTIVE COMPOUNDS, BIOFUELS, FINE CHEMICALS)
21 BIOCATALYSIS (FUTURE MICROBES AND ENZYMES)
22 NOVEL PROCESSING (E.G. MICROBIAL FUEL CELLS), DOWNSTREAM PROCESSING
23 FROM SMALL TO LARGE (NANO-BIOTECHNOLOGY, SCALE-UP/SCALE DOWN, LARGE-SCALE PRODUCTION)
24 SYSTEMS BIOTECHNOLOGY AND METABOLIC ENGINEERING
25 PROTEIN AND ENZYME STABILITY
26 ENVIRONMENTAL BIOTECHNOLOGY
27 BIOFILMS IN INDUSTRY AND BIOMEDICINE
28 CHEMICAL PRODUCT DESIGN AND BIOPRODUCTS
29 BIOECONOMY
30 BIOREACTOR PERFORMANCE
31 DOWNSTREAM PROCESSING
32 FOOD BIOPROCESSES
33 MICROALGAE BIOENGENEERING
34 MODELLING, MONITORING, MEASUREMENT & CONTROL
35 REGENERATIVE MEDICINE MANUFACTURING

The scientific programme of ECCE12-ECAB5 features more than 1200 Lecture and Poster presentations, including 6 plenary lectures and 8 keynote lectures by outstanding Researchers.
This Book of Abstracts consists of a summary of the topics treated and listed in the Congresses.

"Perspectives for CO2 Utilization"

Flavio Manenti

Politecnico di Milano l.

CO2 is dramatically impacting our life: climate change and consequent social-economic problems are identified as Grand Challenges of current century. Main agencies identified that 87% of anthropogenic CO2 emissions are due to combustion of fossil fuels and it is estimated that overall average anthropogenic carbon emissions were 30 Gt/y in last years. The technological problem with anthropogenic CO2 is not only inherent in the molecule chemistry but also in the form of exhausts: these are gases released into atmosphere at low pressure, in large amounts, where CO2 is mixed with H2O, N2 and other combustion products. As a consequence, it realizes to be difficult and costly to process such exhausts; CO2 sequestration by chemical-physical washing and subsequent disposal in remote storages still remains a challenging and questionable technique. In the last two decades, a large portion of the scientific and engineering community has faced the problem from upstream, therefore focusing on mitigation of CO2 impacts by reducing its production (i.e. renewable energies); on the other hand, the problem can be faced from downstream also by implementing utilization processes of produced CO2. Use of exhausted or atmospheric CO2 for direct methanol production (by CO2 hydrogenation), as proposed by Olah, represents an example of downstream approach to the problem and, according to post-Horizon2020 directives of European Community, CO2 utilization seems to be a faster track with respect to other routes to tackle CO2 emissions and the plenary contribution will mainly focus on existing and promising processes for bulk reusing of produced CO2 providing CO2-free perspectives for main chemical synthesis.

An Initiative on Safety Across the Chemical Engineering Curriculum

H. Scott Fogler

doctor honoris causa 2016, Universitat Rovira i Virgili, Tarragona, Spain Ame & Catherine Vennema Professor of Chemical Engineering,

and the Arthur F. Thurnau Professor

The University of Michigan

Ann Arbor, Michigan 48109-2136

Sometimes chemical process safety is taught in a separate safety course within the chemical engineering curriculum, and sometimes it is taught only in the senior year as a part of the process design course. The purpose of this initiative is to provide faculty and students with real case studies and resources so that process safety can be more effectively and easily learned throughout the curriculum and become an integral part of chemical engineering culture.

To achieve this culture, safety modules have been developed to be used as homework problems in every core chemical engineering lecture course (http://umich.edu/~safeche/). Each module consists of viewing a Chemical Safety Board Video, filling out an analysis of the accident, doing a course specific calculation, assigning the NFPA symbols and filling out a Bow Tie Diagram for the accident. For example, in the chemical reaction engineering course, the T2 laboratories accident and the ExxonMobil Refinery Fire are examples presented and analyzed.In addition to the core lecture courses, six video snippets (2-5 minutes each) on Laboratory Safety are included on the website.

In addition to the modules, tutorials are given on such things as the NFPA diamond, the Bow Tie Diagram, the Fire Triangle, the Process Safety Triangle and A Safety Analysis of the Incident. The solutions to the homework problems are also given on the website, but instructors will have to email the author to receive the password to enter the solutions. The website is free and accessible to all.

Challenges in modelling of biocatalytic reactions

Jürgen Pleiss

Institute of Biochemistry and Technical Biochemistry, University of Stuttgart, Germany

Enzymes are promising catalysts for a wide range of biocatalytic processes. Because protein engineers still lack a deep molecular understanding of biocatalytic systems, finding the optimal biocatalyst is time consuming, and trial-and-error strategies are widely used.

A more directed rational design strategy responds to three challenges. Although enzyme-substrate interactions are successfully modelled by molecular simulation and experimental data are successfully modelled by macroscopic ODE based models of enzyme kinetics, both modelling methods are separated by many orders of length and time scales. Therefore, the major challenge is to bridge the gap between molecular and kinetic modelling. The second challenge is a holistic model, which includes reaction conditions. Kinetic models describe the reaction medium by adjustable parameters and can therefore become complex. In contrast, molecular simulation allows for the reliable prediction of thermophysical properties of mixtures from first principles. The third challenge is data management. Due to high-throughput experimentation techniques for biocatalytic experiments, enzyme data is rapidly growing, complex, and unstructured. Making big biodata accessible to data mining and modelling is widely seen as a major bottleneck to the digitalization of industrial biotechnology, and rules for data management such as the FAIR data principles or the STRENDA recommendations are increasingly accepted by the scientific community.

Advancing Chemical Development through Process Intensification, Automation, and Machine Learning.

Klavs F. Jensen

Department of Chemical Engineering Massachusetts Institute of Technology 77 Massachusetts Avenue Cambridge MA 02139

Process intensification via continuous operation combined with automated optimization and screening techniques offer opportunities for faster development and more efficient manufacture of diverse chemical products. This presentation starts with advances in process intensification and green chemistry achieved through micro-reaction technology and continuous multistep synthesis (flow chemistry). Case studies include individual intensified reaction units as well as on-demand synthesis of common pharmaceuticals in a plug-and-play, manually reconfigurable, refrigerator-sized manufacturing platform. Next, advances in automated screening and optimization of chemical reactions are highlighted as methods to accelerate translation of laboratory discoveries to manufacturing. Examples include optimization of thermal- and photo-chemical reactions in 15 microliter droplets with respect to continuous process conditions
(temperature, time, concentrations…) and discrete process choices (catalysts, solvents, bases …). Finally, machine learning of chemical information is applied to computer aided chemical synthesis - the planning of reaction paths to a given molecular target from purchasable starting materials. With expert user input, the synthesis plans are converted into recipes that are executed by an automated modular continuous flow platform configured by a robotic arm, which sets up the required unit operations. Examples of automatic continuous syntheses of pharmaceutical compounds and libraries illustrate the promise of this combined approach of machine learning, reaction engineering, and robotics.

Chemical recycling of complex plastics

Marinke Wijngaard

MD TNO Circular Economy & Environment

There are too many plastics that we currently burn and do not make the most of. This can be prevented by keeping plastics in the value chain as long as possible, and thus reducing the use of fossil oil for plastic production. TNO achieves this by designing plastics that can be used for longer and which can be easier maintained an recycled and to develop chemical recycling technologies for complex plastics.

Although more simple plastics can be easily mechanically recycled, this is not possible for more complex plastics. For these complex plastics often chemical recycling need to be applied. TNO has broad experience in reclaiming polymers through chemical recycling technologies. In this lecture Marinke shares experience on gasification, pyrolysis and dissolution of plastics.

"Separation challenges in the quest for sustainability"

Immaculada Ortiz

University of Cantabria, Chemical & Biomolecular Engineering
Spain

Needs for separating mixtures are pervasive in many industrial sectors. In past decades the importance escalated with the emergence of new industries in biotechnology and high-performance materials. However, Separation Processes account for 40-70% of both the capital and operating costs in the process industries and are responsible for 10-15% of the world's total energy consumption. This is due in part because of the ubiquity of chemicals in the modern world and in part due to the fact that more than 80% of the energy associated with chemical separations is used in distillation and similar processes such as evaporation that rely on phase changes. Therefore, progress substitution of conventional separation methods by more efficient alternatives is challenging for a more sustainable development.

The drivers for new and more efficient separation alternatives are, i) design of high performance materials (functionalized membranes and nano-structured materials) capable of overcoming equilibrium constraints and increasing the separation selectivity at the same time that keep the productivity target, ii) progressive use of low energy driving forces such as magnetic fields targeting solutes with magnetic properties and, iii) advanced decision-making tools that integrate predictive modeling of separation units and materials function to provide the optimum process configuration that maximizes the profit and the protection of the environment and natural resources.

The Rational Purification of Proteins: Proteomics, Expert Systems, Modelling, Process Conditions and Optimization

J.A. Asenjo and B.A. Andrews

Centre for Biotechnology and Bioengineering, CeBiB, University of Chile
Beauchef 851, Santiago, Chile,
**Corresponding author: juasenjo@ing.uchile.cl*

Highlights

- Selection of optimal chromatographic sequence based on proteomic data of product and contaminants.
- Mathematical modelling of chromatography for accurate simulation including affinity.
- Optimization of chromatography process conditions including "peak cutting".

1. Introduction

Over the past years we have developed a Computer Based Expert System based on Proteomic Data of Proteins for the rational selection of optimal protein purification sequences [1], as well as Mathematical Models that simulate and allow optimization of chromatographic protein purification processes. These systems consider more "generic" purification procedures such as ion-exchange, hydrophobic interaction (HIC) and gel filtration chromatography, but also affinity chromatography both using salt and pH gradients in the selection of chromatographic processes and in the mathematical modelling and simulation of chromatographic performance.

2. Methodology

The chosen methodology was implemented in a computer- based Expert System. Two algorithms were developed, the first algorithm was used to select the most efficient purification method to separate a protein from its contaminants based on the physicochemical properties of the protein product and the protein contaminants and the second algorithm was used to predict the number and concentration of contaminants after each separation as well as protein product purity. Once the type of chromatography is chosen, optimization of the operating conditions is essential. For this two different mathematical models have been used [2]. These were the Plate Model and the more fundamentally based Rate Model. Operational conditions and the peak fraction collection is selected using a cost function of the production process which considers yield, purity, concentration, and process time that are obtained from simulations. This analysis allows optimization of process conditions [3].

3. Results and discussion

The theory developed for ion-exchange, HIC chromatography and affinity separations will be analyzed in this presentation. This is a unique contribution that allows investigation of chromatographic protein purification in a holistic approach that includes ion-exchange, HIC, gel filtration and affinity separations [4, 5, 6]. The methodology and experimental data required to

carry out such optimization will be analyzed and shown. This analysis that considers a first principles approach to rational protein purification will be presented and discussed.

The first step consists of the selection of the optimal chromatographic sequence of operations (2-3, usually) based on the proteomic data of the protein product and the contaminants. The second step consists of detailed and accurate mathematical modelling and rigorous simulation using experimental data of each chromatographic step including parameter estimation, gradient elution, pH and flow rate. Procedures have been carried out at low and high protein concentrations such as those used in process oriented situations [3].

A mathematical function was built that includes parameters to optimize protein production as well as the effects of chromatography performance such as yield, purity, concentration and the time needed to accomplish the separation. Operational conditions in all Chromatographic processes can be selected using this model [3, 7]. This mathematical function was successfully used for the selection of the operational conditions as well as the fraction of the product to be collected (peak cutting).

Finally, the present interest in carrying out protein separation and purification in a continuous process will be analysed and discussed.

4. Conclusions

We have developed a method to select the optimal chromatographic sequence of operations for protein purification based on detailed proteomic data of the protein product and its contaminants. We have also developed accurate mathematical models for the simulation of the chromatographic steps. A detailed procedure was developed that includes all chromatographic parameters to optimize protein production performance including purity, yield, concentration and operational time. This is a holistic approach for rational protein purification [7].

Optimal design of supply chains for carbon capture, storage, and utilisation

Federico d'Amore, Fabrizio Bezzo*

CAPE-Lab - Computer-Aided Process Engineering Laboratory, Department of Industrial Engineering, University of Padova, via Marzolo 9, 35131 Padova PD (Italy).

**Corresponding author: fabrizio.bezzo@unipd.it*

Highlights

- Optimisation of a European carbon capture, transport, and storage network
- Aspects of societal risk and social acceptance can be included in the model
- Mechanisms for costs share and cooperation can foster implementation
- Challenges for carbon capture and utilisation are critically discussed

1. Introduction

The global anthropogenic emissions of greenhouse gasses (GHGs) experienced an exponential increase compared to pre-industrial levels and, among these, CO_2 is the most abundant, with an overall emission that raised globally from 2 Gt/year in 1850 to over 35 Gt/year in 2010 [1]. Carbon capture and storage (CCS), and utilisation (CCUS) has been highlighted as one of the most promising options to decarbonise the energy sector, which still heavily relies on fossil fuel-fed facilities. When dealing with the strategic design of a European CCS infrastructure, it clearly emerges the necessity of employing quantitative mathematical tools to treat the combinatorial complexity of such large scale networks, in particular, mixed integer linear programming (MILP) for supply chain (SC) optimisation [2]. Addressing the problem of the design and optimisation of a CCS SC in the context of Europe, including the possibility to include carbon conversion and utilisation pathways, while considering uncertainty and consequent risk, aspects of societal risk and social acceptance from the public, along with the assessment of financial schemes for cooperation between stakeholders, are still major challenges for fostering an effective implementation of such a complex system.

2. Methods

The base case deterministic framework has been developed according to a MILP model that describes Europe in terms of emissions from large-stationary sources (i.e., coal and gas power plants). Regarding the capture facilities, either post-combustion, pre-combustion, or oxy-fuel combustion have been included as possible options, whereas both pipelines and ships have been described in techno-economic terms as potential transport means [3]. Then, a risk assessment has been incorporated within the modelling framework, accounting for the societal risk generated by a potential leakage in the transport system (quantified according to the seriousness of the hazard), coupled with the choice of installing risk mitigation options (e.g., concrete slabs, deep burying, marker tape, surveillance) [4]. The societal response to CCS have been further analysed through the concept of social acceptance, described through the amount of risk perceived by a population inhabiting within the region where an infrastructure is planned. The social response has been modelled as proportional to the project size, to the amount of population, and to the differential

behaviour of the different European countries [5]. Furthermore, a set of constraints has been employed to balance the spread of installation and operation costs between countries, with the aim of fostering economic costs share and cooperation policies between different players. Finally, the effect of some utilisation pathways have been assessed in terms of economic and environmental benefits.

3. Results and discussion

The CCS models were optimised using the GAMS CPLEX solver on a 32GB RAM computer. Results from the deterministic framework demonstrated the good European potential for carbon sequestration and gave some indications on the total cost for CO_2 capture, transport and sequestration. Capture costs were found to be the major contribution to total cost, while transport and sequestration costs were never higher than 10% of the investment required to set in motion and operate the whole network. The overall costs for a deterministic European CCS SC were estimated in the range of 27-38 €/t of CO_2. The societal risk-constrained optimisation demonstrated the possibility to design a safe transport infrastructure with minor additional costs. Indeed, mitigation actions never represented more than 11% of total cost for installing and operating the transport network. However, no feasible solution could be found for a carbon reduction target higher than 50%, because of the unacceptable level of societal risk. When maximising social acceptance from the public (through minimising risk perception of CCS), results led to a massive exploitation of offshore sequestration solutions with a (possibly unacceptable) a total costs of about 50.88 €/t of sequestered, i.e. +34% with respect to the economic optimum, due to a more complex network configuration characterised by high transport (+434%) and sequestration (+853%) costs. A multi-objective optimisation analysis, however, allowed identifying a possible intermediate solution between the two conflicting objectives (i.e., economics against acceptance), capable of limiting risk perception, without excessively compromising the economic performance of the network. Regarding the model including costs share mechanisms between European countries, results showed that the additional European investment for cooperation (max. +2.6% with respect to a non-cooperative network) should not constitute a barrier towards the installation and operation of such more effective network designs. Finally, a preliminary analysis on CCUS indicated that some CO_2 utilisation pathways for the production of chemicals (e.g., PPP, MeOH) can have a positive effect in decreasing costs of the overall supply chain.

4. Conclusions

In this work it has been developed a time-dependent, multi-echelon, spatially-explicit, large-scale, European digital optimisation tool, aiming at the strategic high-level definition of a CCS SC. These models will provide valuable insights into the optimal economic deployment of CCS technologies at a noteworthy scale that was never investigated before, and will be able to steer relevant research and policy into addressing correctly the problem of global warming through CCS.

Highlights

- Preparation and optimization of Cu-ZSM-5 and Cu-Al_2O_3 extrudates catalysts
- Complete characterization of porous extrudates catalysts
- DBD Plasma-assisted low temperature methanol production from CO_2 hydrogenation
- Efficiency comparison between plasma and conventional catalysis in the CH_3OH production

1. Introduction

Carbon dioxide is one of the main greenhouse gases (after water vapor) and also an abundant source of C1. CO_2 is a non-toxic, non-corrosive, nonflammable molecule [1] and very stable thermodynamically, requiring thus large amounts of energy for its dissociation. CO_2 is produced from almost all combustion processes causing an increase in the world average temperature. To prevent its release into the atmosphere, one of the existing technologies is the capture and storage of CO_2 in underground reservoirs [2], but this does not benefit from this potential carbon source. A more valuable technology could be the chemical recovery of this captured CO_2 by its valorization into hydrocarbons, more specifically its chemical transformation into methanol.

CO_2 hydrogenation to methanol is accompanied by the reverse water-gas-shift (RWGS) reaction, which produces CO. These reactions have been well studied in the literature and two main problems have been detected: the important amounts of energy required for breaking the CO_2 bonds, and catalysts needing fairly high temperatures for activating the CO_2 molecule, both situations favoring the undesired RWGS reaction.

To address these problems, we propose a new catalytic process using copper catalysts synthetized on various supports and used in a cold DBD plasma reactor. This original technique allows to work at atmospheric or under moderate pressure and favoring methanol production.

2. Methods

We have first developed our own catalyst Cu/NaZSM-5 and compared it to Cu/Al_2O_3. These catalysts are in the form of cylindrical extrudes of 5 mm x 3 mm, aiming to deliver results closer to

industrial exploitation. In the literature, little research has been done on the use of the sodium form of the ZSM-5 to produce methanol [3]. A green template-free process to synthesize NaZSM-5 is used in this work. All corresponding characterization analyses have been conducted for the supports (N_2 physisorption, pyridine adsorption and XRD) and for the catalysts as well (N_2 physisorption, pyridine adsorption, H_2 chemisorption, CO adsorption, ICP, TPR and XRD).
Second, we have performed experiments using a non-thermal plasma reactor, which is able to activate the CO_2 molecule at room temperature and atmospheric pressure, increasing the CO_2 dissociation rate in gas phase and the methanol yield over catalysts. All experiments were performed with a molar ratio of H_2/CO_2 = 3 using argon as a vector gas to increase the dissociation rate of CO_2, inside of a dielectric barrier discharge reactor using Cu/Al_2O_3 and Cu/NaZSM-5 as catalysts, in parallel with a classic fixed-bed configuration in order to compare their catalytic performances in terms of methanol production.

3. Results and conclusions

Catalysts extrudates were successfully prepared, and their preparation was optimized. It was observed that there is an ideal range for the HNO_3/boehmite molar ratio (between 19 and 37) where reducibility and dispersion of the copper present on the catalyst were improved when compared to the acid-free catalysts. Also, the addition of HNO_3 improves the strength of the Lewis' acidic sites at temperatures higher than 200 °C, which are the usual reaction temperatures for the conventional fixed bed reactors.

First results have been obtained showing that methanol is produced when using both Cu/Al_2O_3 and Cu/ZSM-5 catalysts under cold DBD plasma at atmospheric pressure. The plasma assisted catalytic tests were evidenced to be more efficient than the conventional ones and a clear improvement was observed in terms of methanol yield and CO_2 conversion. A schema of the reactor is shown below:

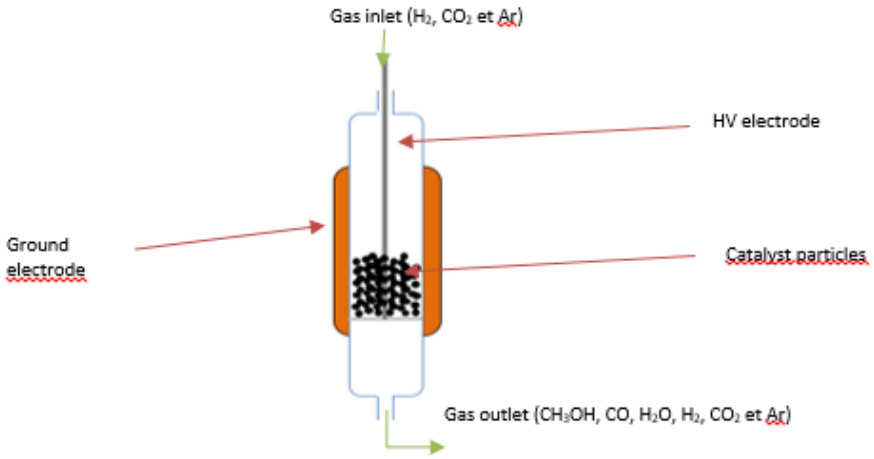

Figure 1. Cold plasma DBD reactor used for CO_2 hydrogenation into methanol.

Climate change mitigation: A techno-economic assessment of the formic acid production by electrochemical reduction of CO_2

Marta Rumayor*, Antonio Dominguez-Ramos, Angel Irabien

University of Cantabria, Department of Chemical and Biomolecular Engineering,

Av. Los Castros s/n, Santander, Spain

**Corresponding author: marta.rumayor@unican.es*

Highlights

- Formic acid production by electro-reduction of CO_2 was techno-economically assessed.
- The conventional fabrication process was used as a benchmark.
- Several sensitivity analyses evaluated the profitability of the CO_2 utilization plant.
- Results showed the benefits of the electrification of the chemical industry with FA.

1. Introduction

Turning the European Union (EU) into a resource-efficient, green, and competitive low-carbon economy is the key priority to meet the EU long-term goals by 2050 against climate change. The efforts require cutting-edge technological innovations to reduce our traditional fossil-dependent processes in order to curb the greenhouse gas emissions and the current consumption of natural resources in an economic way. This paper presents a techno-economical and resource saving assessment of an alternative based on the carbon dioxide (CO_2) utilization for the production of formic acid (FA) by electrochemical reduction (ER). The economic feasibility analysis of the plant includes the calculation of key performance indicators (KPIs) as the net present value (NPV) and the benefit/cost ratio (B/C). Several sensitivity analyses will evaluate the profitability of the CO_2 utilization plant for the production of FA by CO_2 ER. The study can help at pushing further the necessary developments towards a successful implementation of the CO_2 ER technology for the production of FA on a large scale.

2. Methods

A mathematical model built by the authors in a previous work [1] is used in the present study to obtain the life cycle inventory (LCI) of a hypothetical ER of CO_2 plan that produces 12,000 ton of FA per year. The system boundaries include the utilization plant itself (Figure 1) involving three main units: i) the ER of CO_2 in the ER cell, ii) the distillation of the azeotropic mixture FA/water to the desired purity (85% wt.), and iii) the compression of by-products H_2 and O_2 to the liquid forms. The ER process is included in the model as a black box unit. It was modelled using three sets of parameters that create the corresponding three scenarios: (i) an ideal scenario that represents the

minimum consumption of electricity and maximum Faradaic Efficiency, FE (100%); (ii) a baseline scenario that uses the current performance parameters obtained within our research group of the authors [2]; and (iii) an optimistic scenario that assumes a long-lasting cathode lifetime (capable to decrease the impact that the consumable cost has in the total cost of production) which is expected in a medium-term term. The conventional route of FA production by hydrolysis of methyl formate is used as the benchmark. Costs involved in the process are estimated using a bottom-up approach [3]. The KPIs of capital (CAPEX), operational expenditures (OPEX), net present value (NPV) and the benefit/cost ratio (B/C) are used to evaluate the economic feasibility of the plant. The reference cost of production is calculated and compared with the current FA market price c.a. 650 €·ton^{-1}. Sensitivity analyses are completed to account for uncertainty in the main variables that influence the process performance and the impacts on techno-economic results.

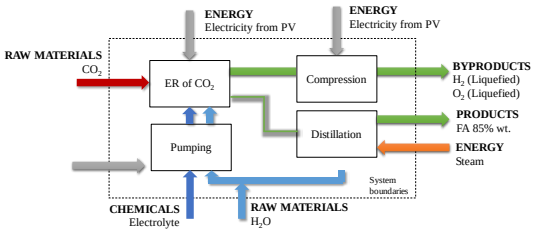

Figure 1. System boundaries

3. Results and discussion

The results display the specific techno-economic parameters such as the cathode lifetime, the CO_2 price, the price of electricity, the market price of FA as well as the break-even production of FA that will become the ER of CO_2 plant profitable while contributing to decreasing the CO_2 emissions and the resource depletion. It is demonstrated that under a CO_2 market price of 100 €·kg^{-1}, the break-even electricity market price could be between 23.5 €·MWh^{-1} and 29.9 €·MWh^{-1}; these values are in agreement with the perspective of the European levelised cost of electricity of large-scale PV electricity. The results obtained have shown that the electrification of the production plants of commodities, as FA, through renewables is needed for their future competitiveness.

4. Conclusions

This study has shown the potential of the ER of CO_2 route in the framework of climate change abatement objectives while contributing to a decrease of resources depletion. FA is shown here as an example of the benefits of the electrification of the chemical industry. The results obtained indicate that ER of CO_2 route could be profitable in a mid-term horizon under proper technological developments.

Highlights

- Controlled coprecipitation embeds Pd in the lattice leading to low-nuclearity clusters.
- The superiority of this Pd speciation is elucidated by theoretical and empirical methods.
- Record methanol productivity is sustained for 500 h.
- The benefits of nanoscale design for a sustainable large-scale process are demonstrated.

1. Introduction

Metal promotion is broadly applied to enhance the performance of heterogeneous catalysts to fulfil industrial requirements. Still, generating and quantifying the effect of the promoter speciation that exclusively introduces the desired property and ensures proximity to the active site and durability is very challenging. Recently, In_2O_3 was discovered as a highly selective and stable catalyst with the potential to realize green methanol production from CO_2 at a commercial scale [1]. Activity boosting with the H_2-splitter palladium led to partial success since Pd nanoparticles mediate the parasitic reverse water-gas shift (RWGS) reaction, reducing selectivity, and sinter or alloy with indium, limiting metal utilization and robustness. Herein we introduce a coprecipitation method leading to low-nuclearity Pd clusters anchored to the active site that curtail these limitations.

2. Methods

In_2O_3 and Pd(0.1-10 wt.%)-In_2O_3 catalysts were prepared by precipitation, and coprecipitation or dry impregnation, respectively, followed by calcination. They were characterized by inductively coupled plasma optical emission spectroscopy, N_2 sorption, X-ray diffraction, thermal techniques, electron microscopy, and X-ray photoelectron and absorption spectroscopy. CO_2 hydrogenation to methanol was conducted in a continuous-flow fixed-bed reactor setup at 473-653 K, 5 MPa, H_2/CO_2 = 1.8-5.7, and weight hourly space velocity = 24,000-48,000 $cm^3_{STP}\ h^{-1}\ g_{cat}^{-1}$. Pd speciation and reaction energetics were studied by Density Functional Theory (DFT).

3. Results and discussion

Pd-promoted In_2O_3 featuring palladium atomically dispersed in the oxide matrix was generated by coprecipitation and was benchmarked with dry impregnated systems comprising Pd clusters deposited onto the oxide. The first exhibited a stable activity enhancement compared to bulk In_2O_3

solely directed to methanol synthesis, while the second displayed a decaying improvement of both methanol and CO formation (**Figure 1**, left). Based on structural, spectroscopy, and microscopy (**Figure 1**, middle) analyses, Pd formed clusters of very low nuclearity attached to the lattice in the coprecipitated sample, whereas aggregated to form defined nanoparticles in the impregnated material. DFT calculations indicated that Pd atoms embedded into the oxide structure serve as effective anchoring sites for the noble metal atoms accommodated onto the surface hindering excessive agglomeration, which provides a molecular-level explanation to the profoundly diverse time-on-stream behaviors of the two catalysts. According to thermal characterization, theoretical simulations, and kinetic data, these Pd clusters do not significantly increase the number of active vacancies but impart an improved H_2-dissociation capability without enhancing the RWGS reaction (**Figure 1**, right), leading to a sustained record productivity (0.96 g_{MeOH}^{-1} h^{-1} g_{cat}^{-1} after 500 h on stream). In contrast, Pd nanoparticles supply activated hydrogen that fosters vacancy and methanol formation on In_2O_3 but also convert CO_2 into CO on their own surface.

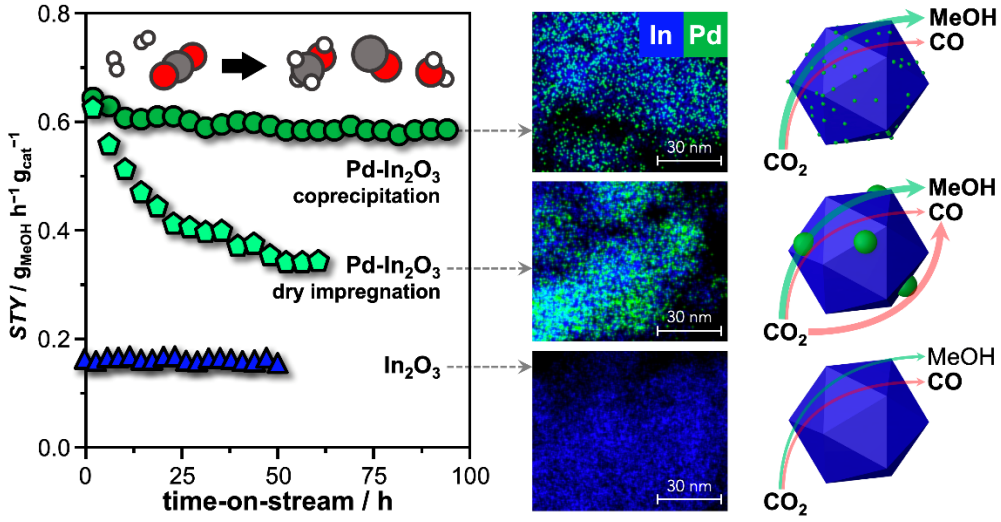

Figure 1. Methanol space time yield (*STY*) *versus* time-on stream over Pd(0.75 wt.%)-In_2O_3 catalysts and pure In_2O_3 during CO_2 hydrogenation at 553 K, 5 MPa, and H_2/CO_2 = 4 (left). EDX maps of In and Pd (middle) and representation of the distinct promotional effect of Pd (right) for the same catalysts after equilibration.

4. Conclusions

Controlled coprecipitation enables a fine tuning of the Pd speciation, generating small Pd clusters strongly bound to the oxide that offer a highly effective use of the noble metal and are robust, granting a sustained unparalleled methanol productivity. This permits to operate the catalyst at reduced temperature, with hydrogen-lean feeds, and in the presence of greater amounts of water, implying strong economic and ecologic benefits for a perspective CO_2-based methanol synthesis process.

Highlights

- SEDMES: direct synthesis of DME from syngas and CO_2 by in situ H_2O adsorption.
- The dynamic cycle model adequately describes the SEDMES experimental results.
- The working capacity can be tuned by the adsorption and regeneration conditions.
- Cyclic stability confirmed for more than 100 cycles.

1. Introduction

Utilisation of CO_2 is expected to play a crucial role to enable sustainable industrial production of carbon-based products, the large-scale storage and transport of renewable energy, and the production of renewable fuels. An important criterion for the value chain for converting the available CO_2, e.g. from biogenic origin, is a high carbon efficiency [1]. Very high carbon efficiencies have indeed been demonstrated for the conversion of synthesis gas and CO_2 to DME (clean alternative fuel and platform chemical) by sorption enhanced DME synthesis (SEDMES) [2, 3], in which water is removed in situ by the use of a solid adsorbent. The concept is based on Le Chatelier's principle stating that reactant conversion to products in an equilibrium limited reaction is increased by selectively removing reaction products. Experimental proof-of-principle has shown increased DME yield, improved selectivity towards DME over methanol and reduced CO_2 content in the product [2, 4]. This contribution will present an elaborate model study on the cyclic SEDMES process, which is conducted in parallel to an experimental research line. The combination of theory and experiments in a fundamental way is crucial for a proper understanding of this type of process.

2. Methods

Both a 1D dynamic cycle model was developed and verified using Matlab, and transient experiments in a packed-bed reactor were performed for various stoichiometric feed compositions and inert N_2, Ar. Commercial copper/zinc oxide/alumina catalyst and commercial zeolite A steam adsorbent (mixed in different ratios) were used experimentally. Adsorption was conducted at 250-300 °C, 25-40 bar(a) and with different feed gas compositions. Regeneration was done by switching to dry gas, depressurisation and eventual heating to 400 °C. Analysis was done by a combination of mass spectrometry and GC.

3. Results and discussion

The results of a representative breakthrough experiment of sorption enhanced DME synthesis are shown in Figure 1. Pre-breakthrough of steam, DME and unconverted CO are the primary products. After steam breakthrough the concentration of DME drops, accompanied with the breakthrough of

CO_2 and methanol indicating saturation of the adsorbent. As can be seen in Figure 1 the dynamic cycle model, using reaction kinetics and a water adsorption isotherm from literature, adequately describes the experimental results. An elaborate model study, supported by experimental work, shows an operating window for the SEDMES process. For example, Figure 2 shows a process trade-off between carbon selectivity and productivity for various space velocities. The working capacity is a key parameter for optimizing the SEDMES process. Improving this capacity can be done by optimizing the reactive adsorption conditions, such as the space velocity, and by optimizing the inherent regeneration procedure.

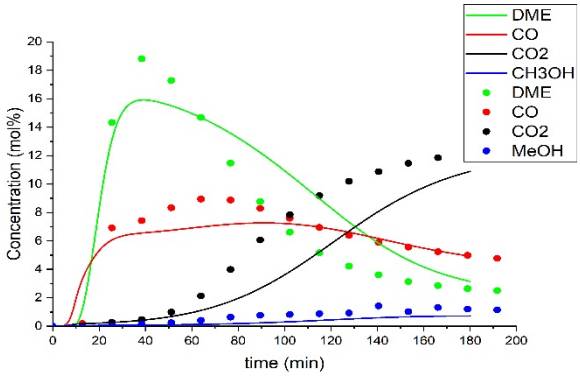

Figure 1. Breakthrough experiment (points) and model prediction (lines) at 40 bar(a), 275 °C, feed H_2:CO:CO_2 = 8:1:2 (regeneration to 400 °C)

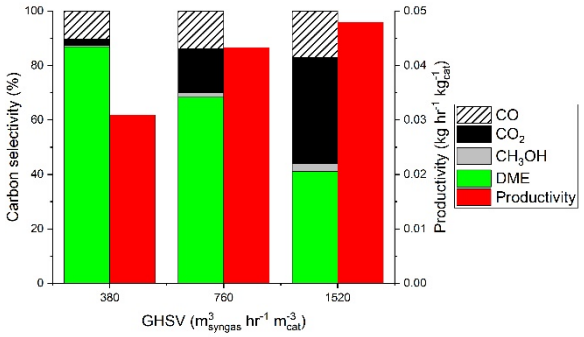

Figure 2. Model carbon selectivity vs. productivity for GHSV of 380, 760 and 1520 hr^{-1} at 30 bar(a), 275 °C, feed H_2:CO:CO_2 = 8:1:2 (regeneration to 400 °C).

In parallel to the dynamic SEDMES cycle model development, different commercial catalysts and steam adsorbents are tested and prove to be promising for further development of the process to industrial relevant conditions. Experimental campaigns, more than 100 cycles without observed degradation, support the model study indicating high carbon efficiency to DME and reduced CO_2 content in the product for a typical SEDMES operating window. The testing focuses on obtaining relevant data as input for validation and tuning of the SEDMES model, which in turn is used for the scale-up of the SEDMES process towards full cycle validation with continuous DME production.

4. Conclusions

The SEDMES process is a promising process intensification, easily achieving 70% single-pass DME carbon yield and minimal CO_2 by-product formation for a three reactor column system. This increased single-pass conversion requires less downstream separation, and smaller recycle streams especially for a CO_2-rich feed. Within EU Horizon 2020 project Fledged, further optimization of the SEDMES process is pursued by experimental and modelling studies.

Highlights

- Synthesis of DEC from ethanol and CO_2 is promising concerning the environmental aspect.
- This study highlights the use of pervaporation to dehydrate the reaction mixture.
- A circulation loop is used to remove continuously water molecules.

1. Introduction

Because of its low toxicity and high biodegradability, diethyl carbonate (DEC) has many potential applications like fuel additive, solvent or monomer. Nowadays it is produced mainly by phosgenation of ethanol, which uses toxic and harmful chemicals [1]. Several new synthesis are developing but the most interesting one concerning the environmental aspect and the sequestration of CO_2 is the carboxylation of ethanol with CO_2 represented in figure 1 [2]. However, yields obtained in the literature for this reaction are still low whatever the catalyst used because of the unfavourable thermodynamics of the reaction [3]. To improve this yield, we can move the equilibrium toward the formation of the diethyl carbonate by removing water molecules produced during the reaction. Our work is focused on the utilisation of a physical way to dehydrate: the pervaporation. This method, which uses a hydrophilic membrane to dehydrate the reaction mixture, is slightly studied in the literature [4].

Figure 1. Ethanol carbonation with CO_2

2. Methods

A 100 mL batch reactor was used to study the reaction of carboxylation of ethanol with CO_2 with cerium oxide (CeO_2) as catalyst. A membrane cell with a membrane PERVAP 4100 purchased from DeltaMem were used to study the dehydration of the solution. The permeate side pressure is maintained at 2 mbar with a vacuum vane pump and the permeate is condensed in two cold traps immersed

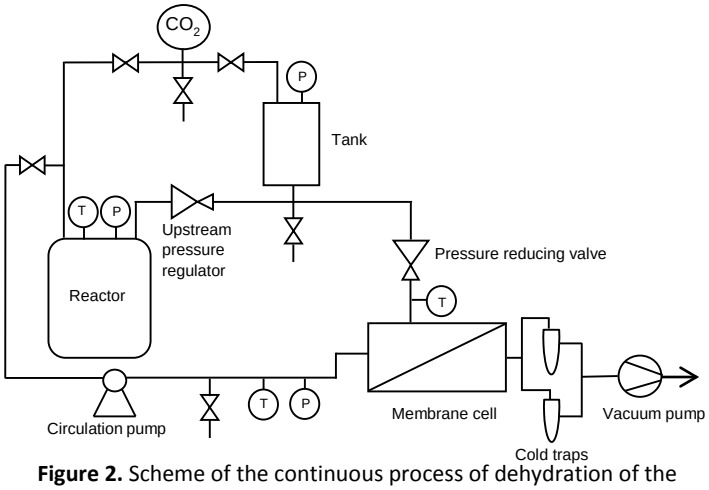

Figure 2. Scheme of the continuous process of dehydration of the reaction mixture of the carbonation of ethanol

in liquid nitrogen. The whole process used to study the dehydration of the reaction mixture in continuous is described in figure 2. As the reaction occurs at high pressure (between 20-50 bar), we used pressure reducing valves to ensure that the pressure on the membrane stays below 4 bar.

3. Results and discussion

A parametric study of the reaction was performed in the reactor to develop a kinetic model. Temperatures from 95 to 125 °C, pressures from 10 to 60 bar and different compositions of water or DEC were tested. The thermodynamic equilibrium was defined based on these experiments. Different mechanisms like Langmuir-Hinshelwood or Eley Rideal were used to develop the kinetic models. The dehydration on the membrane PERVAP 4100 of different solutions was performed. We studied the influence of temperature, pressure and composition in the retentate on the selectivities and fluxes of the membrane. Figure 3 represents an example of the results obtained on the influence of the temperature on the reaction (left) and on the dehydration of an ethanol-water solution (right).

We performed a parametric study on the whole process (figure 2) to optimize the parameters of the continuous dehydration. With this parametric study we can work with a larger range of composition because the amount of DEC is continuously increasing while the amount of water is decreasing. Results obtained are slightly different from the results obtained from the study of the two equipments separately because of the circulation loop. Indeed, temperature and pressure change all along the loop to respect the equipment characteristics and the volume of the solution in the reactor is lower because of the volume of solution in the loop.

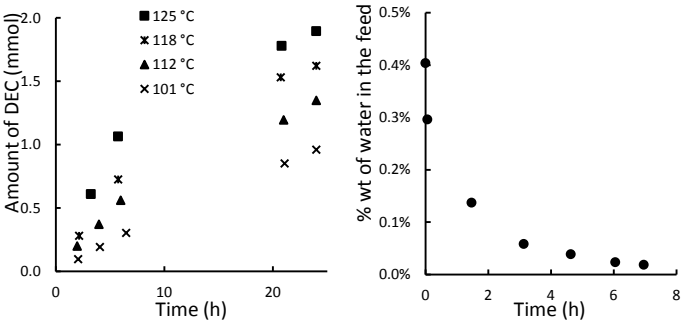

Figure 3. Left: production of DEC during reaction at different temperatures. Right: dehydration of 80 mL of an ethanol-water solution with 0.40% wt of water

4. Conclusions

This innovative work using pervaporation to dehydrate the reaction mixture of carboxylation of ethanol gives promising results. The circulation loop leads us to test the dehydration of the reaction mixture continuously. Temperatures, pressures and loop flow rate are the most important parameters to improve the performances and obtain better yields in DEC.

Maximising carbon efficiency through steam separation enhancement: carbon recycling into carbon monoxide, methane, methanol, DME

Jasper van Kampen[1], Jurriaan Boon[1]

1 ECN part of TNO, Westerduinweg 3, Petten, The Netherlands

**Corresponding author: jurriaan.boon@tno.nl*

Highlights

- Development of steam separation enhanced processes for utilisation of CO_2.
- Development of sorption-enhanced synthesis of CO, DME, and CH_4.
- Development of membrane-assisted methanol and DME.
- Steam separation enhancement key to maximising carbon efficiency CCU process.

1. Introduction

The capture and utilisation of CO_2 (CCU) presents important opportunities for industry in support of climate change objectives, circularity, the large-scale storage of renewable electricity, and emerging CO_2 capture processes [1]. While the relevant products in a CCU scheme can be rather conventional, such as carbon monoxide, methane, methanol, and DME – an optimised CCU value chain requires breakthrough innovation in (among others) the catalytic conversion steps involved in their production. Here, we propose the development and scale-up of steam separation enhanced processes for the utilisation of CO_2.

Conversion of CO_2 with H_2 involves the production of H_2O by-product, and reactions are generally equilibrium limited. By the principle of Le Chatelier, the in situ extraction of H_2O from the reaction mixture will result in a shift of the equilibrium to the product side and enhance the conversion [2]. Figure 1 shows the increase in product concentration for several reactions under representative conditions. Additionally, the reduction in steam partial pressure may improve catalyst performance.

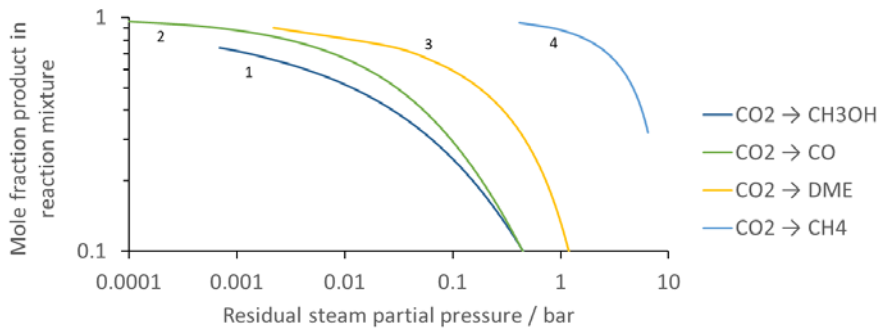

Figure 1. Molar fraction of product for stoichiometric H_2/CO_2 feed for the production of (1) methanol at 250 °C, 30 bar; (2) CO at 300 °C, 10 bar; (3) DME at 275 °C, 30 bar; (4) CH_4 at 300 °C, 10 bar.

Use of high-temperature steam adsorbents and steam permselective membranes will be shown to increase the carbon efficiency by intensification of the production of CO, CH_4, methanol, and DME.

2. Methods

CO, DME, and CH_4 have been produced in fixed bed temperature and pressure swing adsorption processes involving commercial catalysts and LTA zeolites. Methanol and DME are being investigated using ceramic-based membranes. In parallel, 1-D reactor models were developed in order to facilitate data interpretation, reactor design, and process scale-up.

3. Results and discussion

A combined approach of experimental scale-up and model development has been proven successful in the development and scale-up of steam separation enhanced processes. The processes mentioned above will be highlighted from the perspective of maximising the carbon efficiency of the CCU scheme. Exemplary results include (I) CH_4 synthesis by operating conventional methanation and sorption-enhanced methanation in series to allow for a remaining unconverted hydrogen concentration of < 0.1 mol% (Figure 2a), and (II) DME synthesis with an increased single-pass conversion and reduced CO2 content in the product for all syngas compositions and especially for H_2/CO_2 feed (Figure 2b).

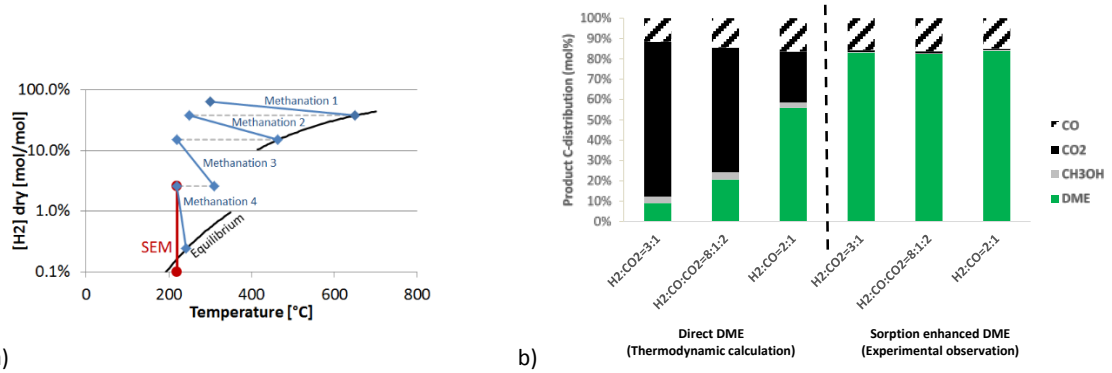

Figure 2. (a) 3 methanation reactors supplemented by sorption-enhanced methanation reach the unconverted H_2 specification of < 0.1 mol% (b) experimentally obtained increase in carbon selectivity to DME in sorption-enhanced DME synthesis relative to thermodynamic equilibrium for three different stoichiometric feed compositions at 275 °C, 40 bar.

It will be shown that crucial aspects in general for reactive steam permeation are the hydrothermal stability of the membranes and their permselectivity, whereas high temperature working capacities and heat management are crucial aspects for reactive steam adsorption. The peculiarities of the highlighted processes will however also demonstrate more specific learnings by, and necessity of, a strong interaction between experimental scale-up and reactor modelling.

4. Conclusions

Steam separation enhanced processes production of CO, CH_4, methanol, and DME have been demonstrated to improve the conversion and the carbon efficiency in the context of CCU.

Electric Steam Reforming – Reduction of CO_2-Emissions by Integration of Renewable Energy into the Steam Reformer

Peter Mølgaard Mortensen, Kasper Emil Larsen, Charlotte Stub Nielsen, Kim Aasberg-Petersen*

Haldor Topsøe A/S, Haldor Topsøes Allé 1, DK-2800 Lyngby, Denmark

**Corresponding author: kap@topsoe.com*

Highlights

- Electrically driven steam reformer
- Significant reduction of CO_2-emissions
- Highly compact

Through the last 20 years, a continuously increasing focus has been on how to limit the human impact on pollution, where especially CO_2-emission has been linked to a global impact on the climate. In parallel, sustainable electricity has made a significant technology leap and sustainable electricity production by wind and sun has become economically feasible. This development is an encouragement to rethink already existing technologies used in the chemical industry.

Many bulk chemicals, including for example methanol, acetic acid, and ammonia, are today produced in a process with multiple steps. Often the first step is steam reforming of natural gas to produce hydrogen or synthesis gas (a mixture with mainly hydrogen and carbon monoxide) followed by the actual synthesis and purification. A key process to produce synthesis gas is steam methane reforming (SMR). This is a strongly endothermic process requiring considerable fuel combustion to reach the desired exit temperature and methane conversion. According to some sources, SMR may account for nearly 3% of global CO_2 emissions. Hence, there is a considerable incentive to modify the technology to reduce the climate impact.

Several initiatives have improved the efficiency in synthesis gas based chemical plants in recent years. These include the use of bayonet type steam reformers, heat exchange reformers, and the use of electrically driven utilities. All of these improve the efficiency thus reducing the CO_2-emissions. However, the extensive use of fuel combustion for the SMR remains. This work presents a novel approach by which electricity is integrated into the steam reformer almost eliminating the need for fuel combustion.

The development of a compact electrically heated steam reformer integrating electricity into the catalyst will be described. Proof of concept experiments will be presented along with CFD and reactor analysis to demonstrate the performance of the technology.

Process development studies have been carried out in parallel to the experimental activities. These studies have been performed for production of hydrogen and carbon monoxide and for various

chemicals. Both natural gas and bio-derived feedstock have been considered. As an example, for a hydrogen plant the electric reformer offers a solution which:

- Uses up to 35% less natural gas compared to a tubular reformer.
- Has up 95% less CO_2 emissions compared to a tubular reformer based hydrogen plant.
- Is significantly more compact in size.

An economical analysis indicates that the electric reformer could be cost competitive to the more classical routes for chemicals production. The actual transition for when the electric reformer would be cheaper than the more traditional fired steam reformer depends on the prices of electricity and feedstock. The use of electricity is in most case more than 70% lower compared to alkaline electrolysis.

The presentation will describe the development of the electric reformer with selected experimental results. The potential of replacing the fired steam reformer with an electric steam reformer will be presented based on process economical calculations in comparison with state of the art technologies. Finally, the perspectives of the new technology as a means to reduce human climate impact will be discussed.

Scenario analysis of carbon capture, utilization (particularly producing methane and methanol) and storage (CCUS) systems

Grazia Leonzio[1], David Bogle[2], Edwin Zondervan[3], Pier Ugo Foscolo[1]

1Department of Industrial and Information Engineering and Economics, University of L'Aquila, L'Aquila, Italy; 2 Centre for Process Systems Engineering, Department of Chemical Engineering, University College London, London, UK; 3 Laboratory of Process Systems Engineering, Department of Production Engineering, Universität Bremen, Bremen, Germany

**Corresponding author: grazia.leonzio@graduate.univaq.it*

Highlights

- Exploring new proposed model for the carbon capture utilization and storage supply chain.
- Optimal layouts for carbon supply chains in Germany and Italy
- Product revenues and incentives strongly influence the supply chain design.

1. Introduction

A carbon dioxide economy has been proposed, characterized by the use of renewable energies as the basis for a circular economy. Atmospheric carbon dioxide reduction can be achieved by storage or by utilization: through production of methanol, methane and a range of other products [1]. Leonzio et al. [2, 3] developed a CCUS supply chain model including options of storage and utilization. The model has been developed for Germany including methanol, concrete, wheat, lignin, polyurethane, calcium carbonate, urea and also for Italy where methane is produced. In paper we evaluated the effects of a carbon tax, economic incentives and revenue on the system outputs of supply chains in Germany and Italy.

2. Methods

The mathematical model was used to determine optimal volumes of captured CO_2 and products [2, 3] and CO_2 sources they should be taken from. The objective function is the sum of total costs less the revenues, carbon tax and economic incentives. The mixed integer linear programming models are solved in AIMMS software.

3. Results and discussion

A local sensitivity analysis was carried out for the CCUS supply chain in Italy considering three levels of carbon tax (20 euro/ton, 40 euro/ton and 80 euro/ton) and economic incentives (240 euro/MWh, 270 euro/MWh and 300 euro/MWh). The minimum target for CO_2 reduction is 77 Mton/year; CO2 that is not captured is released into the atmosphere. Results (Table 1) show that system source locations change with tax rates and economic incentives. Also the total value and methane production are affected: at low, average and high level of these parameters the total values are respectively 12.8 billion euro/year, -2.43 billion euro/year and -70.7 billion euro/year, while methane production is 22.5 Mton/year, 22.5 Mton/year and 101.8 Mton/year. For high values

of tax and economic incentives at optimal profit all possible CO_2 is captured and sent to the utilization section. Results for changing only carbon tax show that only the total value is affected, while system topology (CO_2 source locations) and methane production are constant.

Carbon tax/ Economic incentives	To utilization (methane production)						To storage		
	Low values		Average values			High values	Low values	Average values	High values
CO_2 source	Puglia	Sicily	Sicily	Veneto	Sardinia	All regions	Lombardy	Lombardy	-
Capture technology	MEA	MEA	MEA	MEA	MEA	MEA	PSA	MEA	-
CO_2 captured (Mton/year)	61.8	0.024	37.4	20.3	4.17	279	15.2	15.2	-

Table 1. Results of sensitivity analysis for CCUS supply chain in Italy with Malossa San Bartolomeo as storage site

Similar results are found for the CCUS supply chain producing only methanol in Germany (Table 2). The minimum target for CO_2 reduction is 160 Mton/year and CO_2 not captured is released into the atmosphere. The total value is 16.3 billion euro/year, -30 billion euro/year and -0.197 trillion euro/year respectively for the low, average and high level of the parameters, while methanol production is respectively 203 Mton/year, 968 Mton/year and 968 Mton/year. A sensitivity analysis was again performed: results show that when changing the price of methanol the total value is changed with system topology.

Carbon tax/ Economic incentives	To utilization (methanol production)			To storage		
	Low values	Average values	High values	Low values	Average value	High values
CO_2 source	Dusseldorf	All regions	All regions	Magdeburg	-	-
Capture technology	MEA	MEA	MEA	MEA	-	-
CO_2 captured (Mton/year)	140	665	665	20.3	-	-

Table 2. Results of sensitivity analysis for CCUS supply chain producing only methanol in Germany

For a CCUS supply chain producing different products in Germany it was found carbon tax and revenues lead to a full possible capture of CO_2 and all CO_2 is sent to utilization. For increased carbon tax only the total value is increased. Changing the sales prices of products according to market value causes predicted values for lignin and wheat production change.

4. Conclusions

For the cases studied in this work carbon tax affects only the total value while changing economic incentives and product revenues also changes the system topology. Model optimization is a useful decision support tool for CCUS investment decisions.

Highlights

- VOC of different hydrophobicities were correctly removed by absorption in PDMS
- PDMS regeneration in a pilot-scale TPPB in a continuous mode was efficient for the studied loads
- After several cycles of PDMS regeneration in the process, absorption performances were preserved

1. Introduction

Volatile Organic Compounds (VOC) have harmful effects on both environment, through their global warming contribution, and human health. Several kinds of treatments are possible to remove VOC from air, including adsorption, thermal and catalytic oxidations, absorption and biological processes such as biofilters. Adsorption and oxidation can be very expensive and energy-consuming technologies for large flow rates with low concentrations in VOC, whereas biological processes present low operating costs and are adapted to the treatment of large VOC flow rates at low concentrations; but these latter are mainly suitable for water-soluble compounds removal [1]. For hydrophobic VOC, absorption in a non-aqueous phase (NAP) is possible [2]. Nevertheless, this NAP must be regenerated to reduce the operating cost of the installation. Regeneration methods, such as classic distillation or stripping at high temperature and low pressure can be applied, but they are energy-consuming. Performing a biological regeneration in a Two-Phase Partitioning Bioreactor (TPPB), a multiphasic bioreactor containing microorganisms able to degrade the absorbed VOC [3] would be much cheaper and more eco-friendly. The process studied in this work consists of the combination of VOC absorption in a packed column and biological regeneration of the liquid absorbent (NAP) followed by a separation device insuring a good separation between water, oil and sludge. Th**rough** an industrial partnership, the combined process was tested on a realistic application for the treatment of ~~a~~ complex mixture of different VOC at varying inlet concentrations.

2. Methods

The inlet gas consisted of a mixture of molecules of different chemical natures: alkanes, esters, alcohols, ketones and monoaromatic compounds. The NAP used was silicone oil,

(Polydimethylsiloxane, PDMS), having a viscosity of 20 mPa.s. The pilot unit included a column (diameter 0.15 m, height 1.3 m) packed with a random packing (IMTP), a bioreactor loaded with waste water plant activated sludge (total volume of 1.25 m^3, with 25% v/v of PDMS), a conical settler and a centrifuge (16,000 rpm). The total VOC concentration was measured at the inlet and the outlet of the column owing to a PID (Photo-Ionization Detector, IonScience). The overall pilot unit ran 8 hours a day and 4 days a week.

3. Results and discussion

Figure 1 shows the inlet (red squares) and outlet (blue diamonds) total VOC concentrations of the packed column during 160h of operation. Even if the inlet concentration varied between 5 and 450 mg.m-3 in total carbon (TC) with an average of 150 mg.m-3 TC, the outlet concentration stayed most of the time below 50 mg.m-3 TC, showing the performance of the process. After more than 150h of use, given that the total residence time of PDMS (both for absorption and regeneration) is about 15h, PDMS was biologically regenerated 10 times in the process. Looking at steady VOC removal performances, the studied process was efficient for PDMS biological regeneration. Further trials will be investigated in order to know if each VOC is well degraded and operating parameters will be optimized to improve the VOC removal yields.

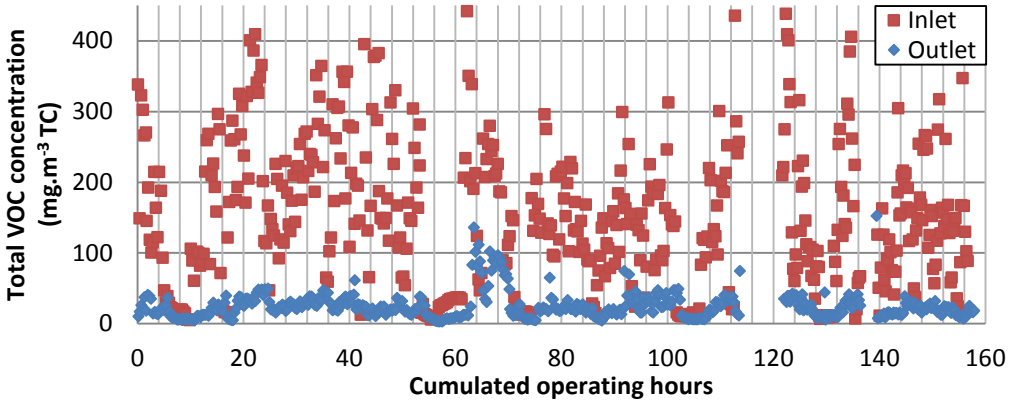

Figure 1. Total VOC concentration at the inlet and the outlet of packed column

4. Conclusions

The combination of VOC absorption in a packed column and PDMS regeneration in a TPPB showed that the early results are satisfactory towards VOC removal. Absorption performances were preserved after several cycles of PDMS regeneration and proved that biological regeneration is suitable to recycle NAP.

Highlights

- AcoD of sewage sludge and industrial wastewater increase biomethane yield.
- COD reduction for both sludge and wastewaters was observed.

1. Introduction

The depletion and environmental impact of conventional fuel in form of greenhouse gases has led to the systemic shift on its dependence for generation of energy into alternative means known as renewable energy. In contrast, food industries are said to utilize large volumes of water daily in their production processes which in turn leads to increase wastewater generation [1]. The characteristics of these wastewater make them a potential source for generation of renewable energy when appropriate technology is applied [2].

This study is geared towards the use of industrial wastewater as co-substrate for digestion of sewage sludge (SS) while optimizing the process parameters to maximize biomethane production and minimize organic pollutants.

2. Methods

Anaerobic co-digestion (AcoD) techniques were employed in this study. The substrates considered were municipal SS, sugar wastewater (SW) and dairy wastewater (DW), while anaerobic digested sludge from the municipal treatment plant was used as the inoculum. Characterization of the substrates were done following the standard procedure for wastewater by APHA [3] for total solid (TS), volatile solid (VS), chemical oxygen demand (COD), mineral nutrients and volatile fatty acids (VFAs) in duplicate.

In order to achieve a good dilution, the ratio of wastewater to sludge used was 3:2 base on volume while the inoculum to substrate (ISR) ratios were varied at 1:2, 1:1 and 2:1. The digestion process was run at 25 and 35^{o}C and as semi-batch so as to accommodate for weekly analysis of the digestion assays for pH, solids and COD.

Gas analyses were carried out every 2 – 3 days to determine the composition of the biogas produced using gas chromatography. Bioreactors with a working volume of 5L were used for the digestion process. Two sets of bioreactors contain varying organic loading were set up in duplicate with a control.

3. Results and discussion

Characterization result indicate that the industrial wastewaters have high COD, VS and substantial minerals for improve microbial activity. The pH, VS, COD and ammonium content of SW were 6.30, 75.6 (%TS), 1778mgL^{-1}, 0.59 and 0.39, respectively while that of DW was 9.10, 86.4 (%TS), 3012.5mgL^{-1}, 0.38 and 0.71 respectively.

Figure 1 shows the preliminary yield of biomethane on a daily basis from each assay. The results reveal that the maximum production was obtained within the first 20 days of the digestion process and that the sugar wastewater has the highest methane content of 73% as compared to 70% for the dairy and 65% for sludge.

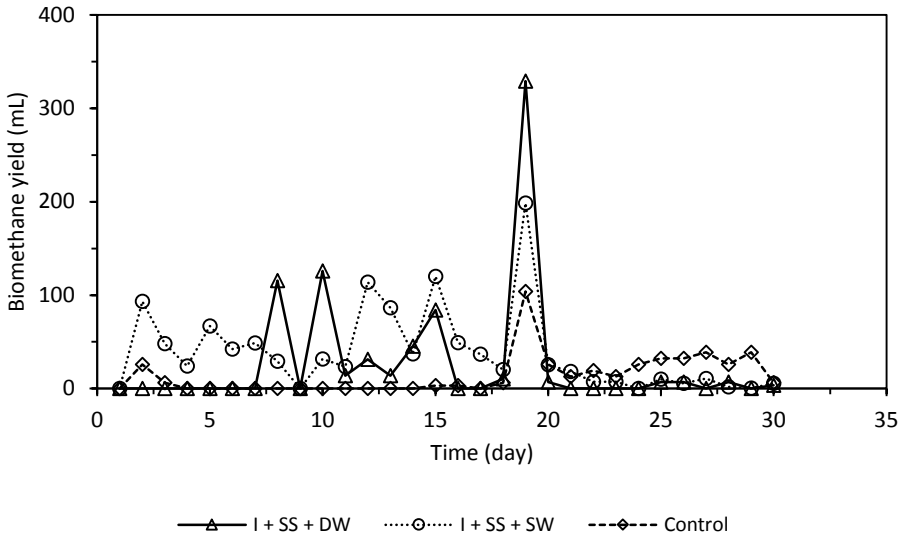

Figure 1. Daily biomethane yield at 35°C.

4. Conclusions

Preliminary analysis indicated that sugar wastewater co-digestion was more efficient for biomethane production as compared to dairy wastewater. Likewise, results show that co-digestion of sewage sludge helps in the reduction of VS and COD content. COD reduction was observed for both wastewaters and sewage sludge.

Recovery of Phosphorus from Sewage Sludge and Subsequent Purification Using Reactive Extraction.

Zaheer Ahmed Shariff, Laurent Fraikin, Angélique Léonard, Andreas Pfennig

Department of Chemical Engineering, University of Liège, Belgium

**Corresponding author: za.shariff@uliege.be*

Highlights

- Development of new process for the recovery of phosphorus from partially or fully dried sludge
- Removal of heavy metals during purification by reactive extraction
- Solid-liquid equilibrium modelling in MATLAB for process optimization

1. Introduction

Phosphorous (P) is an essential element for life and has a limited availability in nature. Mineral P is mainly produced from phosphate rock, which was classified by the European Commission as a critical raw material in 2014. As a result, significant research has been directed towards finding economical ways of recycling P from waste streams which otherwise would be lost to landfills. The Phos4You (P4Y) project, funded under the Interreg North-West Europe Program, is aiming at improving the recovery potential of P from municipal wastewater and sludge, which could substitute for about 26% of mineral P demand in NWE.

In the framework of the P4Y project 6 different technologies for recycling of P will be demonstrated on pilot-plant scale. The university of Liège is developing one of the processes to be demonstrated which is called the PULSE (Phosphorus ULiège Sludge Extraction) process to recover P from fully or partially dried sewage sludge. The PULSE process is a modification of the PASCH process developed at RWTH Aachen to extract P from ashes obtained by incineration of sewage sludge [1]. Acidic extraction (leaching) of sludge or ashes is one of the most common method used for recovering P, however one big challenge is that the acidic leaching also results in dissolution of detrimental metals. Therefore, the removal of metals or purification of leach liquor is required before proceeding to the final step where final P products can be obtained either as salts of calcium or magnesium (struvite) by precipitation or as phosphoric acid.

2. Methods

At ULiège, the recovery of P from partially or fully dried sludge is carried out using acidic leaching. The process is optimized by systematic variation and combinations of different acids, pH, concentration of oxidizing agent, and drying levels. For the purification of the leach liquor, two approaches are tested using reactive extraction: extraction of metals from the leach liquor and extraction of P itself while leaving behind the metals in the aqueous phase. For this purpose, different extractants have been selected based on their extraction mechanism and tested for extraction efficiency. Further, different diluents were tested in order to find the best option in terms

of efficiency of extraction and toxicity, which are compared to at least one bio-diluent such as bio-diesel. Finally, depending on the extraction approach used above, the final product of the PULSE process can either be obtained as phosphate salt or phosphoric acid.

In the first part of the research, the experiments for determining the best process options for each of the unit operation of the PULSE process are conducted at lab-scale applying the cascaded option-tree methodology [2] for guiding through the process development. A solid-liquid equilibrium speciation model developed in MATLAB is used for optimizing process parameters for leaching, extraction, and precipitation.

3. Results and discussion

The leaching of P from dried sludge mainly depends on the pH of the leaching solution, while the type of acid used has little to no influence. The degree of drying and the drying temperature also affect the leaching of P. For the removal of metals, different extractant and combinations were tested. The extraction of metals strongly depends on the type of extraction mechanism, pH of the aqueous phase and also the metal complexes that exist in the aqueous phase. The code written in MATLAB simulates the pH and complexes existing at the corresponding pH. This information is further used to optimize the process conditions.

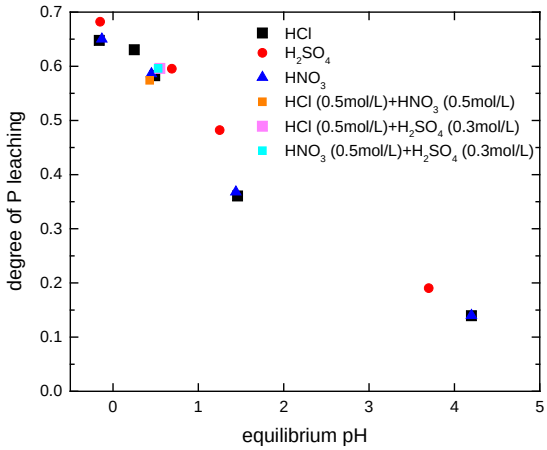

Figure 1. degree of P leaching from fully dried sludge with different acids

4. Conclusions

Drying results in ease of handling and storing of sludge, reduces the consumption of acid required for leaching and also filtration of solids after leaching is much easier. The leaching of P from undigested sewage sludge is optimal at a very low pH < 1. At this pH other metals and heavy metals are also leached, which have to be removed before producing the final P product. In the PULSE process metals are removed by using reactive extraction and finally salts of calcium phosphate are precipitated.

Highlights

- Municipal solid waste
- Biorefinery
- Fumaric acid production
- *Candida blankii*

1. Introduction

Valorisation of renewable resources is nowadays crucial for the production of bio-based products (chemicals, polymers and fuels) through fermentation. The biodegradable fraction of municipal solid waste (MSW) represents a potential low-cost feedstock for the production of bio-based products. Waste composition varies greatly across the world, depending on the level of socio-economic development. Bio-based fumaric acid production is mainly conducted with fungal fermentation on solid or liquid cultures. There are many challenges on fungal fermentations (like oxygen transfer, pellet generation etc) that could be faced by utilising yeasts. The aim of this work is the valorisation of biowaste fraction of MSW, for the production of fumaric acid. The sugar fraction was hydrolysed with crude enzymes that were previously produced by solid state fermentation using a fungus, *Aspergillus awamori*. The resulting hydrolysate was used as a nutrient supplement that contained assimilable sugars, free amino nitrogen (FAN) and inorganic phosphorus (IP). Bioconversion of sugars to fumaric acid was carried out using *Candida blankii*, a natural fumaric acid yeast strain. Fed-batch fermentations were conducted with the MSW hydrolysates in order to optimise the final fumaric acid production, yield and productivity. Separation of fumaric acid and electrocatalytic conversion of fumaric acid to succinic acid was achieved with membrane electrolysis, a novel electrochemical extraction technique in which electrodes are present in the fermentation broth to drive (bio)electrochemical reactions while utilising the electro-motive force to transport charged acid salts from a cathode across an anion exchange membrane (AEM or CEM) into a low volume, acidic anode solution.

2. Methods

The organic fraction of municipal solid waste (OFMSW) contained food waste and yard waste from selected households. Solid state fermentations were carried out with the fungal strain *Aspergillus awamori* at different initial moisture contents (50, 55, 60, 65 and 70%). OFMSW hydrolysates were

produced by mixing varying quantities of OFMSW with the enzyme-rich suspension. OFMSW hydrolysis was conducted at 55 °C with 100 g/L final solid concentration. Value added products were extracted from the raw material using hexane for lipid fraction, ultrafiltration with 3 kDa membrane for protein fraction and treatment with acidified ethanol for pectins. The remaining solids were hydrolysed utilising extracted crude enzyme consortia that were previously produced by solid state fermentation (SSF) using *A. awamori*. The hydrolysate was finally used as a substrate for fumaric acid production through microbial fermentation by *Candida blankii*. Fumaric acid was further converted to succinic acid in the fermented broth using an electrochemical bioreactor.

3. Results and discussion

OFMSW has been used as the sole substrate for the production of crude enzyme consortia via solid state fermentation of *Aspergillus awamori*. Glucoamylase, cellulase, cellobiase, invertase, phytase and protease enzyme activities were determined in order to select the optimal initial moisture content of 55%. Extraction of lipids, proteins and pectins was evaluated using untreated or enzymatically treated OFMSW and material balances were estimated in order to identify the optimal refining scheme. The OFMSW carbohydrates were enzymatically hydrolysed and the sugar-rich hydrolysate was used for fumaric acid production via fermentation with the yeast strain *Candida blankii*. Fumaric acid production exceeded 40 g/L and electrocatalysis was applied for its conversion and separation of succinic acid with a conversion yield of 80 %.

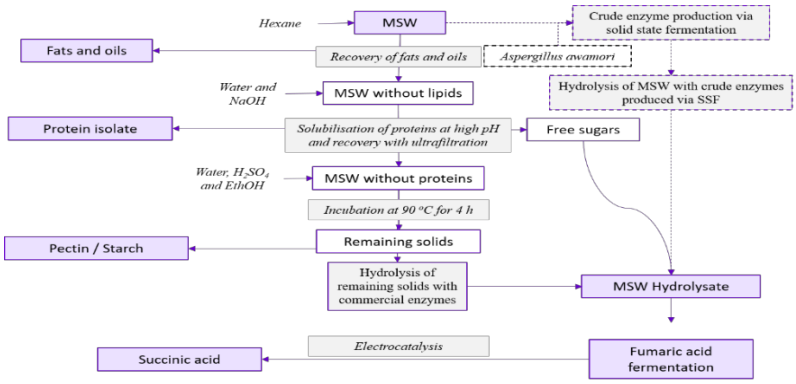

Figure 1. Biorefinery development of MSW

4. Conclusions

OFMSW was used for the production of crude enzyme consortia and fumaric acid. Value added co-products were recovered from OFMSW hydrolysate. Electrocatalytic conversion of fumaric acid to succinic acid was achieved via an electrochemical bioreactor.

Decentralized plastic waste recycling through pyrolysis – a feasibility study

Johan M. Ahlström[1], Ivar Petersson[1], Andreas Svensson[1], Simon Harvey[1], Stavros Papadokonstantakis[1*]

1 Chalmers University of Technology, 412 96 Gothenburg, Sweden

**Corresponding author: stavros.papadokonstantakis@chalmers.se*

Highlights

- Decentralized recycling of plastic waste.
- Process modeling and techno-economic assessment
- Pyrolysis of pure and mixed plastic fractions

1. Introduction

Plastic materials play a major role in society but pose certain challenges. Accumulation in nature has adverse effects on wildlife, and most plastics are currently produced from fossil resources which contradicts the demands on climate change mitigation stated by the UN. Today, a large part of plastic waste is incinerated or landfilled [1]. Legislators are raising the bar for recycling rates, with the EU setting a target of 50 % recycling of plastic packages by 2025 [2]. While mechanical recycling of plastics is efficient, it requires high feed purity and cannot be repeated indefinitely as the material degrades slightly over each cycle.

Meanwhile, thermo-chemical processes like pyrolysis and gasification can decompose plastics into their basic monomers, with lower requirements on feed purity. Pyrolysis of mixed plastics to obtain pyrolysis oil is well researched and companies are presently trying to commercialize the process [3, 4]. However, the potential for pyrolysis of pure plastic streams requires further research. Through pyrolysis, polymers like polystyrene (PS) and poly methyl methacrylate (PMMA) can be cracked into their monomers and repolymerized, allowing a less complex process design [5, 6]. The profitability of such a process will depend on how it is designed, as well as the scale of the plant.

The purpose of this study is to investigate the economic incentives for decentralized recycling of plastic waste, both in pure and mixed plastic fractions. There is a contradiction between achieving the economic benefits of a large process and transport associated costs relating to the corresponding geographical area from where the plastic feedstock is gathered. It is therefore of interest to investigate how a pyrolysis process can be designed to handle different types of plastic waste efficiently, and how large the plant would have to be to achieve economic feasibility. This study uses the Gothenburg region as a reference regarding waste flows, to assess the economic feasibility of implementing different pyrolysis-based processes.

2. Methodology

A literature study is conducted to estimate the quantity of plastics available in the region, and its composition with respect to different polymers. The mass and energy balance of the potential pyrolysis processes are attained through process modeling using process flow sheeting software

Aspen Plus. Knowledge of the product stream composition from different polymers are attained through published literature on experimental studies on pyrolysis of polymers. The most promising polymer feeds are chosen based on the availability of polymer and the benefit of pyrolyzing it separately, i.e. polymers that generate a product with a high share of valuable chemicals. The pyrolysis reactor mass and energy balance are calculated explicitly to mimic published results. Downstream process equipment required to separate and/or refine the products into saleable fractions are rigorously modelled.

The concept of constructing a flexible process which can use different pure plastic streams as well as mixed plastic streams is compared to processes handling a single type of plastic. Capital investment cost is estimated applying the Taylor method [7] as well as using the cost estimation tool in Aspen plus to get a larger span of the capital investment cost. Along with the feedstock and operational costs, the product revenue and economic performance is estimated for each process.

The economic performance depends on the recycling efficiency of the process. There is a tradeoff between product purity and capital costs; recovering more of the products and increasing purity generates more revenue but also requires more process steps and/or larger separation equipment. At a certain point, raising the recycling efficiency starts to have a negative impact on the overall economic performance. After optimizing the plant design, the size of the plant is varied to find the smallest size that is economically feasible, compared to the current waste handling system. The minimum size of the process is then compared to the size of available waste flows in the Gothenburg region, to assess the feasibility of implementation.

3. Results

Based on issues related to current waste treatment and potential value of the pyrolysis products, two types of pure plastic fractions have been identified as particularly interesting, Polystyrene for production of styrene and Polyvinylchloride (PVC) for production of HCl and alkanes or propene, depending on reactor temperature. These are compared to a mixed plastic fraction for production of ethylene.

Design and Conception of a Membrane Pilot Plant for the In-Situ Treatment of Bioleaching Solutions.

Roland Haseneder[1], Arite Werner[2]

1 TU-Bergakademie Freiberg, Institute of Thermal-, Environmental-, and Recourses´ Process Engineering Leipziger Strasse 28, 09599 Freiberg, Germany; 2 Helmholtz Institute Freiberg for Resource Technology, Chemnitzer Str. 40, 09599 Freiberg, Germany

**Corresponding author: roland.haseneder@tun.tu-freiberg.de*

Highlights

- Enhancing of sustainability by a new ore extraction downstream method
- In-situ treatment of leaching solutions by selective membrane technology.
- Presentation of a Membrane pilot plant located at an underground mine site.

1. Introduction

Regarding the advancement of the industrialized world, the demand of strategic elements for the production of high tech products is rising steadily. Furthermore, the worldwide deposits of high-grade ores are going to be depleted within the next decades. The acceptance for new mining activities in the industrialized countries is very low. Consequently, there are two possibilities: First to enhance the processing of low-grade ores, overburden and waste material from former mining activities. Second to use new mining technologies which are more environmental friendly due to the combination of direct winning of solubilized product stream and in-situ down-stream-processing. Biohydrometallurgy is technically and economically employed for the treatment of ore material with depleted metal content as well as increasing complexity (1-3) which finally leads to a more sustainable technology of winning valuable metals.

A testing site for in-situ bioleaching was established in an underground mine to recover indium and germanium from a zinc sulfide ore vein. The downstream processing of the resulting pregnant leaching solution (PLS) is also realized as in-situ application by means of a membrane pilot plant, which was exclusively designed for this special application (4).

2. Methods

In-situ bioleaching is performed at the research and training underground mine ‘‘Reiche Zeche’’ of the Technical University Bergakademie Freiberg. The ore vein is embedded in gneiss as host rock and its main constituents are galena (PbS), sphalerite (ZnS), pyrite (FeS2), arsenopyrite (FeAsS) and chalcopyrite (CuFeS2). Indium is naturally enriched in sphalerite due to geochemical reasons (5).

The PLS is characterized by high concentrations of the main metal ions zinc, iron and copper. On the contrary indium and germanium are less concentrated by several orders of magnitude. The in-

situ bioleaching site has been extensively characterized by geoelectric and seismic measurements to determine the spatial dimension of the ore vein.

The nanofiltration (NF) experiments for the technical design of the membrane pilot plant were performed in cross-flow mode with flat-sheet membrane NF99HF (Alfa Laval) using a synthetic leaching solution (Zn, Fe, Cu, Cd, Pb, In, Ge) to guarantee experimental conditions which are close to the real application.

3. Results and discussion

When performing lab scale NF experiments in continuous cross-flow mode within a pH range between 2 and 8, the separating behavior of Zn, In and Cu is nearly identical and the retention rate is above 70 %. In contrast, germanium shows a significantly lower retention rate in the pH range under review. The high retention of In, Zn, Cu and Fe indicate a positive membrane charge due to electrostatic repulsion between the positively charged metal cations and the membrane charge (6).

Based on the experimental investigations of about 4 years, a membrane pilot plant including a microfiltration and NF stage was designed and constructed for the in-situ treatment of the PLS at the first level of the research mine (-147m). Regarding the extreme environmental conditions in terms of high humidity, the design and choice of construction material was of special concern. Furthermore, due to the compact design of the membrane pilot plant there is only little space required, which is especially suitable for underground mines.

4. Conclusions

Within the scope of current research an in-situ bioleaching testing site has been installed at the research and training mine Reiche Zeche of the Technical University Bergakademie Freiberg including an in-situ treatment of the PLS by using membrane technology. The bioleaching aims to win indium and germanium from a sulfidic ore vein. Lab-scale NF experiments in cross-flow mode showed that the leaching solution is successfully concentrated without a loss of separation performance. The membrane pilot plant was finally designed and constructed based on experimental results with the continuous cross-flow membrane unit.

By using membrane technology in the underground mine PLS is efficiently treated regarding pre-concentration of the valuable metal ions as well as reducing the total amount of process water.

Optimization of Simultaneous Microwave-Ultrasound Assisted Extraction of Bioactive Compounds from Bark

Leyre Sillero[1]*, Raquel Prado[2], Jalel Labidi[1]

1 University of the Basque Country UPV/EHU, Department of Chemical and Environmental Engineering, Biorefinery Processes Research Group, Plaza Europa 1, 20018 Donostia-San Sebastian, Spain; 2 Imperial College London, Chemistry Department, Exhibition Road SW7 2AZ, London, UK

**Corresponding author: leyre.sillero@ehu.eus*

Highlights

- Pine bark was used as source for extraction of biomolecules.
- Potential use of simultaneous microwave-ultrasound assisted extraction (SMUAE) was demonstrated.
- Conditions for the optimum extractions were determined.

1. Introduction

Trees, which are constituted by wood and bark, are a very used natural source where bark is considered as waste. Taking into account that bark is about 9-15% of the total value of the tree [1] it could be consider as available cheap feedstock for biorefinery. Bark is a heterogeneous material and contain large number of bioactive compounds. These compounds could be applied in wide range of applications from bio-based material to pharmaceutical and chemicals.

The selection of an optimum extraction technique acquires a considerable importance due to the low amount of bioactive compounds present in tree barks. The most widely used technique is the solvent conventional extraction which require a huge amount of solvents, time and energy consumption. In order to improve the sustainability of the extraction process alternative extraction techniques are being investigated. Microwave assisted extraction (MAE) and ultrasound assisted (UAE) extraction are two of the most investigated options. They are considered as “Green techniques” because they permit the reduction of extraction time, volume of solvent and energy consumption leading to a higher extraction efficiency [2].

In this work, a simultaneous microwave-ultrasound assisted extraction (SMUAE) was studied and compared with the results obtained with a conventional extraction using pine bark (*Larix Decidua*). For that purpose, the optimization of the extraction yield was carried out varying the different parameters.

2. Methods

Larix Decidua bark was used with a particle size below 0.5 x 0.5 mm. The SMUAE was carried out in an ultrasound-microwave instrument (HIELSCHER UIP500hdT-MILESTONE flexiWAVE) using ethanol/water (50/50 (v/v)) mixture as solvent. Ten grams of dried bark were placed in a 500 mL borosilicate glass with a solid/liquid ratio of 1:10 (w/v). Before the extraction, the extracts were filtrated, and the yield of the extraction was calculated gravimetrically. The extraction yield was

studied changing different parameters values (reaction time (minutes), power of microwave (W) and power of ultrasound (W)).

3. Results and discussion

The preliminary results of SMUAE yield of pine (*Larix Decidua*) bark extracts are shown in a figure 1. The results of three different experiments are represented. The first experiment correspond to 5 minutes reaction, 300 W of microwave power and 100 W of ultrasound power, which match with the optimum point obtained by Luo for the extraction of phenolic compounds from walnut flour [3]. The second experiment correspond to the lower reaction time and the lower microwave and ultrasound power (1 min, 100 W and 50 W), and the third one corresponds to an intermediate between experiments 1 and 2 (5 minutes, 200 W for microwave and 100 W for ultrasound).

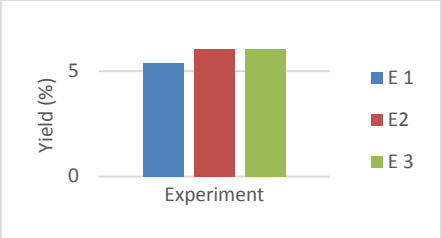

Figure 1. Extraction yield of the three experiments for the extraction of pine bark.

The highest extraction yield was obtained for the third experiment with a very close value to the obtained in the second experiment (6.06 % and 6.05 % respectively). The lowest value was obtained for the experiment with the highest power used in microwave and ultrasound with a value of 5.37%.

4. Conclusions

The lowest extraction yield could be explained by the degradation of the compounds due to the application of an excessive power. The comparison of the result of the first and third experiments confirm the possibility of that degradation. Further work is ongoing to optimize the extractions conditions.

Microwave assisted synthesis of levulinic acid using organic acids as green catalysts

Kinana Aliko, Naomi Adjaklo, Bilaal Ahmed, Paul D Topham, Eirini Theodosiou

Aston Institute of Materials Research, School of Engineering and Applied Science, Aston University, B4 7ET Birmingham, UK

**Corresponding author: Alikok@aston.ac.uk*

Highlights

- Lignocellulosic biomass is a viable feedstock for the sustainable production of levulinic acid.
- Organic acids combined with microwave technology show great promise as a fast and environmentally friendly levulinic acid production route.
- Using maleic acid, in the presence of aluminium phosphate catalyst, can yield up to 45% levulinic acid from biomass waste.

1. Introduction

The chemical industry is moving away from petroleum-based products and focuses on the production and processing of 'green' chemical building blocks. Levulinic acid is amongst these 'platform chemicals' that can be developed in a sustainable way from bio-based sources. It acts as a precursor to a plethora of products, including pesticides, pharmaceuticals, solvents, cosmetics and food additives [1]. The global levulinic acid demand is predicted to reach 3,820 tonnes by 2020, which is a 30% increase since 2013, generating 19.65 million USD revenue.

Until now, the commonest commercial process to produce levulinic acid from agricultural residues depends mainly on a two-stage mineral acids catalysed reaction [1-3], which generates harmful environmental waste. The development, therefore, of a green catalyst for the above reaction remains key to the improved production of levulinic acid.

In this work, we detail the development of an environmentally friendly levulinic acid production route from very cheap and renewable feedstocks, such as barley straw, olive cake, beer waste, tomato peel, spent tea leaves and potato peel. Our process relies on the use of organic acids as catalyst substitutes for the mineral ones. These acids are less corrosive to the equipment, decrease the formation of humin (the major by-product of the reaction pathway) and can be degraded to nontoxic molecules [4, 5]. Our thermo-chemical method uses microwave heating, which compared to traditional heating methods, reduces reaction time and enhances the reaction rate.

2. Methods

Seven organic acids were employed in this study, namely: maleic; acetic; oxalic; malonic; tartaric; formic; and, citric. Dried samples of various biomass waste feedstocks were treated with each of these acids in the presence of different catalysts. The reactions were carried out in a laboratory microwave unit (CEM Discover S-Class, CEM Corporation, USA). The liquid phase was analysed by ^{1}H NMR to identify the composition of the reaction mixture, and HPLC to quantify the yield of levulinic

acid. Design-Expert Ver.11 was used for Response Surface Methodology (RSM) analysis, based on the following variables: temperature; time; biomass to acid ratio; amount of catalyst; and, acid concentration.

3. Results and discussion

Initial experiments using $AlCl_3$ as a catalyst, indicated that of all the acids tested, maleic acid produces the highest yield of levulinic acid (35.7%; see Fig. 1). RSM optimization showed that temperature (T) and acid concentration (A) were the most significant factors, and levulinic acid yields increased to 42% (Fig. 2). Numerical optimization predicted the optimum yield of levulinic acid to reach 50% using the following reaction variables: 180 °C; 0.1 g catalyst; 38 min reaction time; 2 M acid concentration; and, 22 g/ml biomass to acid ratio. The effect of different catalysts (namely: aluminium phosphate, zeolite Y, aluminum chloride and aluminium sulfate) on the final yield was also investigated. Aluminium phosphate proved to be the best option, resulting in levulinic acid yields of up to 45%.

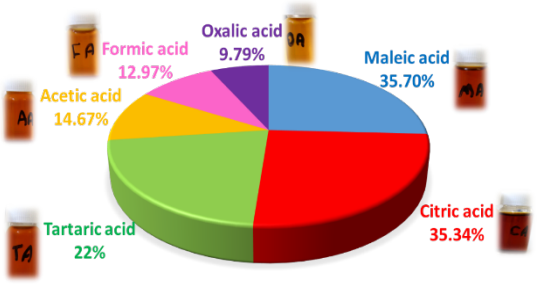

Figure 1. Levulinic acid production from barley straw using different organic acids and $AlCl_3$ as a catalyst.

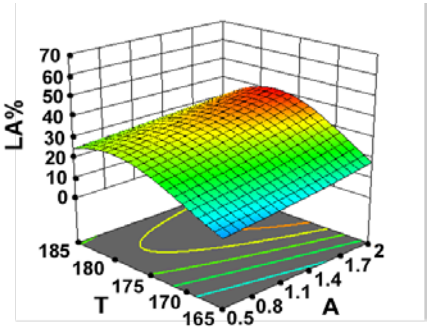

Figure 2. 3D surface plots of the effect of 2-way interaction variables on the yield of levulinic acid. Key: T (temperature, °C); and, A (acid concentration, M).

4. Conclusions

A green route using organic acids, with help of a Lewis acid, can be a viable option in the sustainable production of levulinic acid from inexpensive lignocellulosic biomass feedstocks. The additional use of microwave heating not only speeds up the reaction time, but is also a more environmentally friendly alternative to processes involving mineral acids.

Highlights

- Photocatalytic Oxidation of L-methionine was investigated with a RS-SDR
- High conversions were obtained with short residence times indicating possibilities for improvements in process sustainability
- Results were compared to conventional reactor systems

1. Introduction

In recent years, process intensification (PI) has been a promising pathway to achieve sustainable chemical production [1]. The rotor-stator spinning disc reactor (rs-SDR) is one such PI reactor were high shear force on the feed due to velocity gradients between the rotor and the stator result in high rates of mass and heat transfer [2]. This leads to rs-SDR being a particularly interesting reactor for photochemical applications where photon transfer and mass transfer of the activated species are often limited (e.g. for high concentration). In this study, we demonstrate the potential of a photo-rs-SDR for applications towards photochemical reactions. A challenging reaction where additional gas-liquid mass transfer limitations are observed has been selected for this study [3].

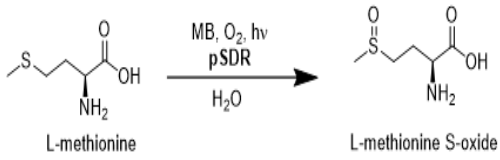

Figure 1: Reaction scheme

2. Methods

The oxidation of L-methionine with methylene blue as the catalyst (Fig.1) was chosen as the model reaction for this proof of concept study. The rs-SDR was illuminated using a solar light simulator (AM1.5G), to ensure no light limitations. The reaction was carried out by co-feeding the reaction solution and oxygen at the bottom of the reactor; samples were collected after a single pass and the reaction conversion was measured using HPLC. The schematic is illustrated in Fig 2.

3. Results and discussion

A few of the results obtained are presented in this abstract. As illustrated in Fig 3, the reaction conversion (residence times between 24—28 seconds) increased with increasing rotation speed

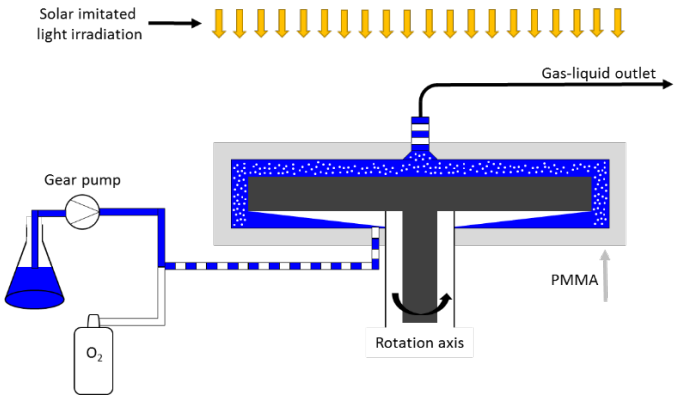

Figure 2: Schematic representation of the reactor set-up

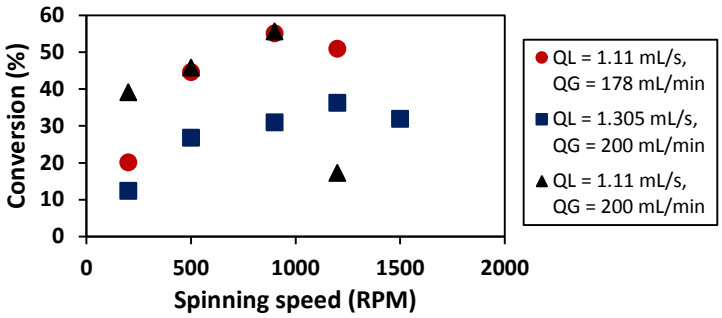

Figure 3: Effect of spinning speed and gas-liquid flowrate on reaction conversion

up to 900 RPM. A maximum conversion of 55% was observed at 900 RPM for an optimum gas-liquid flowrate. Such high conversions within 24 seconds of residence time indicate that productivity of photochemical reactions can be significantly improved. Larger phase separations were observed at higher RPMs which caused inefficient mixing, leading to lower conversions.

The effect of rotation speed, gas-liquid flowrate and catalyst concentration on the reaction conversion have also been investigated under both the solar limit simulator and more limiting conditions. Additionally, the results were compared to two conventional reactors which are currently used in photochemistry: batch and microflow.

4. Conclusions

To the best of the authors' knowledge, this is the first study of a successful synergistic reaction system using photochemistry and the rs-SDR. We are currently investigating the potential of the photo rs-SDR for targeted applications in pharmaceuticals and the fine chemical industries to further illustrate how process intensification can lead to improvements in sustainability.

Highlights

- Hydrogen production from solar and wind.
- Coupling solar and wind energy under Aspen Plus.

1. Introduction

Renewable energy sources continue to increase their share of installed capacity worldwide. This increase is pushed by the commitment to avert the risks that conventional non-renewable sources pose to health, geopolitics, the economy and the environment. According to the IEA, the renewable energy sources represents 13.4 % of the total world total primary energy supply (oil 31.8 %, natural gas 21.6 %, Nuclear 4.9 %, coal 28.1%) [1]. On the other hand, solar photovoltaic and wind energy supply has grown of an average annual growth rate of 45 % and respectively 24 % between 1990 and 2015 respectively [1]. Hydrogen is one of these carriers that has attracted much support from across many countries across the world. In fact, it has the potential to become one of the main energy carriers of the future as it can be easily produced using renewable energy, stored using commercially available technologies and used throughout the entire energy system [2] [3]. Hydrogen is considered today a very promising form of energy carrier by its ability to serve a buffer between renewable sources and the different forms of energy demand. Water electrolysis is considered one of the most mature and clean method to produced hydrogen. Renewable energy sources continue to increase their share of installed capacity worldwide. This increase is pushed by the commitment to avert the risks that conventional non-renewable sources pose to health, geopolitics, the economy and the environment. According to the IEA, the renewable energy sources represents 13.4 % of the total world total primary energy supply (oil 31.8 %, natural gas 21.6 %, Nuclear 4.9 %, coal 28.1%) [1]. In fact, it has the potential to become one of the main energy carriers of the future as it can be easily produced using renewable energy, stored using commercially available technologies and used throughout the entire energy system [2] [3]. Hydrogen is considered today a very promising form of energy carrier by its ability to serve a buffer between renewable sources and the different forms of energy demand. Water electrolysis is considered one of the most mature and clean method to produced hydrogen.

2. Methods

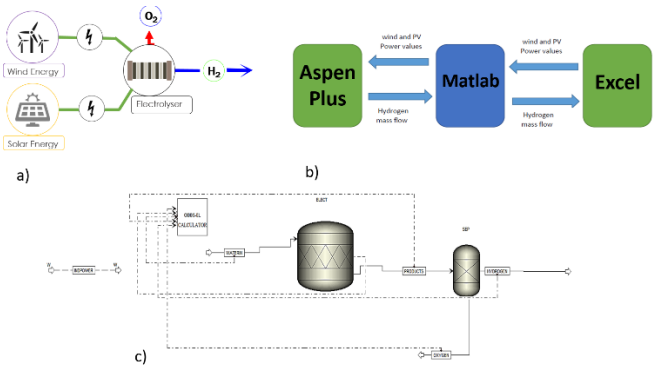

Figure 1: a) Global pilot scheme, b) Coupling Aspen Plus, Excel and Matlab and c) Modeling under Aspen Plus.

The objective of this work is to build a simulation model under Aspen Plus to estimate the hydrogen production from the electrolysis process using wind and solar energy as input power (Fig 1.a). This model will take into account the availability of solar and wind energy for different geographical locations and different PV and wind turbine technologies. The water electrolysis process is modeled in ASPEN PLUS and coupled with the renewable energy models thanks to Matlab and excel interaction. In the case study, the overall model shows a good performance and a high sensitivity to renewable energy availability.

3. Results and discussion

The water electrolysis process powered by renewable energy has been simulated in ASPEN PLUS. A case study in 2 geographical locations has been done to test the model. As a first validation, the results show a very good performance in reflecting the renewable energy availability between different locations and environmental conditions.

4. Conclusions

This work aims to create a techno-economic model and investment decision support tool that can technically and financially optimize the production and the commercialization of renewable hydrogen. The electrolysis simulation model can be enhanced by taking into account the over voltage and the faradic efficiency in an actual elecrtolyser. This will result in more power needed to obtain the same yield of hydrogen in the case of an ideal electrolyser.

ROMEO – A MAJOR STEP TOWARD INDUSTRIAL MEMBRANE REACTOR APPLICATION FOR HYDROFORMYLATION

Introduction

The hydroformylation is one of the most prominent industrially applied reactions. More than 10 million tons of chemical products rely on this homogeneously catalyzed reaction step every year; thus, a permanent improvement of the hydroformylation process is of utmost interest for many chemical companies like Evonik. Especially, it is the researcher´s and company´s aspiration to find a heterogeneous-like catalyst. The improvement done within Evonik followed several approaches in the past including optimization of process technology as well as optimizing the catalytic system. Most of these developments were achieved by public funded projects together with experts from academia.

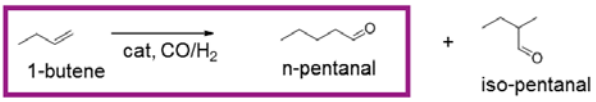

Fig. 1. Hydroformylation reaction formula

Experimental

This presentation gives an overview of the most relevant results of the currently running EU funded project ROMEO (Reactor Optimization by Membrane Enhanced Operation).

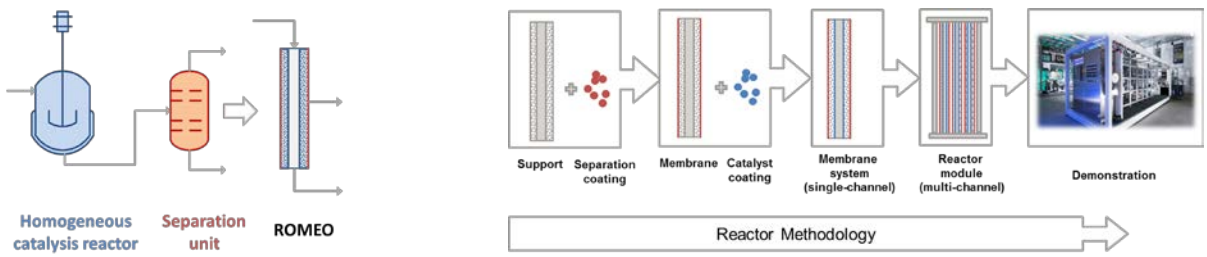

Fig. 2. 2-in-1 reactor principle (left) and reactor methodology (right)

The project aims at the combination of a catalytic reaction with the separation step on a single support structure. This combination in an innovative “2-in-1” reactor opens the possibility to omit or at least significantly downsize the separation units. In case of catalytic processes that are performed close to the chemical equilibrium the constant removal of one reaction partner from the reaction enhances the efficiency.

Results and discussion

The catalytic system contains of a ceramic support combined with a membrane coating and an impregnated hydroformylation catalyst. In order to evaluate the relevant long-term stability of such a catalytic system, a modular demonstration plant with a switchable reactor system was manufactured. With this modular design it is possible to compare the performance of a single monolith reactor with a multi-monolith reactor module. To operate the reactor with a technical industrial feed, a start-up procedure, an *insitu* catalyst impregnation and a catalyst recovery technology were developed.

The presentation will show relevant long-term experimental results as well as some sensibility studies of the membrane reactor modelling.

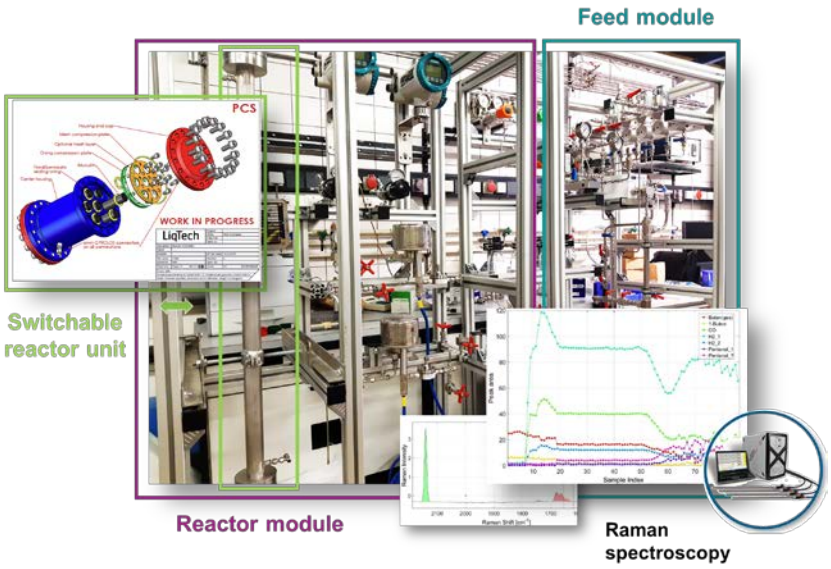

Fig. 3. Modular demonstration plant for long-term hydroformylation operation

Conclusions

Membrane optimization in terms of mechanical stability and material selectivity is still a challenge of the project but long-term demonstration already shows a significant economic benefit compared to the benchmark process concerning catalyst costs. The implementation of a pilot reactor to the benchmark process will be the next step to evaluate the technology in a bypass stream.

ROMEO has received funding from the European Union’s Horizon 2020 research and innovation program (grant agreement No 680395).

The Power-to-Liquid Concept: A Novel process for the production of (Poly-) Oxymethylene Dimethyl Ether (OME)

Franz Mantei[1,2], Lara Theiss[1], Mohamed Ouda[1], Dr. Achim Schaadt[1]

1 Fraunhofer Institute for Solar Energy Systems ISE, Heidenhofstraße 2, 79110 Freiburg, Germany
2 Chair of Chemical & Process Engineering, TU Berlin, Fraunhoferstraße 33-36, 10587 Berlin, Germany

**Corresponding author: franz.mantei@ise.fraunhofer.de*

Highlights

- A sustainable and efficient production of OME
- Overall Process energy efficiency of > 55 % starting from H_2 and CO_2
- Yield of > 45 % OME starting from H_2 and CO_2

1. Introduction

OME have interesting thermophysical and chemical properties which make them suitable for different applications as CO_2 absorption, solvent, in direct oxidation fuel cells (DOFC) and as diesel fuel blend or alternative. [1-3] OME have a relatively high energy density and are environmental benign which adds to their advantages as a fuel or chemical/solvent candidate. Especially OME_n with the chain length of n = 3-5 show fuel properties close to diesel fuel. Due to their high molecular bound oxygen content and missing C-C bounds, already low blends to diesel fuel can reduce soot emission considerably which enables a reduction for NO_x emissions. [4]

However studies regarding their applications and potential use as alternative fuel are extensive; a sustainable, economical, scalable and efficient industrial process for the production of OME_{3-5} is still not realized. In this work a simple and efficient OME synthesis process will be introduced. The aim is to reduce the number of process units and to increase the process energy efficiency and total yield of OME_{3-5} while considering scalability and economic feasibility. [5] The novel process addressed in this work comprises two steps, namely: (1) the oxidative dehydrogenation of MeOH towards Formaldehyde (FA) and OME_1 in a single reactor unit. (2) This mixture can subsequently be converted to OME_{3-5} at mild conditions. A major challenge for the OME processes is the water management, since it is produced as a side product of the reactions starting from MeOH. Its separation using thermal separation units is a complex challenge due to the formation of several azeotropes, reactions and miscibility gaps, thus some research is done investigating alternative separation tehnologies using membranes, adsorption or extraction. [6, 7]

2. Methods

In order to evaluate the potential of the investigated process based on the oxidative dehydrogenation of MeOH to produce OME, the process was simulated using commercial process simulation software. Different process units were experimentally validated to ensure realistic behavior of the applied models. To increase the process energy efficiency, heat integration was conducted for the whole process covering the MeOH synthesis based on H_2 and CO_2 and the subsequent OME synthesis. To compare this process with alternative OME synthesis processes,

key performance indicators (KPIs) were evaluated. Finally preliminary production cost estimation was conducted identifying the economic advantage of the investigated process.

3. Results and discussion

The production capacity of 35 kt OME per annum starting from H_2 and CO_2 to MeOH and further oxidative dehydrogenation to FA and OME_1, water separation and finally OME_n synthesis, is introduced. A scheme of the process is shown in Figure 1. The KPIs show great potential for the process in terms of process energy efficiency > 55% and yield of OME_n > 45% with estimated costs of > 1000 US$/$t_{OME}$. The costs are mainly influenced by the scale of the process and the costs for renewable H_2 which can be reduced in regions with lower costs for renewable electricity.

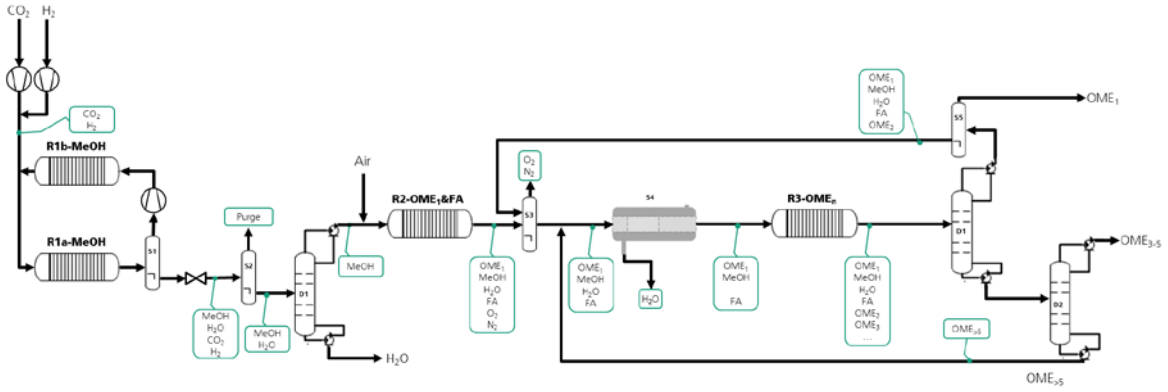

Figure 1 Scheme for the production of OME_n via oxidative dehydrogenation of MeOH starting from H_2 and CO_2

4. Conclusions

OME show promising properties for different applications. However, a sustainable, economical, scalable and efficient industrial process for the production of OME_{3-5} is still not realized. A novel process for a sustainable and efficient production of OME at high yield > 45% and high process energy efficiency > 55% with production costs of ca. 1000 US$/$t_{OME}$ was introduced. This cost is rather high for fuel applications but is promising for the chemicals and solvent market. The process steps are being validated in lab- and mini-plant scale and should be scaled up to several kt/a to validate the industrial application. In conclusion, the introduced process with the discussed KPIs offers a sustainable and economically feasible solution for the production of OME.

Highlights

- Techno-economical evaluation per route shows that reaction section is critical part
- Comparison between two processes to conclude which is inherently favored
- Separation section is remarkably similar for both processes
- Economic evaluation shows need for 50% drop in PG price for an economically viable process

1. Introduction

The price of Propylene Glycol (PG) is expected to drop dramatically with the increasing use of biomass as feedstock, since it is a byproduct of sugar hydrogenolysis [1, 2]. This could make PG a promising raw material to be upgraded to Acrylic Acid (AcrA). Two process designs for the conversion of PG to AcrA are proposed, either by oxidation of PG to lactic acid (LA) and dehydration to AcrA or by dehydration of PG to allyl alcohol (AA) and oxidation to AcrA [3] . A conceptual design for both routes was proposed, followed by a techno-economical evaluation on a basic engineering level. Both processes were evaluated individually on heat integration, sustainability, CAPEX and OPEX. The minimum PG price to reach economic break-even for the two routes was compared for a capacity of 150 kta for glacial acrylic acid (>99.5 % purity) from a 50/50 mol% water/PG feed.

2. Methods

Douglas methodology is followed - with different levels of detail, based on hierarchy of decision. During the process, several options are evaluated and the best alternative is chosen based on theoretical analysis and simulated results[4]. Consequently, a Process Flow Diagram is developed and evaluated using Aspen Plus V10 software. An improved heat integration system is suggested for both processes using pinch analysis. Finally, an economic analysis is performed to calculate the CAPEX and OPEX related to the process.

3. Results and discussion

Both flowsheet designs start with two reactors without a separation and recycle in between. Due to limited information of all the reactions, the same overall reaction yield for both processes is assumed in the paper. Despite the various by-products, the separation section for both processes is remarkably similar. Water removal is the key function of the first separation unit which in both processes is a liquid-liquid extractor. For the LA route, DIPE was found to be the most optimal solvent, whereas for the AA route octanol was found to be the most suitable, based on energy consumption and solvent recovery. Further purification is performed by (vacuum) distillation. AcrA recovery for the LA route and AA route are 99.7% and 99.1%, respectively, showing only minor differences in the separation.

Significant differences can be found in the heat integration. A high-temperature oxidation reaction (325 °C) in AA route provides valuable energy and covers almost all the hot utilities needed. The liquid phase oxidation in the LA route results in availability of energy at 80 °C, which is too low for steam generation and needs cooling by an external utility. Evaporation of the product stream in the LA route is expected to give polymerization issues. A novel spray evaporator unit was proposed to solve this problem by inducing instantaneous evaporation of both LA and water. This is however an expensive and high energy consuming unit.

Both processes will profit tremendously by reducing the required amount of water dilution. Table 1 shows the water usage per ton product for both routes. Less water present in the system reduces the volume of operation units, lowering the CAPEX and OPEX significantly. The difference in solvent loss (Table 1) between the two routes is mainly the result of a difference in the thermodynamic modelling of the extraction.

For both routes, the reactor section is a major cost contributor accounting roughly 50% of the investment. However, since the reactor design suffers from a lack of information, this cost factor is highly uncertain. Advances in the reaction section, such as higher catalytic performance, might lead to a significant reduction of the total investment. The largest difference between the routes is in the use of an air separation unit for the LA route, whereas the AA route uses air. This leads to a preliminary estimate of the total investment of 203 M$ for the LA route and 170 M$ for the AA route. Raw materials are by far the largest costs for operation in both routes. The AA route benefits from lower costs for utilities, since heat can be integrated better and the LA route uses a spray evaporator, which is a large energy consumer. In the end the necessary break-even price of PG on a preliminary basis for the LA and AA route is 940 $/ton PG and 1070 $/ton PG, respectively. With the current uncertainty margins of ± 30% in all economic calculations, a conclusion concerning a more attractive process would be premature.

Table 1. Important comparison parameters for both designs.

Description	LA route	AA route
Acrylic Acid recovery (%)	99.7	99.1
Heat integrated (MW)	55	89
Hot Utility (MW)	4	13
Cold Utility (MW)	141	52
Water usage (ton water/ton product)	5.1	3.9
E-factor (kg waste/kg product)	1.1	1.0
Solvent losses (kg/ton product)	139	23

4. Conclusions

The constructed processes show similarities regarding the flowsheet, proposed unit operations, CAPEX and sustainability. Liquid-Liquid extraction is used in both processes as the main separation unit due to the presence of large amounts of water. The reaction section design suffers from a lack of information but forms a critical difference between the two routes. The break-even feedstock price of PG is quite similar for both routes at this point. Further investigations should show which process is more feasible. Producing AcrA via high temperature dehydration and subsequent high temperature oxidation is shown to be inherently favoured, due to the opportunity to integrate the reaction heat available at high temperature. To conclude, the price of PG has to drop dramatically to replace the conventional production of acrylic acid with one of the routes proposed here.

Highlights

- H_2O_2 combined with iron or manganese complex is an efficient system for starch oxidation
- Interplay between catalyst stability and applied process parameters dictates efficiency
- *In situ* Raman spectroscopic technique is developed to monitor catalyst stability
- Studies on model compounds provide insights into the mechanism of starch oxidation

1. Introduction

Oxidation is an attractive strategy to effectively reduce the high-molecular weight of native starch and improve its stability for various applications in paper and textile industries. Sodium hypochlorite (NaOCl) is a common oxidizing agent due to its efficiency in lowering the viscosity as well as introducing carbonyl/carboxyl functionality in the polysaccharide structure (**Figure 1, left**). However, it is highly desired to replace NaOCl with more environmentally-benign alternatives. In this work, H_2O_2 is used instead, in combination with iron (III) tetrasulfonatophthalocyanine (FePcS) or manganese (IV) 1,4,7-trimethyl-1,4,7-triazacyclononane (tmtacn) as the catalyst (**Figure 1, right**).

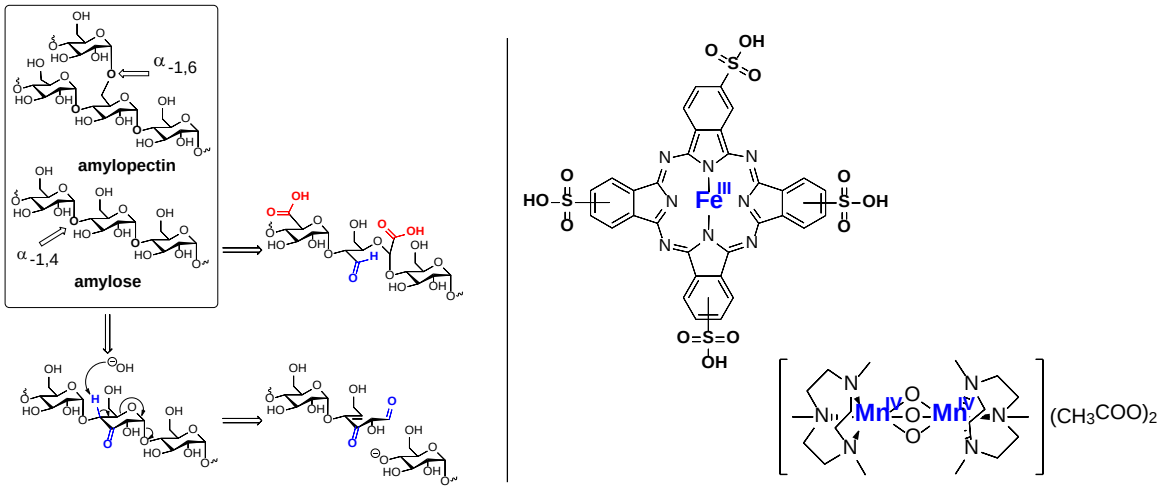

Figure 1. Catalytic oxidation of hydroxyl groups to carbonyl and carboxyl groups, and subsequent cleavage of the glycosidic bonds (left). Structure of iron and manganese complexes as catalysts used in this present work (right).

2. Methods

Typically, potato starch slurry in water (39 wt.%) was prepared and heated to the desired temperature. The pH was adjusted to 10 or 11 using NaOH. The catalyst was subsequently added, followed by H_2O_2. The influence of process parameters (i.e., time, temperature, oxidant, and catalyst and starch concentrations) for reactions carried out in both batch and continuous-flow set-ups on yield, viscosity, and degree of substitution (DS) was investigated. Yields were calculated based on the dry weight of product. Moisture content and urea viscosity were determined using a moisture analyzer and a rapid visco-analyzer, respectively. The carboxyl and carbonyl contents were determined by IR spectroscopy and by titration. Product properties were further characterized using various techniques including PXRD, SEM, FTIR, 2-D NMR HSQC, GPC, HPLC, and ESI-MS.

3. Results and discussion

At optimum batch conditions for the H_2O_2-FePcS system, a product yield of 91% was obtained with substantial degree of substitution (DS_{CO}=0.41, DS_{COOH}=0.014), combined with degradation to lower molecular weight (197 mPa·s) (**Table 1**). However, high [H_2O_2] and temperature promoted the degradation of the FePcS catalyst (by *in situ* Raman spectroscopy). For the H_2O_2-Mn(tntacn) system, starch oxidation was a clear function of time and showed a linear dependency with respect to carboxyl group formation, whereas an exponential decay was found for starch degradation. H_2O_2 and catalyst concentrations of 2 wt.% and 20 ppm, respectively, were already sufficient to significantly reduce the viscosity of starch samples within benchmark specifications (144 mPa·s with DS_{COOH}=0.04). For both catalytic systems, the morphology and structure of the starch remained unchanged after oxidation. A clear shift of the cumulative weight fraction to lower regimes was also obtained (by GPC), consistent with the observed extent of depolymerization and formation of water-soluble oxidized compounds. Studies on model compounds (i.e., glucose, fructose, maltose, cellulobiose, beta-cyclodextrin, inulin, amylose, and amylopectin) provided insights into structure-property relationships as well as the mechanism of oxidation and depolymerization.

Table 1. Catalytic oxidation of native potato starch with FePcS and H_2O_2 at 50 °C and pH 10 in batch.

Entry	FePcS (µM)	H_2O_2 (M)	time (min)[a]	Urea viscosity (mPa·s)	DS_{COOH} (mol mol^{-1})	DS_{CO} (mol mol^{-1})	Yield (wt.%)[b]
1	331	0.2	135-80-72	3692	0.004	0.15	97.4
2	331	0.4	112-90-90	1360	0.011	0.22	95.2
3	166	0.4	180-120-120	1690	0.010	0.33	95.0
4	166	1.0	180-120-120	197	0.014	0.41	90.7
5[c]	166	1.0	180-120-120	198	0.012	0.40	91.0

[a] H_2O_2 added in one or three steps dropwise with a concentration distribution of 30-35-35%.

[b] Weight of isolated oxidized starch divided by the initial weight of starch on a dry basis (total wt. 100 g).

[c] Upscale experiment of entry 4 with five moles (1000 g) of potato starch.

4. Conclusions

Environmentally-friendly oxidant, H_2O_2, in combination with low loadings of water-soluble Fe- and Mn-based catalysts are highly effective in the oxidation of abundant starch and starch derivatives. Some deactivation of FePcS was observed using *in situ* Raman spectroscopy depending on reaction conditions. These systems provide a promising alternative to hypochlorite (NaOCl) starch oxidation.

A Combination of Bio- and Chemo-Conversion of the Hemicellulose Xylan to Xylitol

Highlights

- Enzymatic hydrolytic hydrogenation of xylan to xylitol is possibel
- A hybrid one pot process achieved over 70% xylitol yield

1. Introduction

Lignocellulosic biomass consisting of the fractions cellulose, hemicellulose and lignin is a promising sustainable basis for a future biorefinery. They are many applications for cellulose for example in the pulp and paper industry. For an efficient operating of a future lignocellulosic biorefinery it's essential to include the fractions lignin and hemicellulose. Hydrolysis is a key step in this process. The focus of this work is the simultaneous use of chemical and biological catalysts and the combination of their advantages in one reactor for the conversion of xylan (beechwood) to xylitol. This involves the discussion of a classical one-pot and a new two-step process.

2. Methods

The experiments were carried out in a stainless steel batch reactor (Parr Inst.) with an inner volume of 300–600 ml. The analysis was performed by an HPLC (Smartline®, Knauer GmbH) unit. Hydrolysis was done by using commercially available enzymes. The subsequent refinement of the hydrolysis products was realized with the aid of a Ru/C catalyst.

3. Results and discussion

The classical one-pot process was carried out at a temperature of 60 °C, 20 bar hydrogen pressure and a stirring speed of 1000 rpm. The process realized under the before mentioned conditions achieved a xylitol yield below 20% after 8 hours. This is very low compared to the existing industrial process using Raney-Nickel.

The two-step process is composed of the following steps: 1. step hydrolysis followed by the 2. Step hydrogenation. The hydrolysis (1) is carried out at 250 rpm (low shear-stress), 50 °C and atmospheric pressure for 24 hours reaction time. After the hydrolysis phase the subsequent hydrogenation (2) was carried out at process conditions of 10 bar hydrogen pressure, 140 °C, stirring of 750 rpm under use of gas-entrainment and a reaction time of 4 hours. Comparably mild reaction parameters were chosen to maintain the enzyme activity for as long as possible under hydrogenation conditions. During the hydrolysis, with different enzyme loadings, a xylan conversion of around 70% was achieved. In the subsequent hydrogenation, the xylan conversion increases by approximately 10%. Control experiments show that under these conditions no xylan hydrolysis without enzymes takes place. After the second process stage, a xylitol yield of over 70% is achieved.

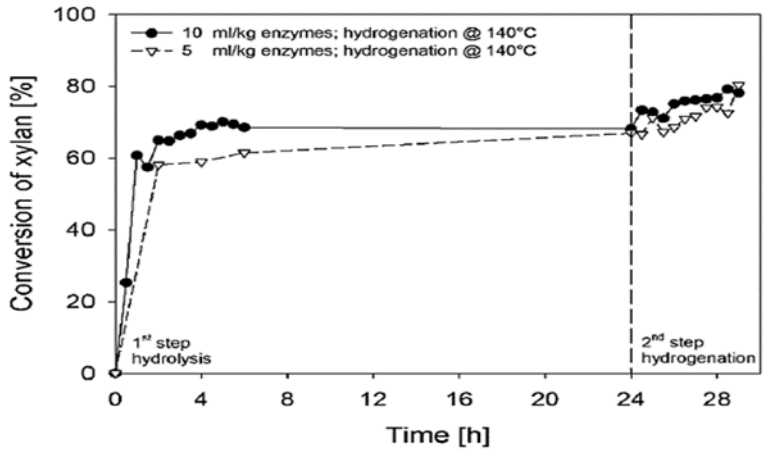

Figure 1. Fig. 1 xylan (1 wt%) conversion via two-step process with different enzyme loadings (250 rpm, 50 °C, atmospheric) during the 1st step 24 h and hydrogenation at 140 °C during 2nd step 4 h at 10 bar H_2 in the presence of 3 g/kg Ru catalyst (5 wt% Ru on act. C) [1]

4. Conclusions

The experiments show that enzymatic hydrolytic hydrogenation of xylan to xylitol is possible at low (60 °C) temperatures. The xylitol yield can be considerably increased by the application of a suitable reactor operating mode as a two-step process.

Highlights

- Chemical process simulation could predict conductivity in a recycled tissue mill.
- Conductivity sources are raw material, chemicals, water and anaerobic activity
- Inhibiting microbial anaerobic activity may reduce conductivity two-fold.
- Water management strategies must be evaluated by a thorough simulation study

1. Introduction

Reduction of fresh water usage in papermills has some consequences on process water quality. In particular, organic and inorganic dissolved and colloidal substances build-up can cause operating difficulties. Increase of organic dissolved and colloidal substances have an impact on drainage, chemical additives, microbial activities and deposits. Solutions exist to limit their disturbing effects such as separation of water loops, counter-current washing or recycling bio-treated effluents. On the other hand, inorganic dissolved species may become the limiting factor for further circuit closure as they interfere with charged polymeric additives [1]. We present a chemical process simulation approach to predict salinity increase in process water. This will help determining acceptable conductivity limit for paper production and adequate water management strategies.

2. Methods

First, conductivity sources throughout the circuits are identified. Four types of sources are considered (i) raw materials, (ii) fresh water, (iii) chemicals and (iv) anaerobic activity.

For pure chemicals, dedicated sources are available in the chemical process simulation (for instance: caustic soda, sodium bisulfite, etc.). For charged polymers, their specific contribution to conductivity is firstly determined by plotting a dilution curve. Then corresponding sources of counter ions are implemented (Na^+ for anionic polymers and Cl^- for cationic polymers).

The process simulation (Fig.1, left) determines the conductivity by resolving chemical equilibria together with biochemical equilibria resulting from anaerobic activity [2], [3]. Chemical speciation is used to calculate the corresponding conductivity.

3. Results and discussion

The conductivity calculated from the simulated ionic distribution fitted the measured conductivity profile quite well (Fig.1, right). The simulation made it possible to estimate the relative contribution of each conductivity source. In the tested tissue mill case, all sources contributed significantly to conductivity. Raw material released various ions. Fresh water was a significant

source of ions as well. Chemicals were a significant source of conductivity as producing wet-strength grades requires alkaline conditions for broke repulping. In closed circuits conditions, anaerobic activity may cause important conductivity rise. The simulation showed that inhibiting anaerobic activity could reduce conductivity two-fold, as it is coupled to the other sources and effects, e.g. dissolution of calcium carbonate filler from the raw material due to produced organic acids.

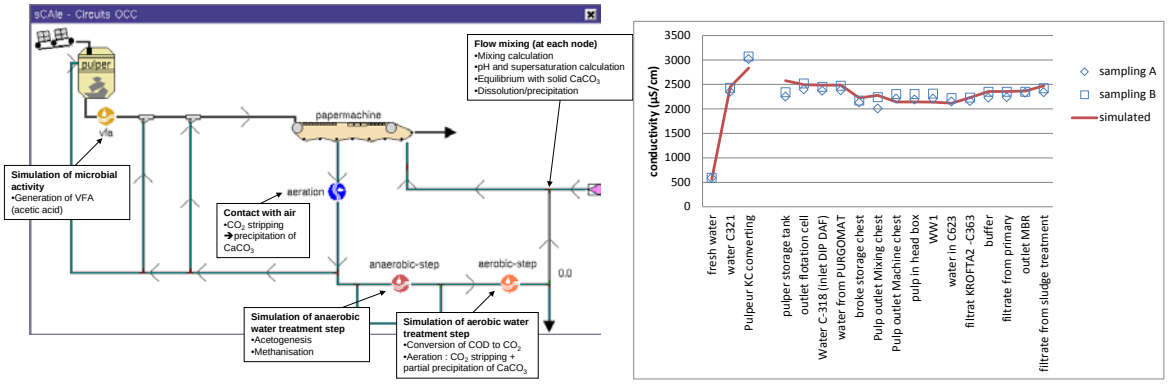

Figure 1. Simplified view of the process simulation with chemical modules (left) and prediction of conductivity throughout the process (right).

4. Conclusions

Results have shown that the relative contribution of each conductivity source is very mill-dependent. Therefore the strategy to help reducing conductivity rise in closed circuits conditions will be specific to each situation. This depends on produced grade, fresh water quality, initial water consumption, chemicals used and water management strategy.

The simulation can now be used to test various wastewater recycling scenarios. One promising option is to reduce fresh water consumption by recycling bio-treated effluent back to the process. This makes use of the waste water treatment plant as a kidney for organic material, but also deconcentrates the circuits in calcium as calcium carbonate is precipitated in the aerobic treatment. This has potential to help papermills limiting ionic species build-up when reducing their water footprint.

Highlights

- Electrochemical carbon dioxide reduction.
- Electrochemical chlorine production.
- Paired electrolysis.
- Sustainable energy.

1. Introduction

Organic electrosynthesis is a potentially cost-effective, scalable and green method of synthesizing organic products using renewable electricity. In most cases, however, the chemistry that occurs at the counter electrode yields a waste product, which holds little economic value. To overcome this issue, paired electrolysis seems promising since it forms useful products at both electrodes. The electrochemical reduction of CO_2 has become one of the most interesting topics because of the worldwide interest in its conversion into valuable chemicals and fuels. The use of CO_2 as a C1 feedstock for the formation of more valuable chemicals offers the use of an easy, available and renewable carbon source, which is non-toxic and abundant.
On the other side, chlorine (Cl), the second most abundant halogen, is incorporated in about 70% of all manufactured chemical products. Nevertheless, some of the chlorine frequently combines with hydrogen, becoming hydrogen chloride (HCl) – a corrosive and hazardous waste material. In this context, pairing electro-oxidation of chloride with electro-reduction of CO_2 offers the possibility to make valuable chemicals on both electrodes.

2. Methods

Electrochemical measurements were carried out with an Autolab potentiostat connected to an H-type two compartment electrochemistry cell, which were separated by a Nafion 117 membrane. The anodic compartment was fed with 0.1 M HCl while the cathodic compartment was fed with 0.5 M $KHCO_3$ saturated with CO_2 gas. Platinum wire (Φ = 11 cm^2) , Au wire (Φ = 6.44 cm^2) and Ag/AgCl were used as working, counter and reference electrodes, respectively. Before electrolysis, cyclic voltammograms were performed for each reaction in a single cell. After matching the current density obtained for each single reaction, electrolysis was performed in galvanostatic mode during 1.5 hour. In order to compare the results with a more realistic system, electrochemical measurements were also carried out in a micro flow cell purchased from ElectroCell with two different compartments separated by a anionic exchange membrane (Nafion). The working electrode (WE) was a platinum plate (Alfa Aesar, 99.9%) with a surface area of 10 cm^2 and the counter electrode (CE) was a gold foil with a surface area of 10 cm^2. The anolyte and the catholyte were both recirculated through the electrochemical cell with a flow rate of 25 L/h. In both cell, the

cathodic compartment was connected to the gas chromatograph (Interscience) (GC) in order to identify gaseous products, while the anodic compartment was connected to a filter containing 1.0 M NaOH in order to collect the gas chlorine (Cl_2) produced. The concentration of Cl_2 was analyzed by using UV-vis.

3. Results and discussion

Based on the cyclic voltammograms (Figure 1) obtained for each single reaction, we found that a current density of 8 mA cm^{-2} matches for both electrochemical CO_2 reduction and Cl^- oxidation. The following discussion is based on the results obtained by using flow cell setup. Electrolysis electrolysis was performed by applying the corresponding current during 1.5 h. The cell voltage measured during electrolysis was 4.3 V *vs.* Ag/AgCl, which was stable from the beginning to the end of measurements. The anode potential (Pt – Cl_2 production) was 1.85 V *vs.* Ag/AgCl while the measured cathode potential (Au – CO_2 reduction)) was -2.5 V vs. Ag/AgCl (not showed).

During the simultaneous redox reaction, hydrogen and carbon monoxide were detected by GC as gaseous products from CO_2 reduction on Au electrode. The data are showed in Figure 2. According to the results, higher concentration of CO was obtained in the beginning of the reaction (3200 ppm) and it decreases to around 500 ppm over time, however the concentration of hydrogen increases. According to Surendranath et al.[1] it happens because of gold electrode deactivates during reaction due to the adsorption of metal impurities on the surface of the electrode leading to a decrease in product formation. Aliquots of NaOH solution, used to capture the Cl_2 produced at the anode was analyzed before and at the end of the electrolyses. The measured concentration of Cl_2 found was 930 mg / L.

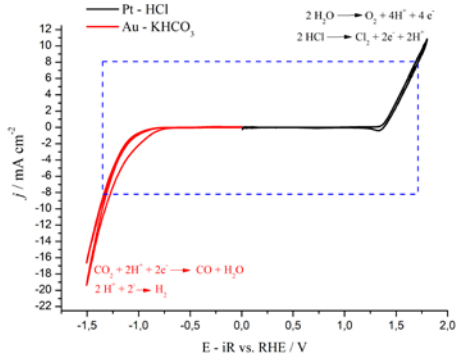

Figure 1. Cyclic voltammograms obtained at 10 mV s^{-1} for electrochemical CO_2 reduction (red line) and Cl^- oxidation (black line) on Au and Pt, respectively.

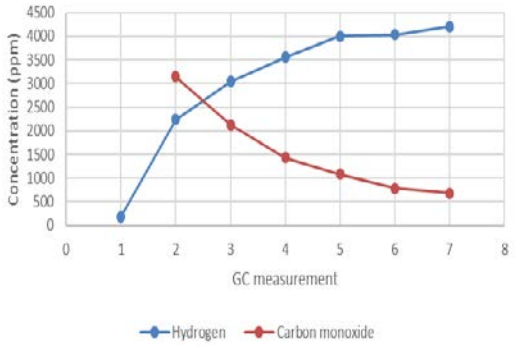

Figure 2. Concentration of CO and H_2 measured during electrochemical reduction of CO_2 on gold electrode paired with Cl_2 production.

4. Conclusions

Despite the low concentration of CO produced during the CO_2 electro-reduction reaction, our results proved the principle of the paired electrolysis of CO_2 reduction and Cl_2 production. New tests will be done in order to optimize the system, moreover this is a technology which can be applied not only for production of CO but also to other CO_2 electro-reduction products, such as ethylene, formic acid, ethanol and etc.

Highlights

- Life cycle assessment of the extraction was performed with ethanol as solvent.
- Carbon footprint of bioethanol-extracted soybean oil is smaller than hexane-extracted.
- Bioelectricity may be co-product of the ethanol-soybean oil plant.

1. Introduction

The replacement of non-renewable solvents in industrial process will contribute to the consolidation of the low-C economy. In 2015, Brazil signed the Paris agreement and committed to reduce 37% of greenhouse gases emissions, based on 2005, until 2025. Other commitment was to reach 45% of renewable energy sources on the Brazilian energy grid and to promote clean technologies in the industrial sector. Brazil is the second larger producer of soybean, responsible for 35.38% of the worldwide production in 2015. According to [1], the 2020 soybean production forecast is 114.7 million metric tons and 10 million of tons of soybean oil. Although hexane is the conventional solvent used for soybean oil extraction the extraction of oilseeds with ethanol is a sustainable and technically feasible alternative [2,3,4]. Both anhydrous ethanol and hydrous ethanol (1G bioethanol from sugarcane) can be used for seed oil extraction. Besides, in order to contemplate a future biorefinery integration, vapor and electricity demands may be supplied in a cogeneration system using sugarcane bagasse. This work aims to simulate these oil extraction process, and to quantify the environmental impacts of this solvent replacement through LCA.

2. Methods

The process was simulated in the equation-oriented Environment for Modelling Simulation and Optimization (EMSO). The process consists of a cracker, conditioner, flaker, expander, extractor, desolventizer, toaster, evaporator, degumming, deacidified and solvent recovery section. Four scenarios assessed, using the solvents hexane, hydrous ethanol, anhydrous ethanol recovered by glycerol extractive distillation, and anhydrous ethanol recovered by mono ethylene glycol (MEG) extractive distillation. The solid fraction from the extraction proceed to the desolventizer-toster in

order to remove the solvent from the meal. The liquid fraction is carried to an evaporator and then to a solvent recovery section. Hexane is recovered in a set of evaporators and a stripping column. Hydrous ethanol is recovered through distillation. The anhydrous ethanol is recovered by extractive distillation using either MEG or glycerol. In order to proceed with LCA, an inventory of raw-materials, emissions and products was done. GWP gases emissions for each process were calculated, within a birth to gate scope (including the harvest in the field for soybean and sugarcane) and considering energetic allocation to the multiple products.

3. Results and discussion

Ethanol requires a higher solvent-soybean ratio when compared to hexane. So, the energy demands for the first alternative is higher. On the other hand, in a biorefinery concept, more bagasse will have to be burnt, and so more surplus bioelectricity may be sold to the grid. LCA shows that GWP emission in the whole ethanolic process of extraction are slightly higher, due to the higher vapor and cooling water demands. However, since more bioelectricity is produced, the GWP related to soybean oil with ethanol extraction is lower than the one with hexane extraction.

4. Conclusions

A life cycle assessment of the extraction of soybean oil with ethanol was performed, and compared to the conventional hexane extraction. The GWP emission related to the soybean oil extracted with ethanol was lower than the one with hexane. Boeletricity and vapor generated play an important role in this process. Further studies could contemplate the integration with ethanolic biodiesel processes.

Highlights

- Environment.
- Geological Storage.
- Operational costs.
- Global warming..

1. Introduction

Human actions, such as the burning of fossil fuels, the use of aerosols, and biomass combustion, liberate greenhouse gases (GHG) into the atmosphere [1]. The most abundantly released gases and therefore the most responsible for the greenhouse effect are N_2O, CH_4 and CO_2. In particular, CO_2 causes global warming and consequently climate changes.

Carbon sequestration through the Capture, Transport and Geological Storage of CO_2 (CCS technology) is an important alternative for reducing emissions [2] and stabilizing the atmospheric concentration of GHGs from a sustainable development perspective. The geological storage of CO_2 can be safely performed in three types of reservoirs: depleted oil and gas reservoirs, saline aquifers and coal layers. In depleted oil and gas reservoir after the beginning of CO_2 injection, the reservoir pressure increases and an increase of the oil production. However, when the geological storage is in saline aquifers the competitive differential between companies and industries will be based on providing services and manufacture of products with low carbon emissions. However, the main obstacle for CCS implementation in Brazil and in the other countries is the high financial cost [3].

This paper presents the CO_2 storage in a saline aquifer and oil and gas reservoir based on scenarios for the application of CCS projects, investments and operating costs.

2. Methods

The amount of recoverable oil by CO_2 injection varies as a function of the oil displacement mechanism and the characteristics of the field. The maximum amount of oil that can be recovered can be calculated using Equation as follows [4]. The extra percentage of recoverable oil due to CO_2 injection (%EXTRA) is an estimated value based on the API gravity of the oil. Probabilistic studies and simulations were performed by the IEA GHG to determine %EXTRA and was used in this study.

3. Results and discussion

To give an example of the estimated financial profitability resulting from CCS projects applied for CO_2 injection, the historical average of the Brent oil price [5] was designed between the years 2005 and 2018 (Figure 1). In this case study considers the Roncador field (original oil in place is 9.7 billion barrels). For the purpose of comparison, the extra recoverable oil percentages as a result of CO_2 injection were estimated to be 1.3%, 5.3% and 9.3%. From the analysis presented it can be observed that CCS projects yield variable amounts of gross revenue. This variation is directly linked, among other factors, to variations in oil prices and recoverable oil percentages.

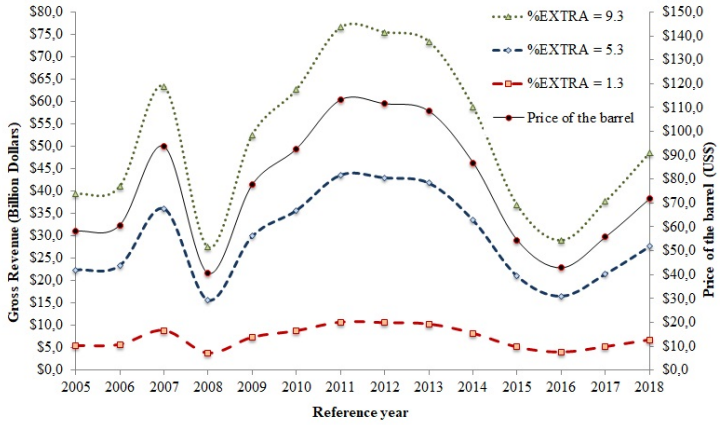

Figure 1 Variation of the average price of the Brent oil barrel and the gross revenue resulting from CCS projects.

The CO_2 storage potential in saline aquifers was analyzed: the Paraná Basin, Solimões Basin and the Santos Basin. These basins have, respectively, CO_2 storage potentials equal to 462 000, 252 000 and 148 000 MtCO2.

4. Conclusions

Using mathematical models, it can be concluded that the Roncador field presents higher gross revenue when the amount of extra oil that can be retrieved is 9.3% (US$ 48.55 billions approximately in 2018). Additional calculations show that the Paraná saline aquifer has the highest gross revenue (US$ 6.90 trillions in 2018) when compared to the Solimões (US$ 3.76 trillions approximately in 2018) and Santos saline aquifers (US$ 2.21 trillions approximately in 2018) if a CCS project were to be employed.

Reuse of coke oven and flue gases into methanol: a techno-economic assessment.

Jean-François Portha[1], Wilmar Uribe-Soto[1], Jean-Marc Commenge[1], Laurent Falk[1]

[1] *Université de Lorraine, Laboratoire Réactions et Génie des Procédés, UMR 7274, 1 rue Grandville, BP 20451, 54001 Nancy Cedex, France.*

**Corresponding author: jean-francois.portha@univ-lorraine.fr*

Highlights

- Methanol synthesis process is simulated using a computer aided design software.
- A techno-economic assessment is performed to evaluate the process viability.
- A preliminary carbon balance is performed.

1. Introduction

The iron and steel industry is one of the main energy intensive industrial sectors in the world. The associated CO_2 emissions are then very large representing, in 2006, 30% of the 7.2 Gt of direct CO_2 industrial emissions [1]. To mitigate these Greenhouse Gases (GHG) emissions, the development of Carbon Capture and Utilization (CCU) processes to reuse wasted gases is a crucial point to succeed in the energetic transition. These gases can be converted into Added Value Products (AVP). Various studies [2] have shown that methanol is a serious candidate as an AVP because it represents an interesting intermediate in chemical industry and offers the possibility to recycle a large quantity of carbon. Moreover, the methanol synthesis process from syngas is available at a commercial stage.

Three main off-gases are generated in the steelwork sector: the Blast Furnace Gas (BFG), the Basic Oxygen Furnace Gas (BOFG) and the Coke Oven Gas (COG). These gases, produced transiently, are classically used for energy integration in the steel mills or even burnt in flares without any profit. The development of transient processes able to convert these gases could be an interesting solution. This work focuses on the thermochemical reuse of COG that can be produced either in a steelwork or in an isolated coking plant. Interesting ways of COG reuse could be considered such as hydrogen recovery, syngas production or chemical looping [3]. Different process structures are investigated and assessed to produce methanol by COG conversion and by CO_2 reuse from flue gases.

2. Methods

COG contains mainly H_2 and CH_4 leading to two main case studies considered in this work to produce almost pure H_2: (i) the direct recovery of H_2 in the COG, and (ii) the reforming of CH_4 contained in the COG into H_2. Besides, the required quantity of CO_2 is extracted from flue gases to be hydrogenated into methanol. Both solutions are modelled, simulated and assessed from economic, energetic and environmental point of view. The process structure is divided into four main building block: H_2 separation, CO_2 capture, COG reforming and methanol conversion/purification. For each block, the available technologies are compared based on

heuristic criteria [1,4]. Then, the selected technologies are modeled considering some hypothesis and simulated on a Computer Aided Design (CAD) software (Aspen Hysys) enabling to determine mass flow rates, utility needs and the equipment size. A pinch analysis is performed to improve the heat integration among the different process units. The *levelized cost of methanol* is then calculated using a factorial method. A preliminary carbon footprint analysis was also performed in order to evaluate the potential savings in terms of GHG. The main calculated criteria was the *avoided* CO_2 which corresponds to the CO_2 that is not emitted in the atmosphere with respect to a reference system (methanol from natural gas) of methanol production and takes into account the quantity of CO_2 entering in the reuse process.

3. Results and discussion

The *levelized cost of methanol* is equal to 228 €/ton (+/- 30 %) for the case study (i) and to 268 €/ton (+/- 30 %) for the case study (ii). At current conditions (fossil fuels price, methanol price on the market and level of carbon tax), the cost of methanol from COG is slightly higher than the one produced from fossil fuels. Nevertheless, for a price of Natural Gas (NG) of approximately 3 €/GJ, the methanol production cost of the fossil fuels route will be comparable to the one of the reuse route. Concerning the *avoided* CO_2 criterion, the results obtained for case study (ii) are in good agreement with those obtained in the literature [5].

4. Conclusions

Two process structures describing the reuse of COG and flue gases into methanol are studied. The techno-economic evaluation has enabled to evaluate the CAPEX, the OPEX and finally the *levelized cost of methanol*. This cost is slightly higher than the current production cost of methanol from NG. Nevertheless, the evolution of the NG price on the market together with the evolution of the carbon price may offer some interesting perspectives.

Highlights

- The chemical degradation of PET in sub- and supercritical water.
- Complete depolymerization of PET at short reaction times.
- High yield of monomer TPA.

1. Introduction

Polyethylene terephthalate (PET) is a semi crystalline polymer derived from terephthalic acid (TPA) and ethylene glycol (EG). It has excellent tensile and impact strength, chemical resistance and appropriate thermal stability. Because of the low price it is suitable for wide use. Typical PET products are mainly foils, different plastic bottles, glazing panes, advertising, synthetic fibres [1,2]. Natural decomposition of PET waste is very slow, however, the amount of waste of this material dramatically increases every day on a global scale and consequently, recovery and recycling of PET waste seem to be the best alternatives to minimize its hazards [2]. PET waste can be recycled with four main methods namely, primary (re-extrusion), secondary (mechanical), tertiary (chemical) and quaternary (energy recovery) recycling. Chemical recycling is the most desirable process because the polymer is converted into its monomers (raw materials), which can be used for reuse [3]. Hydrothermal degradation of polymers e.g. PET with sub- and supercritical water is an attractive method for chemical degradation of waste plastics into a wide range of useful products, without expensive and often harmful organic solvents. Furthermore, sub-and supercritical water has a great advantage in use such as: short reaction times, use without catalysts, high yield of monomers and simple after treatment technology [4]. In this study, hydrothermal degradation of PET with sub- and supercritical water has been investigated.

2. Methods

The hydrolysis reaction of PET was carried out in a high pressure and high temperature batch reactor at different temperatures from 250 °C to 400 °C, for reaction time from 1 to 30 min and water/PET waste ratio 10/1. The certain amount of colourless post-consumer PET bottles and water was placed into the batch reactor. The batch reactor was several times flushed with N_2 to avoid oxidation. The initial pressure of N_2 was 20 bar. In addition, the batch reactor was heated to desired temperature and then maintained at the certain temperature for selected reaction time. When the hydrothermal reaction was completed, the reactor was immediately cooled down, the reaction products were collected and analysed. The main degradation products (TPA, EG) and secondary products were determined by HPLC and FT-IR analysis.

3. Results and discussion

PET waste treated in sub- and supercritical water at 250, 300, 350 and 400 °C and at reaction time 1, 10 and 30 min completely decomposed in each case. The experimental results showed that with increasing temperature and reaction time up to 300 °C and 10 min, the yield of TPA increased and then it started to decrease, or it remained the same. The highest yield of TPA has been identified at subcritical conditions, namely at 300 °C and at reaction time 10 min, and it was 96 %. The yield of TPA decreased at supercritical conditions, which can be a consequence of formation of higher amounts of secondary products (benzoic acid, 1,4-dioxane). The purity of precipitated TPA was also analyzed and it was very high (95 %).

4. Conclusions

PET waste was successfully decomposed to main products TPA and EG in sub- and supercritical water. The high yield and purify of monomer TPA were achieved under mild conditions. It was concluded that sub- and supercritical water is an excellent reaction medium for chemical recycling (decomposition) of synthetic polymers.

Reactive Extraction and Solvent Regeneration for Efficient Biobased Byproduct Isolation.

Daniela Painer[1], Susanne Lux, Matthäus Siebenhofer

1 Graz University of Technology, Institute of Chemical Engineering and Environmental Technology

**Corresponding author: d.painer@tugraz.at*

Highlights

- Reactive extraction is perfectly suited for recovery of dilute carboxylic acids.
- Reactive distillation shows high potential for efficient solvent regeneration.
- High yields of methyl esters were achieved in reactive distillation with catalysis.
- Homogeneous catalyst circulation between extraction and distillation is feasible.

1. Introduction

In the biorefinery, downstream processing is often faced with dilute multicomponent mixtures with high tendency to azeotrope formation. In pulping for example, a wastewater is produced, which contains carboxylic acids, mainly acetic acid and formic acid. For a 200 000 t a^{-1} pulp production capacity Sjöström [1] calculated the formation of carboxylic acid and hydroxycarboxylic acid with 75 500 t a^{-1}. Depending on the process, the volatile carboxylic acids are evaporated from the black liquor with the water before the black liquor is incinerated. Due to environmental reasons the carboxylic acids need to be removed from the wastewater. By isolating the pure acids wastewater treatment could contribute to process economics. State of the art process for the recovery of carboxylic acids from aqueous streams is reactive extraction with several distillation steps (e.g. entrainer distillation, vacuum distillation), necessary for solvent regeneration. The aim of this project is to simplify downstream processing for the economic recovery of carboxylic acids from pulping.

2. Methods

Process concept: Reactive extraction is well investigated and perfectly suited for acid recovery from aqueous effluents. For solvent regeneration, reactive distillation is investigated to improve separation performance in distillation. Therefore, the carboxylic acids are esterified with methanol to produce low boiling methyl esters. The esters are continuously separated in the distillate, which forces the reaction equilibrium composition in the solvent to complete conversion. The regenerated solvent with the reaction water is cycled back to the extraction step, where the reaction water is transferred to the raffinate.

Reactive extraction: Liquid-liquid equilibrium experiments were performed for single acid and multi acid aqueous mixtures with Cyanex®923 as reactive extractant (70 w% in *n*-undecane) at 25 °C. The influence of a strong acid (4-dodecylbenzenesulfonic acid) in the solvent phase on the equilibria was quantified.

Reactive distillation: Solvent regeneration was investigated in batch reactive distillation experiments with different acid concentrations and molar ratios of methanol to acid. To increase the reaction rates, strong acidic catalysts were admixed. For catalysis, Amberlite IR-120, a heterogeneous catalyst, and the homogeneous catalyst 4-dodecylbenzenesulfonic acid were studied.

3. Results and discussion

Reactive extraction: The reactive extractant Cyanex®923 showed good extraction efficiencies in single and multi-acid mixtures. In single-acid experiments, formic acid and acetic acid were extracted in a similar extent while for a multi-acid mixture, formic acid was preferably extracted to the solvent phase. This occurs due to the tendency of Cyanex®923 to adduct formation with stronger acids. This behavior was also observed when 4-dodecylbenzenesulfonic acid was admixed to the solvent phase. In this case, Cyanex®923 formed the adducts with the strongest acid, limiting the extraction efficiencies of formic acid and acetic acid. However, at low acid concentration like in wastewater from pulping, enough reactive extractant is available in the solvent phase for adduct formation with all acids. [2]

Reactive distillation: High solvent regeneration efficiency is essential for appropriate extraction efficiency. Uncatalyzed batch reactive distillation experiments showed already high yields of methyl formate transfer to the distillate of 95 %. Acetic acid reacted too slow for appropriate solvent regeneration. The low rate of acetic acid esterification was the main reason for admixing 4-dodecylbenzenesulfonic acid to the solvent phase for catalysis. The yield of methyl acetate increased from 19 % for uncatalyzed to 88 % for catalyzed experiments with an amount of 5 w% 4-dodecylbenzenesulfonic acid in the solvent phase. [2] The heterogeneous catalyst Amberlite IR-120 increased the reaction rate to a similar extent. The main advantage of heterogeneous catalysis is, that catalyst separation from the solvent is not necessary as it is fixed in the distillation column. However, a temperature limitation has to be considered.

In homogeneous catalysis, the drawback is the catalyst separation step. To avoid an additional process step, the influence of the catalyst in the solvent phase during extraction was investigated. As already mentioned the reactive extractant Cyanex®923 prefers adduct formation with strong acids, loss of catalyst to the aqueous phase can be neglected. The limited extraction efficiency can be circumvented by increased phase ratio of the solvent to the raffinate phase. Because of the partition characteristic of the system carboxylic acid/Cyanex 923 based solvent/water, which is a Langmuir-type liquid-liquid equilibrium, low acid concentration in the aqueous phase does not suffer from admixture of 4-dodecylbenzenesulfonic acid.

4. Conclusions

Reactive separation shows high potential for efficient downstream processing of aqueous multicomponent mixtures. Combination of reactive extraction and reactive distillation for solvent regeneration offers the opportunity of economic isolation of acetic acid and formic acid from waste effluents by transferring them into their methyl esters.

Highlights

- Formate was obtained in a continuous mode with a single pass in a filter-press reactor.
- Bi-GDEs were able to work at a current density up to 300 mA cm^{-2}.
- At a 200 mA cm^{-2}, 4 g L^{-1} of formate was obtained with a high faradaic efficiency (80%).
- Concentrations of formate of up to 18 g L^{-1} were obtained.

1. Introduction

Electrochemical reduction of CO_2 is being considered as an interesting option to store energy from intermittent renewable sources in the form of chemical valued-added products. Among all the different valued-added products, formate is an attractive product used for several industrial applications and particularly, it has been highlighted as a promising fuel for low-temperature fuel cells and as renewable hydrogen carrier [1].

Our previous research on using Catalyst Coated Membrane Electrodes (CCMEs) using tin nanoparticles as catalyst [2] achieved formate concentration up to 19.2 g L^{-1} with a faradaic efficiency (FE) of 50%, a rate of 1.15 mmol m^{-2} s^{-1} and an energy consumption of 244 kWh $kmol^{-1}$ of formate in the output stream of the electrochemical reactor. These results could be improved using Bi as a catalyst material in the cathode according to the growing number of promising results that point to the possibility of electroreducing CO_2 to formate at lower potentials than other metals [3]. This communication is focused on the development of Gas Diffusion Electrodes using carbon-supported Bi nanoparticles (Bi-GDEs), operating in a continuous mode in a filter-press reactor.

2. Methods

Bi-GDEs were prepared by depositing carbon-supported Bi nanoparticles over a Toray carbon paper, used as a carbonaceous support. In the filter-press cell, Bi-GDEs were used as the working electrode and a Dimensionally Stable Anode was used as the counter electrode, whereas an aqueous solution of KCl+$KHCO_3$ and KOH is used as catholyte and anolyte respectively. A cation exchange membrane (Nafion 117®) divides the cathodic and anodic compartments in the cell. The concentration of formate is analyzed by ion chromatograph (Dionex IC 1100).

3. Results and discussion

Working with a electrocatalyst load of 0.75 mg cm^{-2} and electrode area of 10 cm^2, different experiments were carried out at different current densities and electrolyte flow/area ratios for continuous electroreduction of CO_2 to formate in the filter-press type cell, with only one pass of the electrolyte through the cell.

Working at a current density of 300 mA cm^{-2} and electrolyte flow/area ratio of 0.57 mL min^{-1} cm^{-2}, a formate concentration of 5.2 g L^{-1} with a FE, rate and energy consumption of 70%, 11 mmol m^{-2} s^{-1} and 410 kWh per kmol of formate, respectively, were achieved. Decreasing the current density from 300 mA cm^{-2} to 200 mA cm^{-2}, keeping the same value of electrolyte flow/area ratio, the formate concentration decreased to 4 g L^{-1} with a FE and rate around 80% and 8.3 mmol m^{-2} s^{-1}.

Subsequently, the influence of electrolyte flow/area ratio was analyzed in order to obtain a formate product as concentrated as possible, as can be shown in Figure 1.

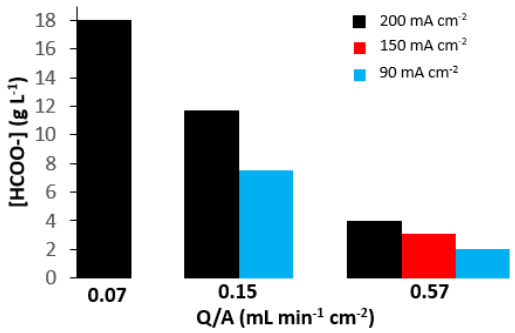

Figure 1. Formate concentration as a function of the current density and electrolyte flow/area ratio.

These results confirm that Bi-GDEs allow working in a continuous electrochemical reactor with higher current densities values compared with recent contributions in literature.

4. Conclusions

It is important to remark that these results were obtained working at higher current densities than previous studies reported in the literature, and they were also obtained in a continuous mode with only one pass of the catholyte through the filter press cell. These conditions are mandatory to remark the feasibility of the continuous electroreduction process using Bi/C-NPS in Bi-GDEs.,

Electrochemical Production, Downstream Processing and On-Site Application of Hydrogen Peroxide

Carsten Cremers, Jan Meier, Dusan Boskovic, Angelika Eberhardt, Alexander Mendl, Giancarlo Piscopo, Stefan Loebbecke[1]

[1] *Fraunhofer Institute for Chemical Technology ICT, 76327 Pfinztal, Germany*

**Corresponding author: Stefan.loebbecke@ict.fraunhofer.de*

Highlights

- Green electrochemical synthesis of hydrogen peroxide
- Purification and concentration of H_2O_2 by means of membrane distillation units
- Process analysis for monitoring H_2O_2 concentration
- On-site production and forward integration of H_2O_2 streams into subsequent reaction processes (here: selective oxidations)

1. Introduction

Today, in many countries the percentage of produced electricity that is obtained from renewable sources is significantly rising. This energy transition has led to the generation of low-carbon electricity, which opens up new pathways for the design of current-driven (›power-to-X‹) chemical processes.

Hydrogen peroxide H_2O_2 is considered one of the most versatile and powerful chemical oxidants for a wide range of chemical reactions. It is environmentally friendly, selective and also highly active for various oxidation processes including chemical production, paper and pulp bleaching, waste water treatment or disinfection processes. Today, hydrogen peroxide is mainly produced in world-scale production facilities consuming not only huge quantities of energy and organic solvents but also generating substantial quantities of waste. Moreover, large scale production processes of hydrogen peroxide require significant logistical resources concerning transport, storage and safety. Many users of smaller and medium quantities, however, would prefer to avoid the complicated logistics and storage, and to produce H_2O_2 themselves as required at their own location, using simpler methods.

2. Methods

We have developed a demonstration process for the decentralized electrochemical production of hydrogen peroxide and its continuous supply to a downstream chemical process. The key element of the here presented small-scale process is an on-site and on-demand production concept for H_2O_2 to avoid the transport, storage and handling of huge amounts of highly concentrated hydrogen peroxide.

3. Results and discussion

The demonstration process enables the continuous, electrochemical production of H_2O_2 in the aqueous reaction system through the cathodic partial reduction of atmospheric oxygen. Key issues were the development of suitable electrocatalysts and the design of the electrochemical reactor including the up-scaling of appropriate gas diffusion electrodes.

The synthesis is conducted in acidic electrolytes which are later separated in the process. Continuous processing techniques, some of which use micro-structured process components, have been developed for the subsequent purification and separation of the produced H_2O_2 from the electrolyte, and for the reuse of the electrolyte in the electrochemical process. The produced hydrogen peroxide can be directly connected to subsequent chemical processes where H_2O_2 solutions are required. As a consequence, the downstream processing of the electrochemical synthesis includes also a concentration step, where beforehand purified H_2O_2 is concentrated to the single-digit percentage range as it is typically required in fine chemical oxidation processes. Both separation units are based on membrane distillation. Raman spectroscopic process analysis allows tracking of the hydrogen peroxide concentration almost in real-time along the entire process chain (synthesis, separation, concentration, and hand-over to subsequent process).

The forward integration of the pre-treated H_2O_2 stream has been demonstrated using the example of a selective oxidation reaction being applied for the desulfurization of fuels. Through the parallel development of suitable oxidation catalysts, full conversion and fast desulfurization rates were demonstrated using low-concentrated (e.g. 3%) H_2O_2 solutions.

4. Conclusions

The application potential of decentralized, small-scale units for the continuous on-site production of H_2O_2, which can ideally be operated with 100% sustainable electricity, goes far beyond classical chemical synthesis processes. There is an increasing demand for environmentally-friendly oxidation and bleaching processes in numerous other sectors, such as medical and hygiene technology, food technology, agriculture, water treatment and the textile and cleaning industry.

A new heterogeneous organocatalyst for Knoevenagel Reaction process intensified by microwaves

Highlights

- Heterogeneus organocatalyst under microwave heating
- Comparison between conventional and microwave heating for knoevenagel reaction
- Reuse of organocatalyst

1. Introduction

Sustainability in chemical synthesis is one of the main objectives nowadays, meant to be addressed by maximizing the industry production efficiency and minimizing the environmental costs. In order to develop an eco-friendlier relationship with our planet, the society has created new legislations which encourage the design of organic reactions using greener strategies such as the combination of microwave heating with effective, low cost and reusable catalysts.

One powerful and commonly used reaction for the formation of carbon-carbon bonds is the Knoevenagel condensation, an addition of a carbanion to an electrophilic carbonyl group in the presence of a weak base. Several reaction methodologies have been reported so far in literature and the interest is mainly focused on the development of environmentally and economically friendly reaction protocols. In this work, the Knoevenagel reaction was tested using 1,4-diabycyclo [2.2.2] octane (DABCO) an organic molecular catalyst (organocatalyst) which is attractive due to its easy reproducibility and low cost.

Various experimental conditions have been tested in order to obtain a greener protocol. The major drawback found was the difficulty to recycle the organocatalyst used due to its inherent instability and miscibility with solvents (2). To facilitate the reuse of the catalyst, the immobilization of DABCO over the mesoporous silica MCM-41 was done. To the best of our knowledge this was done for the first time in literature.

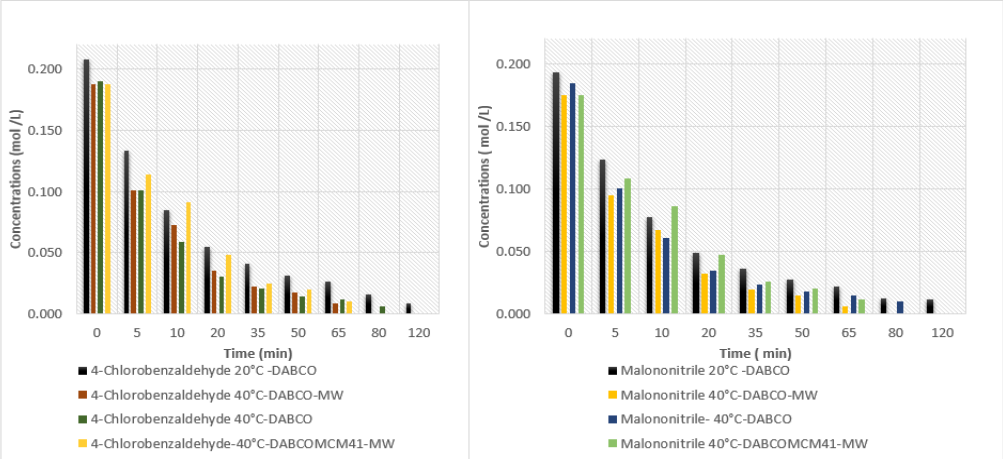
In this investigation, the objective was not only limited to a cleaner protocol but also extended to energy efficiency. The latter was achieved by coupling the process with microwave heating which resulted in a significant reduction in reaction time, precise control of temperature and hence better

energy efficient. The combination of these techniques promise to be an interesting way to intensify Knoevenagel condensation based processes.

2. Methods

The knoevenagel condensation using 4-chlorobenzaldehyde and malononitrile as reagents to obtain 4-chlorobenzilidene malononitrile as a product, was done using organocatalysts as DABCO and DABCO supported on mesoporous silica-MCM 41, allowing to have a homogenous and heterogeneous medium of reaction. The reaction was tested both in microwave and classical heating. For the identification and quantification of reagents and products a GC-FID (Gas Chromatography-Flame Ionization Detection) is used. The given results are used to calculate the reaction yield in time.

3. Results and discussion



Graphic 1. Reagent's Concentration evolution with time for different operational conditions (Malononitrile = 0,20 mol/L 4-Chlorobenzaldehyde=0,20 mol/L DABCO= 0,00217 mol/L Agitation = 8 Pressure: 1 atm) *MW= Microwave heating

This supported catalyst was tested under the conditions same as its homogenous analogue (DABCO), resulting in the same efficiency in addition to the fact that it could be recovered from the reaction mixture and reused without any significant loss of activity. Microwave heating was also compared to classical one.

4. Conclusions

A new heterogeneously supported DABCO catalyst has been developed for improving the Knoevenagel reactions. It allows easy recovery of the catalyst and its reuse, without any significant loss of activity which is a great improvement towards more sustainable processes. The combination of this type of catalysts with microwave heating is also promising by reduction of reaction time and cost, and by using a non-toxic and environmentally friendly reaction protocol.

Highlights

- Applied research work for the refinery process optimization
- Experimental data from pilot plant to calculate reaction kinetics, analyze aromatics & H consumption
- Study Impact of the changes on catalyst activity, product yield & product quality
- sustainability objectives to reduce waste generation, recycle and reuse of spent catalyst

1. Introduction

Gas Oil (GO) hydrotreater in the ADNOC refinery is designed to process Heavy Gas Oil (HGO) and Light Gas Oil (LGO) coming from crude/condensate units and produce Gas Oil with total sulphur ≤ 10 ppmw. During turnaround, GO hydrotreating (GO HDT) catalyst was unloaded from this unit after serving one cycle of 4 years. On other hand, at the time of catalyst selection it was envisaged that this catalyst can be used for two cycles. So this catalyst still having useful life leftover was considered for reuse in other hydrotreaters viz. Naphtha HDT and Kerosene HDT units in the refinery. Naphtha HDT unit is processing Whole Naphtha (WN) coming from Crude Distillation Unit (CDU) to produce max 0.5 ppm sulfur content of Heavy Naphtha (HN) which is the feed stock of Catalytic Reforming (CR) unit. Kerosene HDT unit is processing Kero or light gas oil to produce Kero with less than 10 ppm sulphur. Hence pilot plant study was undertaken to evaluate the reuse of catalyst for the second cycle to process WN and Kero, to produce on spec product, to evaluate regenerated GO HDT catalyst, Estimate the H2 Consumption, Analyze product PONA at higher WABT & Assess the performance of catalysts at higher nitrogen content more than 10 ppm wt.

2. Methods

Hydrotreating experiments were carried out according to refinery unit test conditions, with reference feed stock Whole Naphtha & raw Kerosene and were processed using a GO HDT regenerated catalyst in a pilot reactor at fixed operating conditions, as listed below Table # 01. The pilot plant test started with LHSV 4 hr^{-1} at 275 ˚C and on specs product for Nitrogen were achieved but sulphur was at 1.3 ppm. Hence WABT was increased to 280 ˚C temperature to achieve product target sulphur content below 0.5 ppm. Test points were created for increased throughput upto to 5 hr^{-1} for NHDT. For Kero HDT, test points were also varied for pressure, temperature & LHSV.

3. Results and discussion

Whole Naphtha has low nitrogen content but the performance of the catalyst was tested at high nitrogen content in the feed (>10 ppm) because GO HDT catalyst has higher HDS activity than HDN activity and it was observed that this GO HDT catalyst is capable to handle feeds having the higher nitrogen range. Hydrogen partial pressure was reduced from 25.5 kg/cm^2 to 23.7 kg/cm^2 and there was no noticeable change in catalyst performance.

Table 1. Test operating conditions

Test	FEED	Pressure	LHSV	H2/HC	Temp	Sulfur in Product	N in Product
Nº		(kg/cm^2)	(h^{-1})	(Nm^3/m^3)	(°C)	(ppm)	ppm
1 - 7	Naphtha	25.5 to 23.7	4 to 5	44	275 to 320	1.2 to < 0.5	<0.3
8	Naphtha (10 ppm N)	23.7	4.5	44	280	< 0.5	<0.3
9-11	Kero	44.24 to 40.26	2 to 2.5	305	275 to 280	3.8 to 1.4 (Mercapan S)	-

For kerosene HDT, pilot plant test was started at LHSV 2 hr^1 at 275˚C and product specs were observed within acceptable range. The mercaptan sulphur in the product was reported around 3 ppm (on specs) for the first test point, then temperature was increased to 280 ˚C to compare the results with current operation of Kero HDT unit. Also at higher LHSV of 2.5 hr^{-1}, on spec Kero with <10 ppm mercaptan sulphur was achieved. Furthermore, hydrogen partial pressure was reduced from 44.24 kg/cm^2 to 40.26 kg/cm^2 and there was no noticeable change in mercaptan sulphur.

Hydrogen consumption has been estimated to 14.67 Nm3/m3 Kero HDT & 2.63 Nm^3/m^3 for Naphtha HDT, by performing a material balance for the selected test points at stable operating conditions accompanied by a series of analysis.

4. Conclusions

Based on the pilot plant test, it was concluded that the GO HDT catalyst is suitable to re-utilize to process whole naphtha and kero to produce on spec product. As per the results from the variable test points, both units can operate satisfactorily at higher LHSV and at lower hydrogen partial pressure without any impact in the product quality. For Naphtha HDT Unit, there is no tendency of aromatic saturation at higher temperature i.e. 320 ˚C. Hence there is no effect on feed selectivity for downstream reforming unit. Also it was observed that this catalyst is capable of handling higher nitrogen content i.e. 13.3 ppm in Naphtha feed. Taking into consideration the lower SOR temperature for Naphtha HDT unit at 280 ˚C and for Kero HDT unit at 295 ˚C, expected cycle length will be more than 4 years.

Life Cycle Assessment of a Biomass-to-Liquids process

Caretta Antonio[1]*, Bua Letizia[1]

[1] Eni spa / Renewable Energy & Environmental R&D via Giacomo Fauser 4, 28100 Novara, Italy
*Corresponding author: antonio.caretta@eni.com

Highlights

- LCA of Biomass-to-Liquids (BTL) process
- Environmental impact assessment of biomass-derived fuel
- Comparison of LCA results to RED and to REDII
- Bio-fuels sustainability

1. Introduction

Reducing the environmental impact of technologies, processes and products is nowadays an important scientific challenge. In particular, the substitution of fossil fuel with biomass-derived fuels helps towards reaching this goal.
The scope of this work is to assess the environmental impact of the Biomass-to-Liquids (BTL) diesel. The Biomass-to-Liquids process (BTL) is a thermo-catalytic pathway to transform biomass to liquid fuels, in particular to middle distillates including diesel cuts.
The main steps of this technology include thermal gasification of biomass, followed by syngas clean up, Fischer-Tropsch synthesis and hydrocarbon isomerization to produce suitable synthetic fuels [1], [2].
The environmental impact of biomass-derived fuels has been calculated following the LCA methodology reported by the Renewable Energy Directive. The result must be compared to the limits imposed by RED (2009/28/EU) [3] and by the most recent RED II (2018/2001/EU) [4].
This study confirmed that the environmental impact (in term of Global Warming Potential, GWP) of BTL diesel is lower than the one of fossil diesel and respects the emission reduction suggested both in RED and in RED II framework.

2. Methods

The methodology followed is the LCA (Life Cycle Assessment) based on the International Organization for Standardization standard procedures (ISO 14040 – ISO 14044 series) [5], [6]. The tool used for evaluation is the software GaBi (property of the company Thinkstep).
The Life Cycle Inventory (LCI) for the LCA come from the BTL model simulation, developed internally during a project related to biofuel production. It is worth to noting that the LCA results are strictly affected by site characteristics and scenario definition.
In *Goal&Scope* definition, the Functional Unit (FU) is defined as 1 MJ of produced diesel and the System Boundaries are extended from raw biomass to bio-fuels products (diesel, naphtha). Starting from the available input data, a *Life Cycle Inventory* (LCI) has been built up and a model for the system has been defined and inserted in the software GaBi for simulation. The results have been expressed in terms of Global Warming Potential (GWP) using a 100-years timeframe according to CML2001–Apr.2013 method [8]. These results give the *Impact Assessment* related to the BTL

process. Each one of the three LCA phases (Goal&Scope, LCI and Impact Assessment) is subject to interpretation for results improvement.

3. Results and discussion

This LCA study describes a competitive path to produce fuels via BTL process. The assessment has been applied to different species of biomass in input. Each kind of biomass causes a different environmental impact. These differences could be related to cultivation procedures, water and fertilizers consumption. Usually, considering the RED, the cultivation phase (CO_2 capture by the biomass) balances the use phase of the fuel. In present study both phases are considered separately, in order to perform a sensitivity analysis related to the biomass.
The comparison between the environmental impact of BTL-diesel and of conventional fossil fuel defined by the RED and the REDII points out the environmental advantages by using BTL-fuels in the direction of reducing global greenhouse gas emissions.

4. Conclusions

The environmental impact of BTL-diesel is biomass dependent. In many cases analyzed it is plenty lower than the impact due to fossil fuel reference both as reported in RED and in REDII datasets and it respects the reduction of GHG higher than 60% as requested in RED (plant in operation after 6th October 2015) and than 65% as reported in REDII (plant in operation after 1st January 2021).

Supercritical CO_2 impregnation of cotton gauze with bioactive compounds from *Olea europea* leaves

Lourdes Casas Cardoso, María Teresa Fernández Ponce, Cristina Cejudo Bastante, Casimiro Mantell Serrano, Clara Pereyra López, Enrique Martínez de la Ossa.

Chemical Engineering and Food Technology Department, Wine and Agrifood Research Institute (IVAGRO), University of Cadiz, Cádiz, Spain.

**Corresponding author: lourdes.casas@uca.es*

Highlights

- The extract from *Olea europea* leaf showed antioxidant and antidiabetic capacity.
- Loaded cotton gauze with olive extract was produced by SSI.
- Applying 100 bar and 55 °C favored olive extract impregnation in cotton gauze.

1. Introduction

Food processing generates a substantial volume of solid organic by-products, which are usually used for composting or even discarded in open areas, thus causing potentially environmental problems. The valorization of food industry waste may include several options including extraction and impregnation of bioactive compounds for utilization in the food, cosmetic and pharmaceutical industries.

Supercritical solvent impregnation (SSI), is an efficient and environmentally friendly technique, that is used to the deposition/incorporation of active agents into polymeric matrices. The impregnation of active molecules occurs as a consequence of the interaction balance between the active substance, the matrix and the supercritical phase, which results in an adsorption or a physicochemical attachment of molecules to the polymeric matrix. Furthermore, some of SSI's advantages are that processes run at moderate temperatures, thus avoiding degradation of thermolabile compounds, and solvent free products can be obtained from the complete desorption of CO_2 gas during the depressurization step.

SSI can be used to develop functional gauze textiles loaded with antioxidant, antimicrobial, anti-inflammatory or antidiabetic agents in order to produce functional textiles with potential applications for instance, in the pharmaceutical field. The main objective of this work was to study the SSI of bioactive leaves extract into cotton gauze. The potential biologically activity of extracts prepared from *Olea europea* leaves were evaluated.

2. Methods

Firstly, an extract from *Olea europea* leaf was obtained by Enhanced Solvent Extraction (Thar Technologies, model SF1000) using CO_2+ethanol (1:1 v/v) at 200 bar and 80 ºC, a flow rate of 10 g/min and during 2 h. Results were analyzed according to the global yield, antioxidant activity determined by 2,2-diphenyl-1-picrylhydrazyl assay [1] and inhibition of α-glucosidase evaluated by p-nitrophenyl-a-D-glucopyranoside [2].

Afterwards, the extract was used as active substance in the supercritical impregnation of cotton gauzes using an equipment supplied by Thar Technologies (Pittsburgh, PA, USA, model SF500). The influence of the operating conditions such as pressure (100-400 bar) and temperature (35-55 ºC) were studied.

3. Results and discussion

The use of ethanol as co-solvent in the enhanced solvent extraction of active compounds from *Olea europea* leaf favored the obtaining of high global yields (12.27 %). The antioxidant activity index of the *Olea europea* leaf extract labels it as "moderate antioxidant" following the Scherer et al. classification [1]. On the other hand, the pharmaceutical potential of olive extract was evaluated by the α-glucosidase inhibition assay as a determination of the antidiabetic capacity. This extract exhibited a total inhibition against α-glucosidase at 130 ppm.

The results from the experiments carried out at different pressures (100-400 bar) and temperatures (35-55 °C) on the SSI process are displayed in **Fig. 1**. It can be seen that extract was efficiently impregnated into cotton gauze. The best result was obtained at 100 bar and 55 ºC.

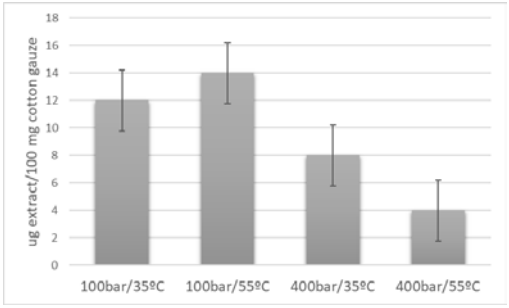

Figure 1. Load of cotton fabrics processed at the different pressures and temperatures.

The impregnation efficiency is governed by the partition coefficient defined as the ratio of equilibrium concentration of the active substance between the polymer matrix and the supercritical phase. In this case, a low solubility of active compounds at 100 bar and 55 ºC favored the impregnation of *Olea europea* leaf extract due to a higher affinity for the polymer matrix.

4. Conclusions

The use of ethanol as co-solvent favored the obtaining of high global yields and the recovery of antioxidant compounds. The extract exhibited a total inhibition against α-glucosidase with 130 ppm.

SSI process has demonstrated to be a promising alternative for the production of active cotton fabrics. Actually, cotton gauze with a high content in antioxidant and antidiabetic were produced in this study. This is a technology that presents an outstanding potential in pharmaceutical applications.

Data intensive based tool for supporting circular economy in agri-food process.

Jean-Pierre Belaud[1], Nancy Prioux[2], Claire Vialle[2] et Caroline Sablayrolles[2]

[1] *Laboratoire de Génie Chimique, Université de Toulouse, CNRS, Toulouse, France;*

Highlights

- To support circular economy with agri-food waste valorization.
- To propose a life cycle thinking based approach for selecting biomass and process.
- To take benefit from public and scientific data.

Each year, agriculture generates 700 million tonnes of waste in Europe and with the increase of the world population this number increases. This augmentation of the waste production creates an increase of its environmental impacts. However, a part of this agricultural waste consists in lignocellulosic by-products which can be transformed into bio-energy, biomolecules or biomaterials. A solution to reduce the agricultural waste is to transform these lignocellulosic by-products thanks to sustainable process operations. The assessment of the sustainability is now integrated to more and more agrifood process. The sustainable development for the agricultural by-product valorization must be economically efficient, socially fair and environmentally sustainable like every sustainable development. A new business model appeared recently -the circular economy and industrial ecology- to lead a more sustainable development [1]. It contributes to reconcile the environmental, economic and social aspects of sustainability. Our application to contribute at this reconciliation is the creation of an approach to help for the choice between different biomasses and industrial paths. The tool created from this approach allows to compare six different biomasses (rice straw, bagasse, corn stover, sugarcane straw, wheat straw and spruce chips) and their associated processes.

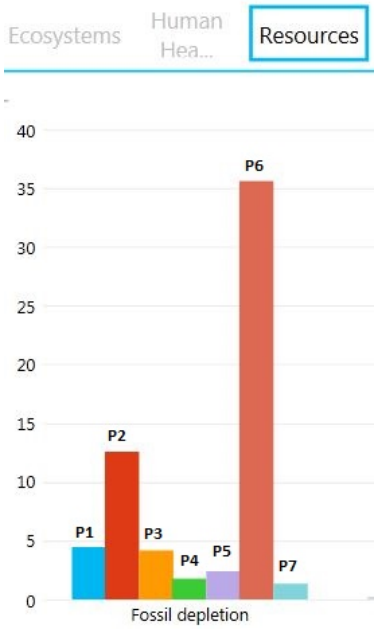
To help the reconciliation, it is possible to use the Life Cycle Thinking (LCT), which considers the full life cycle of the agriculture supply chain. This thinking is used in the Life Cycle Assessment (LCA) method to evaluate the potential environmental impact of a product or service over its entire life cycle. A lot of articles are published to compare different waste management systems under a LCA. The data can be obtained by two ways: directly, by on-site measurement, or indirectly – from different data bases. Generally, the data for the foreground system are obtained directly and for the background system indirectly. There are more and more scientific articles published describing agricultural by-product valorization processes and operations. These articles are a high added value data source for the foreground system. As the on-site measurements are expensive and time-consuming, in this way the scientific articles allows the LCA researcher to save time and money. Yet, prospecting a huge quantity of unstructured data is difficult and cannot be done without some degree of automation. The utilization of the Big Data tools can be relevant to structure knowledge into formal representations for exploitation by computers. The main goal of this work is to develop a data intensive approach and the associate tool to supporting the decision in the context of circular economy in the domain of the agri-food industry. The three objectives set of this goal are (1) to benefit from a large quantity of data for a same process thanks to all the experiments carried out

by the researchers all around the world (2) to avoid experiments which are time consuming and expensive (3) to place the LCA upstream in a preliminary eco-design approach in order to select agriculture supply chain or to fix trends.

The approach proposed in this paper is based on big data tools, sustainability engineering and life cycle thinking for supporting decisions on agricultural by-product valorization dedicated to engineers, academics, managers and policy decision makers. The approach is divided into five steps - It is always possible to return to the previous stage to complete the data or to add details:

1. Definition of the goal and scope of the study
2. The extraction of relevant information from heterogeneous data sources (from big data)
3. Life cycle inventory
4. Indicators calculation (from Life Cycle Impact Assessments, “green chemical” metrics and economic indicators calculations)
5. Ranking the results and analysis (from data visualization)

To validate the approach, a tool is created with VBA-Excel. This tool allows to extract the process data, to make the LCI thanks to the EcoInvent v3 database, to calculate the environmental and economic impacts and then to visualize the results for the comparison of lignocellulosic biomass pretreatment processes. The bioconversion of lignocellulosic biomass is a promising method for the production of bio-energy, biomolecules or biomaterials. This bioconversion involves the enzymatic hydrolysis of the biomass to release glucose. Biomass pretreatment is essential, to decrease crystallinity, increase the specific surface area and porosity, and separate the major constituents.



Corn stover illustrates the approach (picture beside). 7 processes involving different technologies are under study. Their sequence of unit operations are of 3 kinds: only mechanical operations (P7), mechanical and physico-chemical operations with press and separation (P3, P4, P5, P6), and mechanical, physico-chemical operations with press, separation and extrusion (P1, P2). LCA impact indicator “Fossil depletion” from ReCiPe 2008 end-point is shown. The approach should enable researchers, and other users, to identify the “best” process for a specific biomass. That could be improved by enhancing ranking procedures and including scaling (to address industry needs). The interactive visualization also allows the approach user to move in different levels of the results. Furthermore, in the tool created, the environmental indicators from LCA could be combined with economic indicators, providing a more general overview of the various processes and technologies regarding to sustainability management.

**esteban.duranherrera@ucr.ac.cr*

Highlights

- Several perovskites were synthetized; $Cs_3Bi_2I_9$ (1.94 eV) was chosen for evaluation
- A maximum CO yield of 163.87 µmol/g_{cat}·h was obtained
- Highest CO_2 reduction was obtained at 42.5 µL/min and 150 mW/cm^2

1. Introduction

In recent years, research activities in the field of CO_2 reuse to produce synthetic fuels have been greatly stimulated by the growing concern about the effect of CO_2 emissions on global warming and fossil fuel dependency issues. A particularly emerging and promising technology for this process is perovskite-based heterogeneous photocatalysis. Perovskite oxides are promising photocatalysts due to their high catalytic activity, good stability, long charge diffusion lengths, and compositional flexibility that allows precise bandgap and band edge tuning. Furthermore, once an efficient catalyst is developed, the next step is to incorporate it in photoreactors capable of commercially produce the synthetic solar fuels. Multiple designs have been proposed and tested; however, limitations due to diffusional processes (mass transfer) and proper distribution of incident radiation on the reactor, hinder the efficient performance of the photocatalytic system. In this sense, microreactors have emerged as an excellent technological alternative to minimize these inconveniences and maximize the production of solar fuels. In this work, several perovskites were synthetized, characterized and $Cs_3Bi_2I_9$ photocatalytic activity was evaluated using a homemade 3D-printed photo-microreactor.

2. Methods

Perovskites such as $Cs_4CuX_2Cl_{12}$ with X: Bi, La, Al, Fe, Cr; $Cs_3X_2Cl_9$ with X: Sb, Bi, La, Al, Fe; $Cs_4SnX_2Cl_{12}$ with X: Sb, La, Al, Fe, Cr; $Cs_3Bi_2I_9$ and $Cs_3Sb_2I_9$ were synthetized. Band gap calculations were performed using UV-Vis Diffuse Reflectance measurements through Kubelka-Munk (K-M) model and Tauc's plot. Furthermore, some of them were characterized by means of SEM/EDX, ICP, XRD, Stylus Profilometry and Quantum Yield. The microreactor was designed to fit inside a Micronit™ chip holder and in a way that different catalyst-coated glass slides could be easily loaded and tested in the same reactor (see Fig. 1). It was printed using HIPS with a reactor chamber of 25.9 mm x 25.9 mm x 0.5 mm. Synthetized perovskites were coated in glass slides by drop casting and spin coating. A solar simulator (Oriel™ LCS-100) was used as radiation source. 99.99 % CO_2 was bubbled in a NaOH solution and then pumped into the reactor using a syringe pump. The samples at the outlet of the reactor were analyzed by GC-TCD (Shimadzu 2014) with a 30 m Carboxen® 1010 column.

3. Results and discussion

Calculations for direct and indirect band gap through Tauc's plot showed results varying from 1.07 eV to 3.36 eV, indicating promising activities in the visible spectrum for some of the synthetized perovskites. Within the synthetized perovskites, $Cs_3Bi_2I_9$ was chosen for evaluating its photocatalytic activity. CO_2 measurements in the liquid phase at the inlet and outlet of the reactor showed up to 67 % conversion, suggesting that CO_2 was being consumed. Furthermore, the presence of CO, a known product of CO_2 photoreduction, was detected in the product samples, thus leading to believe the photocatalytic reduction of CO_2 with the $Cs_3Bi_2I_9$ was achieved. The effects of operating parameters such as liquid flowrate and light intensity were then evaluated. CO was quantified obtaining concentrations from 1.07 mmol/L up to 6.15 mmol/L and yields from 89.71 µmol/g_{cat}·h up to 163.87 µmol/g_{cat}·h. These results are comparable to methanol yields obtained by Cheng et. Al [1] (111 µmol/g_{cat}·h) and Cheng et. al [2] (454.6 µmol/g_{cat}·h) in UV-microreactors using TiO_2 as catalyst. Analyzing the effect of liquid flowrate (see Fig. 2), the gas-phase concentration of CO at the outlet of the reactor increases as flowrate decreases, as a consequence of higher residence times. However, the amount of CO generated per gram of catalyst per hour (yield) shows a peak value at middle flowrate, due to mass transfer improvement in the reactor. Also, experiments performed using different light intensities showed that yield and CO concentration increase with higher light intensity; this due to the generation of more electron-hole pairs which enhances the reaction rate.

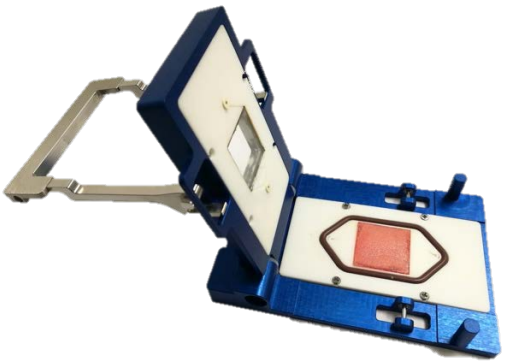

Figure 1. Microreactor

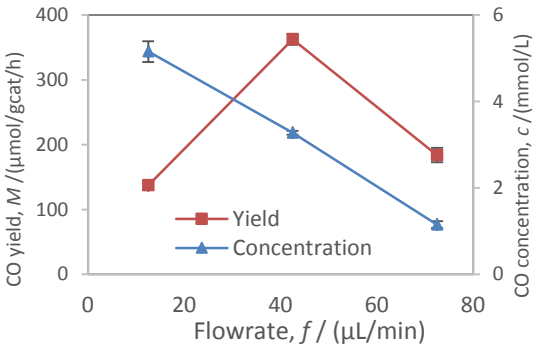

Figure 2. Effect of liquid flowrate on CO yield and concentration in gas phase.

4. Conclusions

Synthetized perovskites showed promising band gap values in the visible region; $Cs_3Bi_2I_9$ (1.94 eV) was chosen to evaluate its photocatalytic reduction of CO_2 in a planar 3D printed microreactor. CO_2 conversions of up to 67 % were determined and CO was identified as a product of the reaction. A maximum CO yield of 163.87 µmol/g_{cat}·h was measured and the effects of liquid flowrate and light intensity were analyzed, determining that maximum yield is achieved at 42.5 µL/min and 150 mW/cm^2.

Highlights

- Arsenic removal by Nanofiltration
- Membrane application for water purification
- Arsenic contaminated groundwater purification

1. Introduction

Arsenic is a toxic inorganic pollutant for both the environment and human health. The removal of arsenic is one of most problematic targets of hydrogeochemical research (Bhattacharya et al. 2002). The WHO drinking water guideline for As has been set to 10 µg/L and it has been adopted by many countries as a drinking water standard (WHO, 2001). For reaching this new value, several separation techniques have been studied. Membrane technology is one of these and pressure driven operation as nanofiltration (NF) and reverse osmosis (RO), often applied on synthetic solutions, have been already proved to accomplish the arsenic value below the drinking water standard (Figoli et al., 2016; Ahmad et al. 2017). In this study, NF has been applied for treating As contaminated groundwaters, coming from an area located in the Sila Massif (Calabria, Italy). Sila Massif represents the major morphostructural high of the Ionian margin of north-eastern Calabria and fall in the northern sector of the Calabrian Peloritan Arc (CPA). The water samples collected, labeled GW1, GW2, GW3, have interacted with the Calabride Complex formed by Hercynian and pre-Hercynian gneiss, granite and phyllite, which underwent intense weathering processes (Van Dijk et al., 2002). The performance (water flux and arsenic rejection) of the membranes has been evaluated too.

2. Methods

The three water samples (GW1, GW2, GW3) differ by the arsenic concentration, which is about 60, 120 and 430 ppb, respectively. The As is present mainly in the pentavalent form (As(V)). NF experiments were performed by using a laboratory pilot unit (SEPA CF). Four types of membrane modules commercialized by GE Osmonics, named HL (Polyamide), DK (proprietary thin-film) and CK (cellulose acetate) and by Microdyn Nadir, named NP030P (Polyethersulfone), were used. The samples, before and after membrane treatment, were analyzed, determining the major elements HPLC (Dionex ICS 1100). The total arsenic was evaluated by ICP-MS, Perkin Elmer/SCIEX, Elan DRCe.

3. Results and discussion

In Figure 1, it is reported the water flux plotted versus the trans-membrane pressure (TMP) variation, for the GW2 sample (feed stream). All the investigated membranes show a linear increase of water flux at higher TMP. In particular, only the NF membrane Type HL shows much higher water flux compared to the other ones, which could be explained by the polymeric nature of the material

as well as by its higher pore-size. The same results have obtained also for the other GW samples containing a lower and higher concentration of As(V).

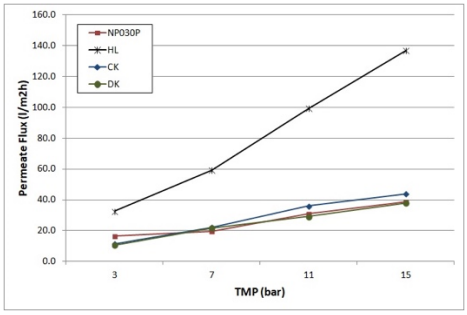

Figure 1. Effect of TMP on permeate flux for GW2 contaminated As(V) sample.

In Figure 2, it is reported the As(V) rejection and the arsenic concentration detected in the permeate (purified water) after the membrane treatment of GW2 contaminated As (V) sample.

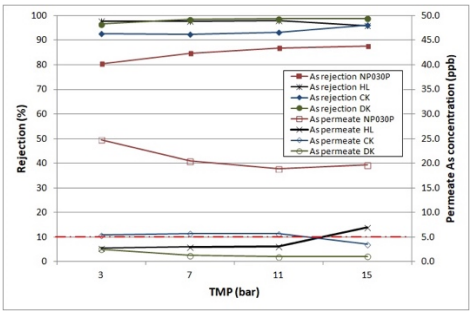

Figure 2: Effect of TMP on rejection (%) and permeate arsenic concentration for GW2 contaminated As(V) sample

The results show that all the investigated NF membra-nes, except the NP030P, reject the As(V) and that the As(V) concentration in the purified permeate water is below the WHO drinking water limit value of 10 µg/L.

4. Conclusions

The results clearly report that NF can be considered a valid technique for arsenic removal in the natural water, producing a permeate (purified water) with the As(V) concentrations within the allowed WHO limits for most of the membrane investigated.

Highlights

- Supercritical carbon dioxide extraction from micronized silverskin matrices
- Extraction simplified model
- Experimental data

1. Introduction

Extraction of oils and other valuable components from wasted biomass, such as roasted coffee silverskin, offers the possibility to recover and create value in a sustainable way. Supercritical CO_2 is one of the most environmentally friendly extraction methods available, especially compared to traditional solvent techniques which are toxic and dangerous. By applying a proper mathematical approach to describe the extraction of natural products from silverskin, it is possible to predict the system behavior in different operative conditions. This enables to develop a reasonable design of experiment and to envisage a possible scale-up in industrial plants by also maximizing the output and minimizing wastes.

For doing so, a simplified mathematical model is proposed describing the supercritical carbon dioxide extraction of high value-added components from roasted coffee bean's silverskin. It is based on that first introduced by Sovová [1] in 1994 and later used in a myriad of cases [2]. Having an empirical approach in defining the mass transfer coefficient between the two phases, these models offer a simple solution, which is analytical, as well as good fitting of data. Through experimental data derived from silverskin extraction, the characteristic parameters of the model have been deduced. Such parameters allow to predict the behavior of the system in different operative conditions and optimize the system.

2. Methods

Experiments are carried out in a 100ml stainless steel vessel which can house approximately 40g of non-compressed micronized silverskin powder. Supercritical CO_2 is pumped at desired pressure by a compressor and flows inside the column from the bottom to the top. The solute extracted is collected in pre-weighted glass vials positioned after a small collection chamber at the exit of the vessel. At desired times the vial is substituted, the solute extracted is measured with a laboratory scale and data are collected. In the adopted model, the desorption of solutes is modeled with two different steps. At first, solute present on the outside of the solid matrix is extracted and later, when that solute is depleted, the extraction proceeds towards the solute present inside the solid. Solubility is the driving force that describes the mass transfer when solute is readily available and

in direct contact with the fluid, on the other hand diffusivity is responsible for the extraction of solute stranded inside the solid matrix.

Original Sovová's model considers also a third transient step. To further simplify the model, Patel [3] proposed to remove this transition period and consider the two principal stages only. It is assumed that an axial solvent flows, at a constant superficial velocity, through a fixed bed of cylindrical shape. The solvent is pure at the entrance. The temperature and pressure are kept constant throughout the fixed bed and the total time of extraction. Additionally, the bed is considered homogeneous in terms of solute distribution as well as particle size. The model also assumes pseudo-steady state with plug flow and neglects the accumulation of the solute in the fluid phase. It considers the solute solubility in the solvent and mass transfer coefficient both in solvent and in solid phases.

To verify the experimental data a non-linear regression is applied, the dimensionless parameters are calculated having the foresight of separating all the operative changing parameters like interstitial velocity or initial mass of solid from the constant ones.

3. Results and discussion

Preliminary results show a good fitting of the experimental data, although at the actual state the model suffers severely from the changing in CO_2 flowrate. In facts, the model right now describes quite good different operative conditions like changes in temperature as well as void factor (by reducing the initial solid in the vessel) but only if the fluid flowrate remains constant.

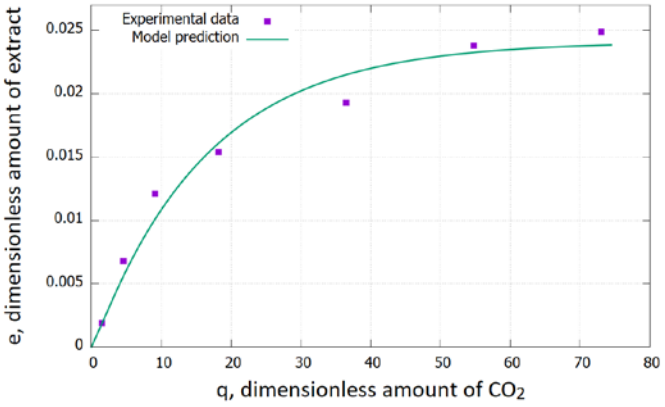

Figure 1. Example of model comparison for 300bar,330K and 4 hours extraction.

4. Conclusions

This model has a good potential but only if it would be possible to apply it to different ranges of flowrates. This problem might be caused by the changing in the mass transfer rates due to the changing in mass flow rate. It is evident that it is necessary to apply some more constraints and a mass transfer theory to further separate the variable parameters from the constant ones. Doing so might enhance the regression of the adjustable parameters making this model suitable to proceed to a possible design of experiment as well as optimization of operative conditions and possibly a scale-up.

Scaling the Biobased chemistry, is decentralised production the future?

Ir. Thomas Ladrak, Zeton b.v., Enschede, the Netherlands;

The recommended approach for scaling biofuel and biochemical technology follows a similar stage gate process to that used in traditional Chemical Process Industry (CPI) processes. But the processing of biomass leads to some subtle differences, and unique challenges, that need to be considered. The typical scaling factors for bioenergy and biofuels processes are an order of magnitude lower, or more conservative, than is the case for an equivalent CPI process. This is as a direct result of the inherent challenges with biomass processing, and the fact that there is little published data, and a lack of experience in general, related to the scale up of advanced biofuels and biochemical processes.

One of the pitfalls of working with biomass projects is scaling up too fast. Often the step from lab-scale to pilot scale is taken with both scaling up significantly the process volume and shifting from batch to continuous processing. Pilot plants provide the first window into continuous processing and often incorporate unreacted feed or product recycles. This often leads to unforeseen challenges, in some cases even jeopardizing the projects. Scaling up from a smaller pilot to a demonstration plant, before working out the commercial scale process, is therefore the norm.

But is scaling up to the traditional world scale production a necessity? The availability of feedstock is often place specific, transport of raw materials reduces the efficiency of the overall processes. Often it is much more interesting to perform the first process steps decentralized, in small, flexible and in some cases even transportable installations. Produce there where the feedstock is! So demonstration scale can even become commercial scale.

Study of the addition of different ashes to cement: reactivity and resistance

Highlights

- The mixtures evaluated show similar behavior to the target
- The BIT-cement mixture presents better resistance after 90 days of curing
- Fly ash from hazardous waste can be used as a replacement for cement

1. Introduction

The world annual production of fly ash is estimated at around 780 million tons per year and has been used successfully in the cement industry for more than 50 years, mainly as a mineral additive in Portland cement concrete and also as a component of mixed cement[1]. They are composed mainly of amorphous silica and alumina [2] with a favorable diameter and size that improves workability and makes this material suitable, even, for the production of geopolymers [2]. Fly ash can be used partially as a substitute for Portland cement or applied as an addition to concrete in the batch plant [3,4]. The use of biomass ash and coal-biomass mixtures in cement has also been widely investigated [5,6]. In this work, the reactivity of hazardous waste, bituminous coal and sugar cane ash as supplementary cement materials was evaluated.

2. Methods

For this work, ash from incineration processes (hazardous waste, sugarcane and bituminous coal) was used. Each one of these ashes was used in different proportions in the mixture with cement. For the case of bituminous coal (BIT) and sugarcane (CAN), a 30% replacement ratio was used. In the case of the ashes of hazardous waste these were previously treated by means of washes (CITA). Both the treated and the untreated ashes were used in replacements. For the treated ashes two ratios of 5% and 3% were used. While for the untreated ashes a ratio of 10% was used. For this, the reactivity of the ashes in cement monoliths was analysed, focusing on thermogravimetric tests as a characterization technique to determine the present phases and compression resistance tests. The ashes were characterized by DRX and FRX, finding low content of SiO_2 and Al_2O_3 in the hazardous waste ashes, while in the coal and sugarcane ashes high contents of these oxides were found. The monoliths were prepared according to ASTM C-305, using a 0.5 water/lime ratio. The hydration process was stopped with acetone at the ages of 1, 3, 7, 14, 28, 56 and 90 days.

3. Results and discussion

After 90 days of curing, it was found that the mixtures presented similar resistance data with white respite, highlighting the 3 and 5% RPL and the bituminous coal mixtures. Similarly, the 10% -RPS mixture has a load very similar to white. It is advisable to perform metal leaching analysis, in order to evaluate possible environmental impacts that may occur in its application as a substitute for cement. Table 1 shows the average of the three failures made to each of the samples on each of the days evaluated. A very good behavior of the mixtures is observed from day 3 of curing of the monoliths.

Table 1. Analysis of the resistance of the different replacements

Day	Sample	Average Load (kgf)
90	UHW(10%)	844
	THW(5%)	1055
	THW(3%)	1094
	BIT	1205
	CANA	884
	WHITE	789

In table 1, it can be seen that on day 1 only the sugar cane has a good resistance compared to the white, but as the curing time progresses, all the mixes present good behavior. In Figure 1, the reactivity of these ashes can be corroborated, in which in the temperature curve between 50 and 200 ºC, the formation of very marked peaks that are related to different types of C-S-H gels are observed.

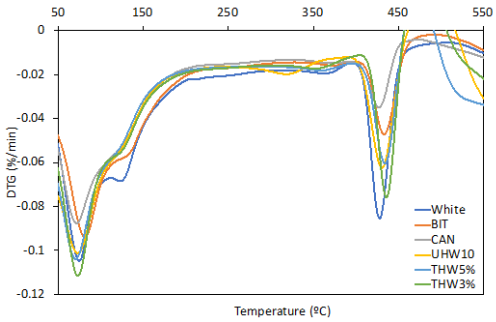

Figure 1. Total mass lost for a given temperature interval (DTG) for different combinations of ash at 90 days of curing.

4. Conclusions

It is observed that the mixtures evaluated have a good resistance and reactivity behavior after 90 days of curing, the DTG curves show the same crystal formations as the white. Likewise, the resistance of all the evaluated monoliths is very similar or even better than those of the target.

Highlights

- Compression tests of cylindrical particles
- Measurement of particle-wall sliding friction
- Magnetic Particle Tracking (MPT)
- For the used particles the stiffness is independent of the number of impact

1. Introduction

In many processes of particle technology, cylindrical particles produced by extrusion or press agglomeration are used and further processed in various production steps e.g. spheronization, fluidization, drying and coating. In order to control and optimize these processes the particle dynamics can be predicted with numerical simulation. The frequently used methods are computational fluid dynamics (CFD), the discrete element method (DEM) or the coupling of both methods (CFD-DEM). There are numerous CFD-DEM studies reported in the literature predicting spherical particles in complex processes, however, only few studies of fluidization processes with cylindrical particles can be found [1–3]. For cylindrical particles, there is a lack of understanding of how particle shape influences the particle contact behaviour during different loading scenarios. Especially for the exact calculation of the particle interactions in DEM, it is essential to describe the particle contact behaviour with a compatible contact model. The modelling of contact behaviour with DEM poses a number of challenges: the shape construction, the contact detection and the contact force calculation for different deformation behaviours [4,5].

2. Methods

In this work, the influence of loading direction (contact geometry) and deformation behaviour (from elastic to plastic) on force-displacement behaviour during compression and shearing of cylindrical particles is investigated. The compression tests are performed with a Texture Analyser®. For the measurement of particle-wall sliding friction, a self-developed setup at the TU Kaiserslautern is used. During the measurement of tangential force, the particles are fixed to a flat holder and moved over a defined wall surface at a constant normal load. In addition, experiments in a fluid bed rotor processor equipped with a Magnetic Particle Tracking (MPT) system are conducted in order to visualize and quantify the real particle behaviour [6–9]. In Figure 1, the function of the MPT system is shown. The anisotropic magnetoresistive (AMR) sensors detect the magnetic field lines of the

magnetic marker particles and allows the analysis of the movement and rotation behaviour of the marker particles.

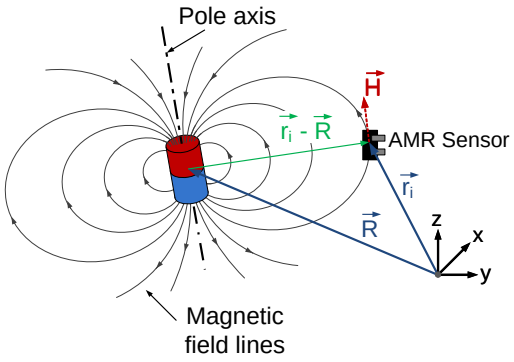

Figure 1. Functioning of the Magnetic Particle Tracking (MPT) system

3. Results and discussion

The intention of these investigations is the experimental calibration of contact models, which can be applied for numerical DEM studies of fluidization processes with cylindrical particles. Cyclic loading tests for different loading positions of the particles show that the stiffness is independent of the number of impacts. For the used particles sizes, different loading positions do not lead to significant differences in stiffness. The behaviour of different particle shape models with the multi-sphere approach is also performed and compared with experimental results.

4. Conclusions

With the conducted compression tests and measurement of particle-wall sliding friction it is now possible to calibrate a contact model, which can be used for DEM studies, in particular for a CFD-DEM simulation of a fluid bed rotor processor.

Highlights

- Modelling of hetero-aggregation by a Monte Carlo – Discrete Element Method.
- Size stabilization by hetero-aggregation.

1. Introduction

Over the last decades much research has been devoted to the study of the aggregation of identical particles (homo-aggregation), but little is known about hetero-aggregation, i.e. the aggregation occurring in systems in which dispersed particles differ in one or more characteristics. The present work aims to simulate the shear-induced aggregation process occurring in a dilute suspension where particles with opposite surface charges are dispersed.

2. Methods

We studied the shear-induced aggregation process occurring in aqueous dilute suspensions of spherical polystyrene particles, with 500 nm radius. Particles bearing opposite surface charges with low surface potentials (±40 mV) and surrounded by a thin electrical double layer (10 nm) are considered. A relatively mild shear rate is assumed to act on the suspension (10 s^{-1}). For this set of

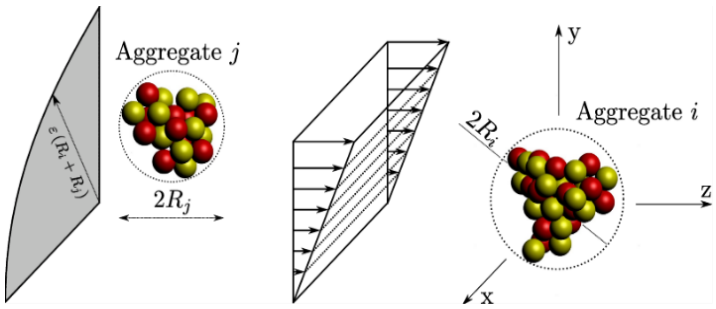

Figure 1. Typical initial setup of an aggregation event in shear flow. The DEM tracks the trajectory of each primary particles

parameters, only aggregation between unlike particles can occur. In dilute conditions, it is reasonable to reduce the aggregation dynamics to a sequence of binary aggregation events i.e., events which involve two aggregates at a time. Based on this assumption, we developed a mixed stochastic-deterministic method built on a combination of a Monte Carlo (MC) algorithm and a Discrete Element Method (DEM), built in the framework of Stokesian Dynamics. Based on the flow

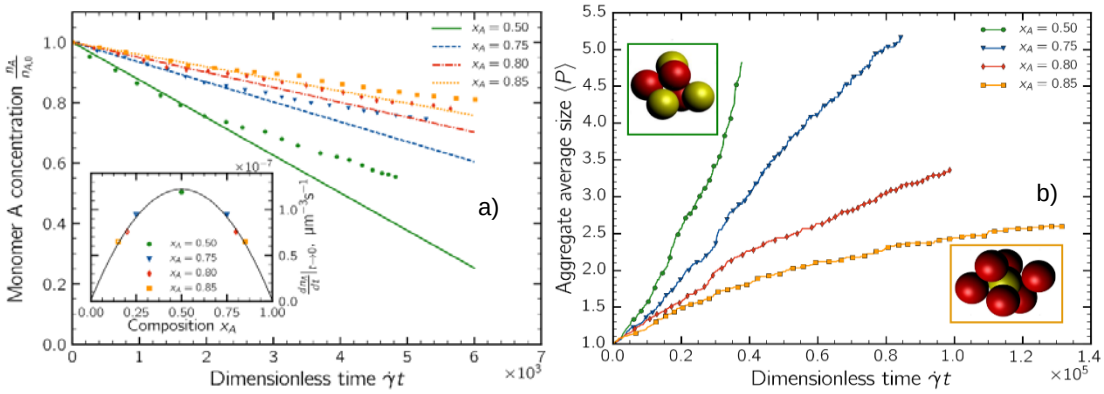

Figure 2. Aggregation kinetics for four different values of the population composition, expressed in terms of number fraction of cationic particles x_A. a) Temporal trend of the concentration of cationic particles. The inset report the dimer formation rate. b) Temporal trend of the aggregate average size, in terms of number of constituent primary particles. The insets show two small sample aggregates (red particles are the majority particles)

and population statistics, the MC is used to sample a statistically expected sequence of encounter events, whereas the DEM is used to simulate in detail each aggregation event [1]. Figure 1 represents the typical initial setup of a DEM simulation.

3. Results and discussion

Simulations were performed to ascertain the effect of the suspension composition, in terms of relative concentration of cationic (A) and anionic (B) particles, on both aggregation kinetics and aggregate morphology. Figure 2a reports the temporal trend of the concentration of cationic primary particles in the early stage of the process; as apparent the rate of disappearance is strongly affected by the population composition: when cationic and anionic particles are present in an equal amount (x_A=0.5) the aggregation is fast. As the composition parameter increases, the aggregation rate slows down. This effect is made more apparent in the inset of Figure 2a, where the rate of dimer formation is plotted together with the theoretical expected one. The late stage dynamics is also remarkably affected by the population composition. Figure 2b reports the aggregate average size as a function of time. In the symmetric system, the growth dynamics shows a self-accelerating behavior, with aggregates that soon reach large size. As the population is enriched in majority particles, the aggregation slows down and for concentration around 85% the aggregation rate progressively reduces in time, until a size stabilization takes place. Stable aggregates with a core-shell structure appear; such aggregates are seen to be formed by a core, in which the particles of the two classes are both present and by an external shell fully covered by majority particles, which provide a shielding effect against further growth.

4. Conclusions

The hetero-aggregation of oppositely charged particles is studied in the present work. Results reveal that in such systems a size stabilization effect should be expected when a large concentration disproportion between the two classes of particle is present.

Controlled Manipulation of Size and Shape of Needle-like Compounds Using Wet-Milling

Ashwin Kumar Rajagopalan[1], Stefan Bötschi[1], Manfred Morari[2], Marco Mazzotti[1*]

1 Institute of Process Engineering, ETH Zurich , 8092 Zurich, Switzerland; 2 Department of Electrical and Systems Engineering, University of Pennsylvania, Philadelphia 19104, United States

**Corresponding author: marco.mazzotti@ipe.mavt.ethz.ch*

Highlights

- Manipulation of size and shape of needle-like compounds using wet-mill as actuator.
- Model-based operating policy is unable to guide arbitrary seed populations to targets.
- Incorporation of feedback action is key for robust performance of milling stage.

1. Introduction

In a crystallization process, the particle size and shape influences various downstream operations. The majority of the crystallization literature deals with manipulation of only the size of the crystals. Thanks to the recent advances in particle size and shape monitoring techniques, particles can be better characterized using multiple dimensions [1]. Even though the available literature on feedback control with the aim to manipulate particle size and shape is limited, model-based and model-free feedback controllers have been proposed recently using temperature as a control actuator [2,3].

For needle-like compounds that exhibit small changes in the shape by using only temperature as an actuator, milling can be a suitable alternative. In this work, several operating and control strategies are proposed, all of them using an *ex situ* wet mill as the control actuator, with the aim to guide various seed populations to different targets in the size and shape plane.

2. Methods

One model-based operating policy and several feedback control strategies were designed and tested in a lab-scale experimental setup. The setup consisted of an *ex situ* stereoscopic imaging device (for particle size and shape characterization), the μ-DISCO [1], an *ex situ* rotor-stator wet mill, and a control computer where the image analysis routines for the imaging device and the control strategies were implemented. The model-based operating strategy utilized a two-dimensional population balance model that describes the breakage phenomenon in the mill [4]. The proposed operating policy and control strategies were put to test using two model compounds, namely β L-glutamic acid (BLGA) and γ D-mannitol (GDM).

3. Results and discussion

Two different seed populations of BLGA and one seed population of GDM were milled to reach three different target average lengths in the particle size and shape plane. For the model-based

operating policy, it was observed that the multidimensional breakage model was unable to predict the rotor speed that would enable reaching the desired targets for arbitrary batches of seed populations. These experiments highlighted the importance of introducing feedback action to overcome unmodeled phenomena and to counteract process disturbances.

Different feedback control strategies using online observations of the evolution of the average dimensions of the populations subjected to milling were designed and applied. These control strategies applied multiple consecutive milling stages with varying rotor speeds, which enabled reaching the targets robustly and irrespective of the seed population and model compound used (see Figure 1).

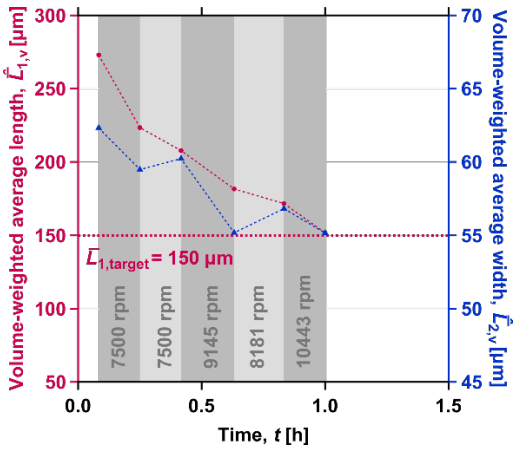

Figure 1. Time-resolved evolution of the measured volume-weighted average dimensions of BLGA seeds with a target average length of 150 µm. The shaded gray region indicates the milling stage with the corresponding rotor speeds.

4. Conclusions

Different operating and control strategies were exploited to manipulate the size and shape of needle-like particles using a wet mill as a control actuator. The control strategies that incorporated feedback action led to robust operation of the milling. Thus, the milling stage is ready to be integrated into complex processes, including crystal growth and fines removal by dissolution, to effectively manipulate the size and shape of needle-like compounds.

DEM simulation of breakage under compressive force using a particle replacement model

Vahid Hassanzadeh[1,*], Christopher Wensrich[2], Roberto Moreno-Atanasio[3]

1, 3 Chemical Engineering Department, School of Engineering, The University of Newcastle, Australia;
2 Mechanical Engineering Department, School of Engineering, The University of Newcastle, Australia
**Corresponding author: vahid.hassanzadeh@uon.edu.au*

Highlights

- A Particle Replacement Model was employed to simulate breakage using DEM.
- The effects of initial overlap during replacement on the system were studied.
- Relaxation factor was used to justify high contact force of particles after breakage.

1. Introduction

Comminution processes are the most expensive particle processing operations in terms of energy consumption as most of the energy is dissipated in the form of sound and plastic deformation. Therefore, this type of processes presents an important opportunity for optimization and improvement [1-3].

After introducing Discrete Element Method (DEM) by Cundall and Strack [4] many researchers took advantage of this simulation technique to study size reduction processes [5-9]. The Particle Replacement Model (PRM) has been proved to be one of the most successful models to simulate particle breakage in DEM simulations [9]. In this model, a broken spherical particle is replaced by a progeny of smaller particles instantaneously [5, 9]. PRM requires to specify the maximum stress at which the particle breaks and a breakage distribution function to determine the smaller progeny particles that are replacing the original particle.

During the replacement process, the progeny particles are required to have an initial overlap. This initial overlap causes high contact forces between the particles. Therefore, a relaxation factor has been used in the previous studies to damp the high elastic force artificially created during the replacement process [5]. In this research work, the effects of the relaxation factor on the single particle and particle bed breakage simulations were studied.

2. Methods

An in-house DEM code was developed in Fortran 77 programming language. The Hertz contact force model and equations of motions in both translational and rotational directions were used. Also, damping force models were employed to simulate the energy dissipation in particle contacts.

To simulate the breakage process the particle replacement model was implemented. When the value of the contact force exceeds a specified value, the particle is substituted by its progeny which is determined by the breakage function. The equation developed by Austin and Luckie (1972) was used to calculate the progeny particle size distribution [10]. In order to study the effect of the relaxation factor in the range between 0.05 and 1.00 two types of systems made of particles of 10

mm in diameter were considered: a single particle and a bed of 100 particles. In order to simulate the bed compression test, particles were randomly positioned within a cylinder of 5 cm in diameter. Then, a piston was moved downwards to compress the particle bed until achieving a maximum value of 450 N. An illustration of the simulations is shown in Fig. 1.

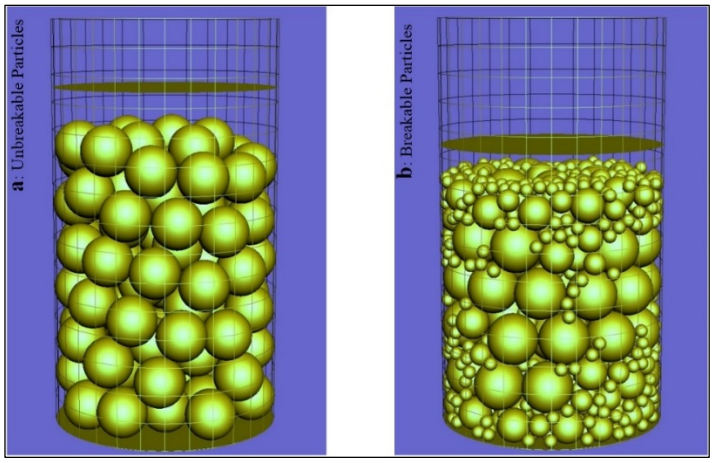

Fig. 1 Simulations of unbreakable and breakable particles after applying 450 N force on the particle bed

3. Results and discussion

In the single particle system, the kinetic energy of the progeny particles exhibited a maximum as a function of time. This maximum value and the rate at which the kinetic energy decayed after the maximum was achieved, increased by increasing the relaxation factor. This could be as a result of large energy dissipations during contacts of high-velocity particles.

For the particle bed simulations, the number of broken particles fluctuated with the relaxation factor. However, the curves of the contact force on the piston as a function of time for different values of the relaxation factor were close to each other and the elapsed times for reaching to 450 N were almost the same.

4. Conclusions

The relaxation factor used in the particle replacement model affects the simulation results considerably. However, it seems that because of the complexity of interactions between particles in a compacted bed, the influence of the factor on the results of the breakage process is not easily predictable. Therefore, it is recommended to find the optimum value of the relaxation factor by comparing the movements of the progeny particles after the breakage in the DEM simulations with the ones in the single particle breakage test. Then, the factor can be tuned finely according to the obtained particle size distribution of experimental data for the particle bed breakage tests.

Analysis of the Microstructure of Particles Obtained by Evaporating Acoustically Levitated Single Droplets Using X-Ray Computed Tomography.

Hassan Abdullahi [1], Thomas Vetter[1*], Christopher L. Burcham[2]

[1] School of Chemical Engineering and Analytical Science, University of Manchester, Manchester, UK;
[2] Eli Lilly & Company, Indianapolis, IN, USA
*Corresponding author: thomas.vetter@Manchester.ac.uk

Highlights

- *Drying of acoustically levitated droplets is investigated.*
- Characterization of the microstructure of the formed particles through X-ray tomography.
- Drying conditions and particle microstructures have been mapped against each other.

1. Introduction

The flowability and tabletability of powders is an important consideration in the manufacturing of pharmaceutical products. These properties can be successfully tuned by crystallising particles of a desired morphology, or, more flexibly, by engineering the microstructure of the individual particles in a spray drying process it can be tuned by altering the formulation and process conditions [1][2]. Therefore, spray drying offers a unique opportunity to design tailor made particles in a single step process involving simultaneous droplet drying and particle formation. However, carrying out an in-depth investigation of particle morphology and microstructure directly on the scale of a typical spray dryer (that contains millions of droplets at any time) is infeasible. Instead, single droplet studies are often used to understand how drying conditions affect the microstructure of the resulting dried particles [3][4].

2. Methods

In the present work, an acoustic levitation approach is used to suspend single droplets in an atmosphere of controlled relative saturation and temperature (Figure 1). Through a camera and automated image analysis, we study the droplet drying dynamics, as well as the macroscopic morphology of the resulting particle. We have further applied Raman spectroscopy and scanning electron microscopy to study the solid state form, as well as the surface characteristics. By applying X-ray computed tomography, we have elucidated the internal microstructure of the formed particles and have uncovered a fascinating variety of structures, depending on the mixture dried (we have investigated combinations of different solutes, solvents, and polymers acting as excipients), as well as the processing conditions (temperature and relative saturation of nitrogen used as drying gas). The results can be correlated with formulation and process conditions to produce drying maps for different systems.

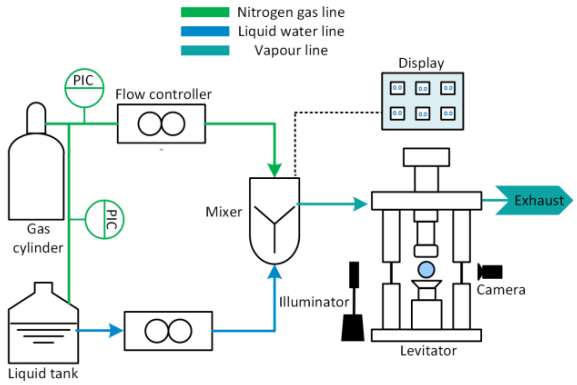

Figure 1: Suspension of a droplet in a controlled atmosphere using an acoustic levitator.

3. Results and discussion

The droplet drying history during evaporation is shown in Figure 2a for an aqueous formulation of mannitol (4.5 wt%) and PVP (0.9 wt%). In the first drying stage, the diameter of the droplet decreases as solvent is evaporated from the droplet surface. In the second drying stage, a shell forms and evaporation occurs through interstices in the shell. The evaporation rate hence reduces significantly due to the added resistance of the crust. When presented as a plot of normalised squared diameter D^2/D_o^2 against time, the two drying regimes can be clearly identified. We have performed such characterisation for a variety of process conditions and the particles obtained can be subsequently analysed to provide useful information on particle properties such as size, shape, porosity, roughness and crystal structure. Figure 2b and 2c shows exemplary images of particles obtained using SEM and micro X-ray computed tomography. By investigating the droplet drying dynamics and resulting particle microstructure, for a variety of mixtures and operating conditions enables us to gain deep insight into the process behaviour and the properties of the resulting particles.

- Electrical conductivity based on the electrode structure via an implemented algorithm

1. Introduction

Lithium-ion batteries are widely gaining popularity as electrochemical power sources, becoming also remarkably successful in the electric power vehicle market. Batteries are composed of electrodes which consist of porous composite materials coated on a substrate. To date, several investigations have clearly confirmed the impact of electrode microstructure on performance metrics such as energy and power densities, cycling stability, cell life and battery safety [1,2].

Bearing in mind the particulate nature of such electrodes, this work proposes a discrete element method (DEM) simulation approach to describe both the behavior of the particles and the binder along the calendering manufacturing step. Additionally, a post-processing tool is implemented to determine the electrical conductivity based on the DEM-generated structures and their connectivity. This electrode property is of considerable importance and ultimately controls the performance of the battery. However, an electrode structure which enables a proper electrical conductivity might hinder the ionic conductivity at the same time. As a consequence, finding optimal electrode architectures that offset competing tradeoffs can be challenging and thus, there is a clear need to fully comprehend the influence of electrode microstructure on cell performance.

2. Methods

Within this project, Li $[Ni_{1/3}\ Mn_{1/3}\ Co_{1/3}]O_2$ (NMC) cathodes were investigated. The discrete element method (DEM) was chosen as a valid simulation approach to represent particulate electrodes. Details on the numerical method can be found in [3]. In general lines, an elasto-plastic contact model was combined with a bond model to reproduce the mechanical response of NMC cathodes by taking into consideration the stiffness of the particles and the binder. The method to simulate the electrical conductivity was based on the connectivity of the numerical structures. To this aim, a pathfinding algorithm was implemented to design an equivalent circuit that can subsequently assess the overall network electrical resistance. Simulations were combined with experiments to calibrate and validate the outcomes. In particular, indentation measurements on

single NMC particles were carried out to parametrize the DEM contact model as shown in [3]. The specific electrical conductivity was measured according to [4].

3. Results and discussion

The calendering manufacturing process was investigated within this work via DEM simulations and real experiments. Once they were validated, the simulations could predict the elastic recovery of the cathode structure, a key aspect that cannot be experimentally determined to date. Figure 1 shows the evolution of the porosity under four different maximum calendering stresses. The elastic recovery of the electrodes, which was proved to depend on the calendering degree, ranged from 10.25 % up to almost 17 %.

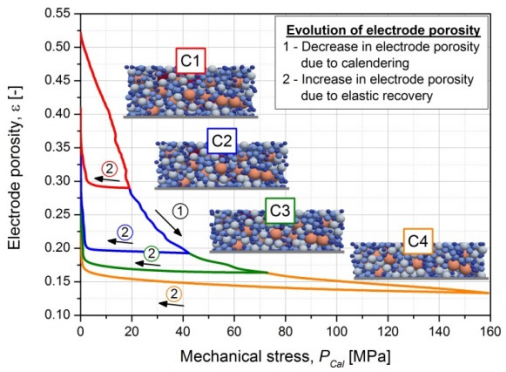

Figure 1. Evolution of the electrode porosity along the calendering process

Electrons move through the electrode particle assembly overcoming electrical resistances. Bearing this in mind, the implemented algorithm was used to identify the electrical pathways within the calendered cathodes. By considering particles as nodes and direct or bond contacts as lines, the structure could be converted into a resistance network. The overall resistance could be resolved afterwards by using Kirchhoff´s circuit laws, which allow to solve complex circuits defining a set of equations for the current and voltage. Results proved that the method could reproduce the experimental trend suitably. Furthermore, it was possible to successfully apply the method to other electrode configurations, which is of great importance in view of improving electrode design for a wide range of applications.

4. Conclusions

Within this work, lithium-ion battery cathodes were simulated to investigate their behavior during the calendering process and assess their specific electrical conductivity. By combining the numerical approach with experiments, the proposed simulation method can give insight into the overall electrode structural, mechanical and transport properties in view of predicting and designing improved materials.

Highlights

- There is vertical stratification within a granular medium located in a reactor.
- The range of force imposed by the blade is all the lower when the speed is high.
- DEM simulations give the structural rearrangement which occurs during trials.
- Spatiotemporal correlations of particle motions observed by PIV could be explained by DEM.

1. Introduction

The study of stress transmission and motion typologies in a powder bed under low shear condition constitutes a challenging issue to achieve a monitoring of processes which involve particle mobility like kneading or agglomeration process [1]. This work deals with the ability of a probe to ensure the particle mobilities in a granular bed disposed in the tank of a reactor. An original experiment is developed (i) to allow the visualization of the behavior of particles in the neighborhood of an intruder (*i.e.* a horizontal flat blade design) in ascendant vertical motion, and (ii) to measure the drag force applied to the intruder during its extraction from an ensiled granular medium. In order to identify the force propagation in a granular ensiled medium, experiments and Discrete Element Method (DEM) simulations [2] are compared to investigate the propagation of the force imposed by the blade at different dimensionless speeds.

2. Methods

Experimental device. The granular medium is a population of glass beads of 1-2 mm diameter with a small span value. The experimental set-up consists of an open glass cell container (51x100x160 mm) made of transparent glass walls. The filling is provided by a funnel and the flow rate is modulated by the output diameter. A flat and rectangular steel probe is especially designed to fit into the glass container. It is screwed on a rod that is linked to a load cell of a texture analyzer (TA.XT2, Table Micro System), which is used as a force sensor. The probe is then removed from the granular packing. The drag force is measured and the velocity field is analyzed by PIV analysis. The visualization of the particle mobilities during the ascendant vertical motion of the probe is carried out using a high-speed camera and then, analyzed by Particle Image Velocimetry (PIV).

Numerical simulation. In order to reproduce the experimental conditions, a code using both the DEM and the coarse-graining method is developed to calculate the force network, the stress fields

and the solid fraction of the granular medium. It allows us to explore all the contacts network between the particles by the calculus of (i) normal and tangential forces, (ii) moment, (iii) mobility of each particle.

3. Results and discussion

Force measurements and PIV technique allow to identify different types of particle motions (compaction, loading and rupture of the chain forces, lateral collapsing, avalanches, etc.) as well as the mechanical state of the granular bed. These behaviors are confirmed by DEM simulations which indicate the evolution of the compactness and the lifetime of intergranular contacts. Fluctuations of stress are identified and depend on the dimensionless blade speed [3]. This result can be explained by successive loading and rupture cycles of horizontal force chains taking place above the blade, leading to fluctuations of the vertical stress. The analysis of spatiotemporal correlations of the velocity fields reveals the existence of a dihedral-shape assembly of grains which constitutes a permanent disturbance zone above the blade during its vertical rise whatever the blade speed. The range of the blade could be defined by a characteristic length links to the development of mobility gradients. A specific study of the velocity gradient generated above the blade is carried out for the different blade speeds.

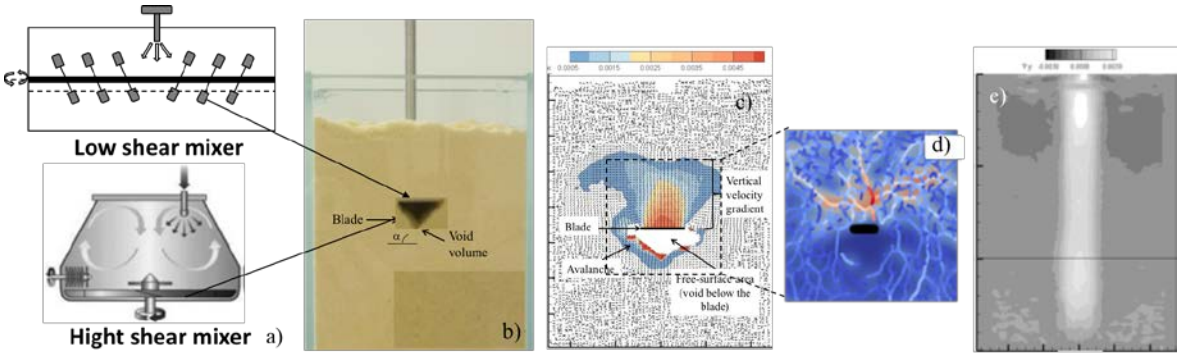

Figure 1. From reactors (a) to the experimental device (b) to identify particle mobilities by PIV (c) and DEM simulations (d) focused around the blade and the active and passive zones of mobilities in the granular medium (e).

4. Conclusions

Experimental observations coupled with DEM simulation allow to access to the phenomenon at the reactor and particle scales. The analysis of the local force network and the microstructure of the granular medium allows to define characteristic length and time. These parameters could be then used to optimize process control that involves particle mobilities induced by a mechanical input.

Corresponding author: manuel.meier@kit.edu

Highlights

- Multi-scale characterization of precipitated silica using SAXS, AUC and REM
- Analysis of aggregate structure using pore size determination techniques
- Determination of fractal dimensions, sediment structure as well as porosity
- Correlation of the measurement data with mathematical models

1. Introduction

Ensuring the cold chain is a prerequisite for maintaining product quality in a global market. The requirements for insulation material are accordingly clearly defined: high insulation effect at low weight, high transport stability and low production costs. A material that meets all the requirements is foamed polystyrene. In terms of sustainability, oil free materials have been under investigation for their use as insulation material for some time now. However, in many cases, alternative materials are overpriced in production or delivery costs. Previous studies showed, that precipitated silica is an interesting alternative to conventional insulation materials. In addition to low production costs, precipitated silica has low bulk density, low flammability and good biodegradability. On market, there are a lot of materials available for a wide range of industrial applications. Nevertheless, most of these materials are developed in the respect of their effect on product but not in particle characteristics. This investigation takes into account both nanoscopic properties such as primary particle and aggregate size, their fractal dimension and the size distribution within the aggregate, as well as mesoscopic properties of the pellets.

2. Methods

This work deals with the metrological description of precipitated silica by a multi-scale characterization. Measurements by means of small angle X-ray scattering (SAXS) and electron microscopy allow a statement to be made about the basic structure levels of an aggregate: fractal dimension of surface, primary particle size, fractal dimension of mass and the aggregate size. To combine information about the aggregate with information about the sediment structure itself, porosimetry and centrifugation techniques were used.

3. Results and discussion

The obtained results allow a realistic aggregate computation and building of a sediment structure of precipitated silica by DEM simulations (see Figure 1). The computation based on a fundamental consideration of the structure of aggregates by diffusion-limited aggregation (DLA) made by Forrest and Witten [1] and Witten and Sander [2, 3]. Assumptions for the modelling of the compactness of the individual aggregates were examined under consideration of geometric and scatter-based approaches.

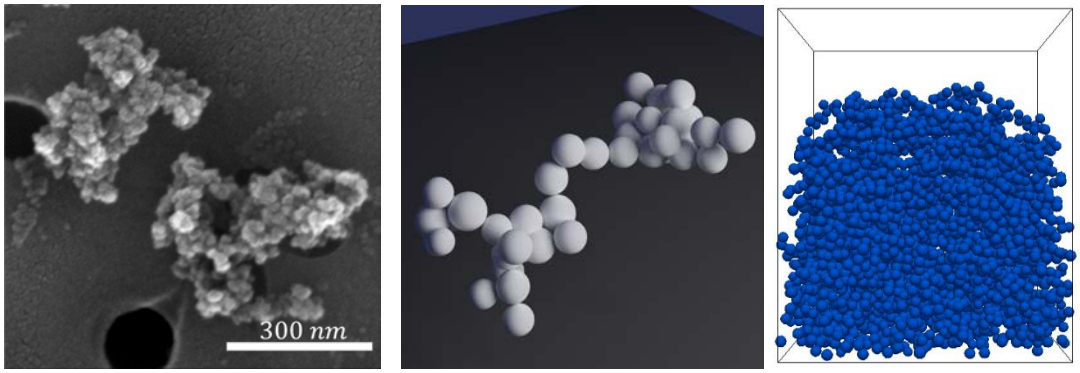

Figure 1. TEM image, aggregate computation and sediment structure of a precipitated silica.

4. Conclusions

In this study we performed a multi-scale characterization of several precipitated silica including small-angle X-ray scattering (SAXS), analytical (ultra-) centrifugation as well electron microscopy and pore size characterization techniques. The correlation of the obtained measurement data with mathematical models allow a statement to be made about the aggregate structure. Pore size characterization techniques using mercury and nitrogen provided information on the porous structure of the aggregates with respect to the pore inlet diameter and the pore diameter itself. The knowledge gained here allows us to gain a deeper understanding of the structure and description of fractal aggregates of precipitated silica.

Synthesis and Characterization of $CaCO_3$ Nanoparticles by Sol-gel Citrate Method: Effect of Citric Acid Concentration

Merve Şener, Çağla Gül Güldiken, Hasan Ferdi Gerçel

Department of Chemical Engineering, Eskişehir Technical University, Eskişehir 26555, Turkey

**Corresponding author: hfgercel@eskisehir.edu.tr*

Highlights

- Cost-effective and eco-friendly $CaCO_3$ nanoparticle synthesis process was developed.
- Calcination temperature was decreased using a sol-gel citrate method.
- Effect of citric acid concentration on particle size and morphology were investigated.

1. Introduction

$CaCO_3$, one of the most abundant minerals in nature, is used in wide range of engineering applications. $CaCO_3$ nanoparticles can be utilized as reinforcing agents in polymer matrix nanocomposites to enhance the mechanical properties and reduce cost [1, 2]. In the present study, $CaCO_3$ nanoparticles were synthesized via a sol-gel citrate method. Citric acid (CA) was used an organic additive in the $CaCO_3$ nanoparticle synthesis to achieve a homogeneous size distribution and smaller sized $CaCO_3$ particles. CA is non-toxic and non-carcinogenic contrary to the hydrazine-based additives which are commonly used for the same purposes. The chemical structures and morphologies of the synthesized nanoparticles were analyzed by Fourier transform infrared spectroscopy (FTIR) and scanning electron microscopy (SEM), respectively.

2. Methods

1 M aqueous solutions of $Ca(NO_3)_2.4H_2O$, as the precursor, were prepared. CA was added to the solution at weight ratios of 0.25 and 1.5 based on the weight of $Ca(NO_3)_2$ and heated to 70°C under constant stirring. Chemical reaction between the precursor and CA was conducted at 70°C for 24 hours. The resulting homogenous solution, obtained from the hydration reaction, was dried at 125°C for 24 hours. The porous and quite swelled product were grinded and then calcined at 600°C for 5 hours. Finally, the calcinated samples were washed several times with deionized water by ultrasonic mixing, centrifuged and dried at 105°C for 12 hours. The synthesized nanoparticles named $CaCO_3$_0.25CA and $CaCO_3$_1.5 CA.

The chemical structure of the synthesized nanoparticles was characterized in KBr disks by using a Perkin Elmer Frontier FTIR spectrometer between 400 and 4000 cm^{-1}. The morphology and particle size of the samples were investigated by using a scanning electron microscope (Carl Zeiss/Supra 40VP) at an accelerating voltage of 15 kV. All the samples were dried and sputter coated with Au/Pd prior to SEM analyses.

3. Results and discussion

Based on the FTIR spectra of the $CaCO_3$_0.25CA and $CaCO_3$_1.5 CA nanoparticles, shown in Figure 1, the wide band at 3645 cm^{-1} arises from the stretching mode of hydroxyl groups of $Ca(OH)_2$. The weak peak at 2885 cm^{-1} are assigned to the long alkyl chains of CA. The strong peak observed at

1428 cm^{-1} corresponds to the C=O stretching vibrations. The sharp peaks at 875 and 712 cm^{-1} indicates the existence of carbonate group. The FTIR spectra of both nanoparticles, which are differing in CA concentration, are consistent. This result shows that increasing CA concentration does not damage the chemical structure of the synthesized nanoparticles [1-3].

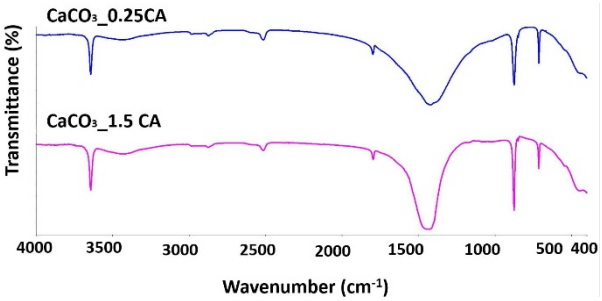

Figure 1. FTIR Spectra in Different CA Concentrations

SEM micrographs of the $CaCO_3$_0.25CA and $CaCO_3$_1.5 CA nanoparticles at 20kX magnification are presented in Figure 1(a, b). It is clearly seen that the particle size decreases with the increasing CA concentration. However, the decrement in particle size leads to aggregation of nanoparticles.

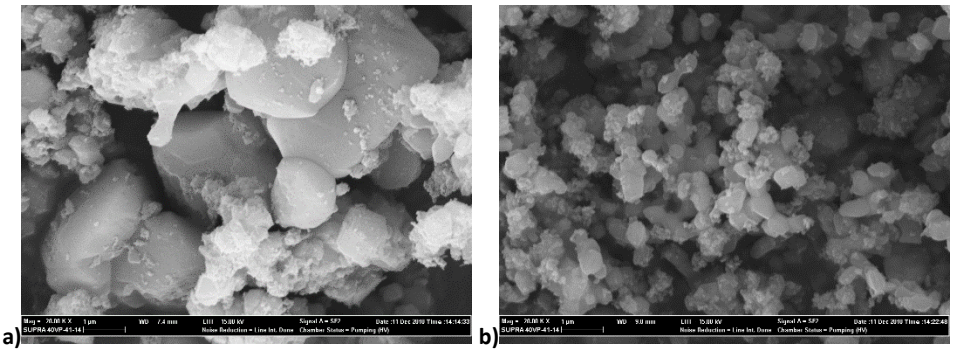

Figure 2. SEM micrographs of the (a) $CaCO_3$_0.25CA (b) $CaCO_3$_1.5 CA nanoparticles at 20kX magnification

4. Conclusions

The chemical structure of the nanoparticles has not been harmed by the addition of CA up to a mass ratio of 1.25 to the precursor. The upper limit for CA mass ratio in synthesis process can be determined in further studies. Based on the result that the particle size decreases with increasing CA concentration during the synthesis process, it can be deduced that nanoparticles with desired sizes can be synthesized by changing the CA concentration. In future studies, different surfactants can be used in the synthesis process to prevent nanoparticle agglomeration due to the particle size decrement.

Highlights

- High-G spray drying intensification
- New radial multi-zone vortex chamber design
- Experimental and numerical study of the flow pattern and drying behavior
- Distinct temperature separation and short particle residence time in the hot zone allows efficient 2-step drying using hot (350°C) air without burning produced milk powder

1. Introduction

Vortex chambers introduce process gas via tangential inlet slots over the entire length of the cylindrical vortex chamber and evacuate the gas via a chimney in one of the end plates of the vortex chamber. A strong rotational flow is generated, allowing high-G operation. The latter intensifies interfacial mass, heat and momentum transfer by easily one order of magnitude and also facilitates the use of fine particles [1]. In previous studies, application to particle drying [2,3] and fine particle coating [4] was demonstrated. Applications taking advantage of the very short gas-solids contact time and combining high-G intensified gas-solids contact, gas-solids separation and solids segregation were also studied [5].

In the present work, a specific design called the radial multi-zone dryer (RMD) [6] is experimentally and numerically studied. Application to spray drying is focused on, characterized by dilute operation and very strong rotational flows. Two distinct temperature zones are created without physical barrier, a radially central zone where hot air with a temperature up to 350°C is injected and a peripheral zone where air at a temperature of around 100°C is injected through the vortex chambers (Figure 1). The proposed multi-zone operation allows significant process intensification while preventing degradation of the product. Liquid droplets are injected in the hot central zone, co- or counter-current with the hot air. Fast initial drying is achieved in this zone while burning the product is prevented by rapid evacuation of the produced particles to the colder periphery under the action of the centrifugal force generated by the vortex chamber(s). Typical residence time of the particles in the hot zone can be limited to a few milliseconds. Drying is continued in the colder periphery where high-G operation intensifies interfacial mass, heat and momentum transfer and ensures efficient gas-solids separation.

2. Methods

The experimental set-up that was used is flexible and allows studying various multi-zone concepts, varying the dimension/design of the different zones and the type of spray nozzle. Extension

chambers allowing to minimize air consumption and to optimize gas-solids separation can be added. Tests were carried out with total air flow rates of maximum 1000 Nm³/h, liquid flow rates of up to 6 g/s and hot air temperatures of maximum 350°C. Both hollow-cone and full-cone nozzles were tested. Three types of experiments were carried out: (i) in the absence of liquid injection, (ii) injecting water, and (iii) injecting milk. The axial and radial temperature profiles in the device were measured by means of 16 thermocouples. Comparison of the profiles in the three types of experiments and visual observations allowed gaining understanding in the complex flow pattern of the gas and droplets and the extent of evaporation in specific regions. Deposition of powder on the walls and in the gas and solids outlets was also carefully analyzed. Protection of the nozzle from fouling required a new protective sleeve design. To gain further insight in the flow pattern, CFD simulations were carried out, adopting the RANS-approach and a coarse-grained discrete particle model to track the motion of the droplets. Evaporation was accounted for and the behavior of droplets of different size studied.

3. Results and discussion

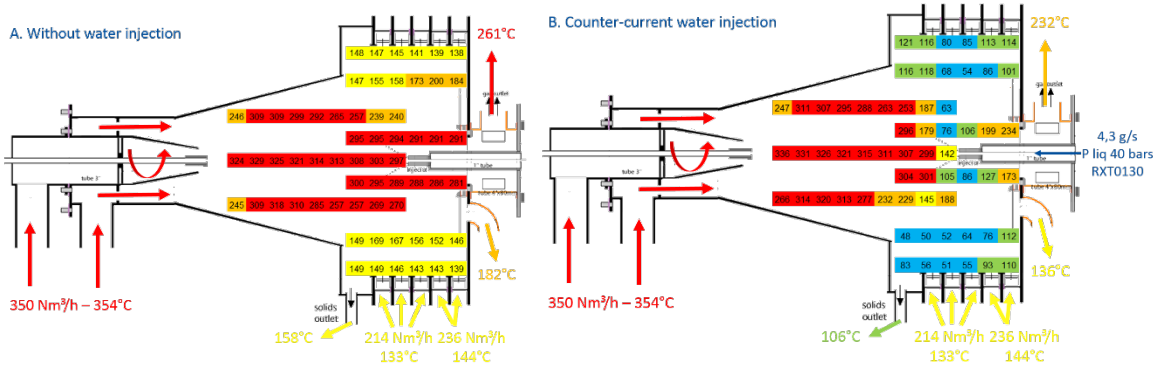

Figure 1. Measured temperature profiles in a radial multi-zone vortex chamber spray dryer with and without water injection.

The droplet/particle trajectories could be tracked by comparing detailed temperature measurements in the absence and presence of water injection (Figure 1) and by means of the CFD simulations. With a counter-current configuration (Figure 1), an S-shaped particle trajectory was observed. Radial multi-zone operation and mastering the axial motion of the gas and droplets/particles and the related residence times in the different zones remains challenging. Fouling also needs to be addressed. Promising results were obtained with an optimized radial multi-zone dryer design with a full cone nozzle and high-quality powder could be produced. Distinct separation of the two temperature zones was confirmed and could be maintained in the presence of droplets/particles (Figure 1), allowing efficient 2-step drying of the powder. A counter-current configuration (Figure 1) was found to be more efficient than a co-current configuration. Protection of the nozzle tip from fouling required a new protective sleeve design.

4. Conclusions

Experimental studies and CFD simulations of spray drying in a radial multi-zone spray dryer show that the technology is feasible and promising for intensified two-step drying. Efficient separation of a hot central zone and cold periphery and an extremely short residence time of the droplets/particles in the central hot zone can be achieved. As a result, using 350°C hot air, high-quality milk powder could be produced. A full cone nozzle was shown to be more efficient and stable than a hollow cone nozzle, especially with counter-current injection of hot air.

Spray drying of alumina powders – impact of process parameters and powder properties upon final product

Antoine Marie[1], Mallorie Tourbin[2], Anne-Charlotte Robisson[1], Carine Ablitzer[1], Christine Frances[2]

1 CEA, DEN, DEC, Cadarache 13108 St Paul les Durance, FRANCE ; 2 Laboratoire de Génie Chimique INP – ENSIACET, 31400 Toulouse, FRANCE

Highlights

- Alumina spray drying was studied under different process conditions
- The spray drying gas temperature impacts the proportion of fines in the product
- The initial powder size distribution has an effect on the spray-dried agglomerates
- Ultrasonic nozzle technology allows producing strong alumina agglomerates

1. Introduction

Spray drying is a quite usual process in powder industry for the production of pharmaceutics, food or ceramics [1]. Concerning ceramic powders, alumina powders for instance can be dried by spraying in order to provide better flow properties [2]. The physical properties of spray-dried product (size distribution, agglomerate shape) depend on several parameters, in particular spray drying conditions (gas temperature or suspension flow rate [3]) and the properties of the initial suspension (particle size distribution, solid content, …). The spray dryer nozzle geometry also may affect the product properties. If bifluid nozzle has been widely used [2] [4], ultrasonic nozzle was less commonly mentioned [5]. The purpose of this study is to evaluate the influence of these main parameters and of the nozzle technology used on the spray-dried powders.

2. Methods

In order to study the aforementioned parameters, several suspensions of alumina were prepared, using 3 different powders supplied by Baikowski (CR6, CR15 and GE15) having different initial specific surface area (respectively 6, 15 and 14 $m^2.g^{-1}$) and different median size (respectively 0.5, 0.4 and 8 µm). Several tests were performed with a Büchi Mini Spray Dryer B290, using a bifluid or an ultrasonic nozzle under various operational conditions, varying parameters such as gas temperature, suspension concentration or suspension flow rate. Nozzles mainly differ in the technology used to form the spray: in case of bifluid it is formed by shear forces resulting of contact between liquid and high-speed air flow; with ultrasonic nozzle, by vibration induced by high frequency sonication.

Characterizations were led, pairing size distribution analysis (by laser diffraction) and Scanning Electronic Microscope (SEM) pictures to get the morphology of the dried agglomerates. The device used to evaluate the agglomerate size distribution (Malvern MS3000) was also used to investigate the de-agglomeration and re-agglomeration behavior of the spray-dried powders by changing the air flow pressure used to disperse the particles.

3. Results and discussion

The spheroidization of the particles by agglomeration generated by the spray drying technology was observed by comparing SEM pictures before and after the spray drying process. Size distribution analysis points out the impact of spray-drying on granulometry: the operation tends towards narrowing the size distribution of the powder.

Some results, showing the influence of several parameters: process temperature, suspension concentration and suspension flow rate using a bifluid nozzle on the CR6 particle size distribution, are illustrated on figure 1. If the two last parameters do not seem to have a huge influence upon granulometry, temperature appears to affect the proportion of fine particles (submicronic ones).

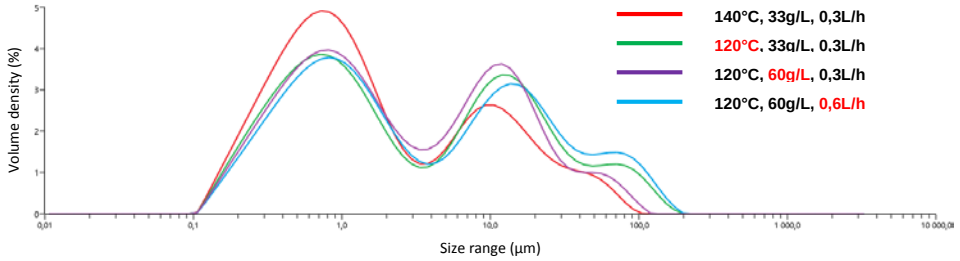

Figure 1. Size distribution curves depending on some process parameters

It was also found out that initial size distribution has an impact on powder behavior during spray drying since powder GE15, which has a higher median size than the two other powders, was not agglomerated but only dried during the experiments. Indeed, no significant change in morphology before and after spray drying was noticed using the bifluid nozzle for this powder. On the contrary, the ultrasonic nozzle allows GE15 powder to form spherical agglomerates, which let think that this technology is less sensitive to the initial characteristics of the powders.

The de-agglomeration tests performed under air flow pressure variations using the Malvern MS3000 dispersing system show that the agglomerates were more or less strong depending on the initial powders and process conditions. Indeed, some spray-dried powders with the bifluid nozzle tend to de-agglomerate increasing the air pressure while nearly no changes were observed with agglomerated powders produced using the ultrasonic nozzle. The ability of re-agglomeration of powders was also investigated in wet conditions.

4. Conclusions

The impact of some spray drying process parameters such as temperature or suspension flow rate, as well as suspension parameters like alumina concentration or powder initial granulometry, was studied. It appears that temperature has an influence on the proportion of fine particles (and consequently the size distribution) more distinctly than the other process parameters using a bifluid geometry in the spray-drying process. Runs were also performed using a recent nozzle technology (ultrasonic system) showing promising results, especially when an initial coarse powder, not easily agglomerated with a conventional bifluid system is used. More robust alumina agglomerates, not easily dispersed in air flow, were then obtained using the ultrasonic nozzle. The ability of the spray-dried powder to de-agglomeration or re-agglomeration phenomena is also discussed in this work.

Highlights
- Arabic Gum is an efficiency polymeric material to encapsulated Geraniol.
- The system has up to 15 days stability in environmental conditions.
- This system has great potential for use in crop protection and pollinators' attraction.

Introduction

Geraniol (GRL) is an acyclic monoterpene alcohol ($C_{10}H_{18}O$) derived from essential oils plants and showed several uses, such as pharmo-therapeutics (antitumor), preservative (bactericide), odorizing (for food and cleaning products), attraction agent to pollinators insects and repellent of a large number of insects considered as pests in agriculture [1-4]. However, GRL does not draw the interest from agro-industry when it is used "*in natura*" due to its short activity time since it is easily volatilizing or degrades by its high sensitivity to light, temperature and humidity [4,5]. One strategy to preserve unstable materials is the encapsulation. In this system essential oil is surrounded by a mono or multilayer coating layers that are able to preserves or control the release into the environment [6]. As example, the micro or nano carrier systems can be produced from different polymeric matrices such as Maltodextrin (ML) and Arabic Gum (AG) as well as by different encapsulation techniques (spray drying, fluidized bed, coacervation, extrusion and molecular inclusion). The atomization technique, also known as "Spray Drying" demonstrated efficacy in the studies with essential oils, besides its low cost [7-9]. The spray-drying process combines fluid colloidal materials in an emulsion (hydrophobic substance and polymer matrix in solution or suspension) converting them to dried particulates by the action of heated air in a drying chamber. In this study ML and AG were used in different proportions to produce the polymeric wall in the encapsulation process of GRL using spray drying technique as an alternative to protect the GRL when exposed to field conditions. In this way, this study open perspectives for the use of encapsulated GRL in crop protection as well as attractive for pollinators.

Methods

Three different formulations were prepared with GRL and polymeric materials wall. Each blend had 200 g as the final mass following these compositions (% w/w): A1 (30% ML, 10% GRL, 60% water); A2 (30% AG, 10% GRL, 60% water); A3 (15% ML, 15% AG, 60% water). Each sample was emulsified by ultraturrax (IKA T-18 ultra turrax emulsifier) at 17,000 rpm for 5 min (200 mL). Each emulsion had an aliquot diluted in deionized water at 1:1000 (v:v) at the 10, 20 and 30 minute intervals and

zeta potential was analyzed in triplicate using Zetasizer (Nano-ZS 90 Malvern Instruments). The zeta potential demonstrates that the stability of the emulsion along the drying period in Spray Dryer process. Spray dryer was setup using air inlet temperature 95 °C ± 5 °C; compressed air pressure 5 bar; compressed air inlet flow 40 L/min; blower flow 3.9 m³/min; liquid flow rate 0.5 L/h. The dried material obtained in the atomization was collected from the Spray Dryer and storage to characterization studies.

Capsules characterization - Encapsulation efficiency: The encapsulation efficiency of GRL was determined by the quantification of GRL loaded and unloaded using gas chromatography (GC). Capsule morphology: size, shape, influence of the matrix in capsule parameters were determined by scanning electron microscopy (SEM). Oil stability/release profiles: each capsule preparation was kept in a stability chamber (30 °C and 65 % humidity). The samples were kept in the chamber along 15 days and in the periods of 1, 7 and 15 days the materials were submitted to moisture analysis (% - using thermogravimetry at 80 °C) and oil content inside and outside the capsule (by gas chromatography) and morphology. (by SEM).

Results and discussion

To prepare A1 samples we have been used only ML as material to form the wall. After mixing all components and emulsifying them by Turrax, the water and ML formed an unbalanced system. As consequence, the ML concentration was increased to 40% and the matrix continued with heterogeneous aspect. The same behavior was described by Reineccius [10] where maltodextrin when used as an emulsifier providing an unstable film formation. In this way, due these results, the sample A1 was not considered in this study. However, for samples A2 and A3 were stable by visual analysis and for this reason they were considered in the next steps. In this context, the zeta potential was measured with 30 minutes, and the samples A2 and A3 presented stable values (A2 = 38 ± 2 mV; A3= 36 ± 3 mV). In addition, we have been observed that the zeta potential was also stable in acid pH (pH ~ 4) [11]. The SEM analysis showed that both samples presented spherical shape (**Figure 1**). The stability results showed that for A2 and A3 at t_{1day}, t_{7days} and t_{15days} a low decreasing in the internal volume of the capsules. This effect can be explained by the substitution of the geraniol present inside the capsule along the incubation time (15 days) in water in the stability chamber conditions (**Table 1**).

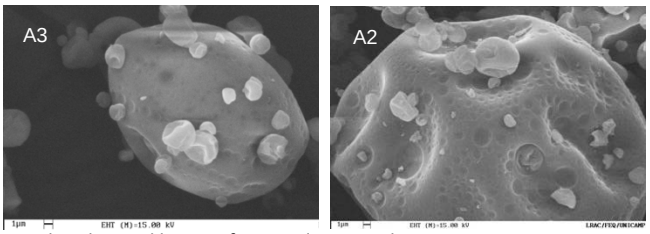

Figure 1. Morphology of the capsules obtained by SEM for samples A2 and A3.

Table 1. Results obtained for A2 and A3 samples:GRL assay (surface and inside capsules) and H_2O assay during the stability studies. Both results behaviors have correlation analyzed by Person in Microsof Excel® software.

Sample	Time (days)	GRL Assay inside (% w/w)	GRL Assay surface (%w/w)	H_2O assay (%w/w)	Person Correlation (H_2O and GRL assay)
A2 - AG	t_1	22.40	> 1%	5	-0.80
	t_7	21.06	> 1%	12	-0.80
	t_{15}	14.35	> 1%	18	-0.80
A3 - ML + AG	t_1	16.70	> 1%	11	-0.91
	t_7	14.30	> 1%	14	-0.91
	t_{15}	10.25	> 1%	21	-0.91

Also, the release of GRL from the capsules as described in **Table 1** can be explained by the two mechanisms: i) release of GRL by diffusion and ii) the degradation of GRL in/out the capsule. Another point is that there was an inverse relation between the increasing in the water inside and the decreasing in GRL inside the capsules. In addition, it is observed a strong linear correlation between these two variables that was determined by the analysis of the Person coefficient. These results were probably observed due the porosity increasing in the capsules and also to the exposure of GRL to oxygen that converts Geraniol ($C_{10}H_{18}O$) to Geranial and consecutively Geranioic acid ($C_{10}H_{16}O_2$).

Conclusion

The results showed that GRL and GA (as material wall) and its association with ML showed good results to produce capsules using Spray Drying technique. The characterization of both samples (A2 and A3) showed that the encapsulation efficiency remained in discrete decreasing in the first week (7 days) reaching approximately less than 50% of the total after 15 days. These results indicate that the encapsulation of Geraniol in both wall materials is able to preserve it for at least two weeks, therefore, a largest period comparing to GRL *in natura*. The results open perspectives for the use of GRL encapsulated in crop protection in field studies conditions.

Highlights

- α-Sepiolite is modified with poly(ethylene glycol) through hydrogen bonding interactions.
- Thermal stability of the composite is improved with modified α-sepiolite.
- Tensile properties are enhanced by modified clay addition to the structure.

1. Introduction

The incorporation of inorganic additives into a polymer matrix can improve the properties such as thermal stability, mechanical strength, ion exchange abilities, and solvent resistance [1,2]. Recently, clays have become increasingly popular as inorganic fillers in the field of organic-inorganic hybrid materials due to their superior properties such as their high surface area for polymer–filler interactions, small particle size, lightweight and low cost. In the present study, organo-modification of α-sepiolite, a natural clay, was performed using poly(ethylene glycol) (PEG) to improve the compatibility of the inorganic phase with the organic matrix. The modified α-sepiolite was introduced in the poly(ethylene oxide) (PEO) matrix to develop a composite film. The effect of modified clay additive on the mechanical and thermal properties was studied by comparing with the neat PEO film.

2. Methods

α-Sepiolite (Eskisehir/Turkey) was dried at 105°C for 24 hours and then ground into powder. PEG (Mw=950–1050) and α-sepiolite (1:1, wt/wt)) were added to water-ethanol (99.8%) (1:2, v/v) solution and ultrasonicated for 30 minutes. The resulting mixture was stirred overnight. Finally, the solution was poured into a petri dish, dried at 105°C for 24 hours and ground into powder. The obtained organo-modified clay was named PEG_α-Sepiolite. PEG_α-Sepiolite was distributed homogeneously in ethanol by ultrasonic mixing. PEO (Mw=40000) was dissolved in water (10%, w/v) under constant stirring at 70°C for 24 hours. The resulting transparent and viscous PEO solution was transferred into a beaker and the previously prepared PEG_α-Sepiolite/ethanol mixture was added gradually under ultrasonic mixing. The obtained PEO solution with 1% PEG_α-Sepiolite additive was casted onto a flat glass substrate (20 cm x 20 cm) and dried at 50°C for 24 hours. The resultant semi-transparent film named PEO/PEG_α-Sepiolite composite film. Neat PEO film was prepared following the same film preparation procedure except for the PEG_α-Sepiolite addition for comparison purposes and named PEO_control film. FTIR spectra of neat and PEG_α-Sepiolite samples were recorded as KBr pellets using a Frontier spectrometer (Perkin Elmer). Thermogravimetric analysis (TGA) of the film samples was performed using a STA6000

thermogravimetric analyzer (Perkin Elmer) with a heating rate of 10°C/min, under flowing nitrogen at a rate of 50 mL/min. The mechanical tests of the films were carried out using an Instron Mechanical Testing Machine 5581 test system following ASTM D882 method.

3. Results and discussion

FTIR spectra of the natural α-sepiolite and PEG_α-Sepiolite are presented in Figure 1. The shoulder, observed at 3690 cm^{-1} in the FTIR spectrum of neat α-sepiolite, is assigned to the -OH stretching vibrations of Mg-OH constituent of α-sepiolite and shifted to 3685 cm^{-1} with PEG modification. The wide band at 3570 cm^{-1}, indicating the -OH stretching vibration of bound water, shifted to 3566 cm^{-1} with PEG modification. The weak bands, observed at 1211 and 1018 cm^{-1} in the FTIR spectrum of neat α-sepiolite, corresponding to the stretching of Si–O in the Si–O–Si groups [3] disappeared after organo-modification with PEG. A new peak, indicating C-H stretching, was formed at 2932 cm^{-1} after the organo-modification. These differences may be resulting from the formation of new hydrogen bonding interactions between surface hydroxyl groups of α-sepiolite and PEG molecules, indicating the compatibility of α-sepiolite with PEG. Based on the TGA thermograms of the PEO_control and PEO/PEG_α-Sepiolite composite films, shown in Figure 2, both films represent a single-step thermal degradation behavior and the decomposition temperature increases from 355°C to 370°C with α-sepiolite incorporation. Tensile strength was increased from 12 MPa to 18 MPa and Young's modulus increased from 240 MPa to 360 MPa by α-sepiolite addition to the structure.

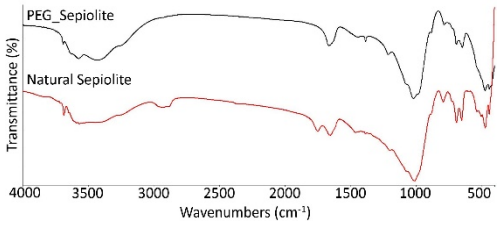

Figure 1. FTIR spectra of the natural α-sepiolite and PEG_α-Sepiolite.

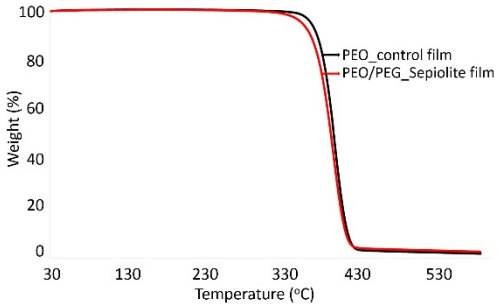

Figure 2. TGA thermograms of the PEO_control and PEO/PEG_α-Sepiolite composite films.

4. Conclusions

Based on the newly formed, disappeared, and shifted frequencies in the FTIR spectra after the modification process, it can be concluded that the organo-modification was achieved. α-Sepiolite, distributed at 1% by weight in the polymer matrix, has improved the thermal stability and mechanical strength of the resulting composite material. Considering the biocompatibility characteristic of PEO and α-sepiolite, potential use of the developed composite film in biomedical fields such as drug release and tissue engineering can be investigated in further studies.

Highlights

- Size and shape of $CaCO_3$ particles were controlled by varying operating conditions.
- Stable calcite particles were synthesized by employed a packed bed reactor.
- High pH values avoid the agglomeration and growth phenomena.

1. Introduction

Nowadays, there are serious environmental issues due to the Green House Gas emissions. The cement, iron and steel production can be included among the most polluting industries. Thus, there is an important need of recovering of CO_2 from combustion gases of these industries, which in turn can be used to obtain added value products. Calcium Carbonate Nanoparticles (CCnP) are widely synthesized via carbonation route (1) and have a large gamma of applications, since their characteristics, such as size and morphology are easily tunable through the synthesis method. They are widely used as filler material and, because of their porosity, non toxicity and biocompatibility, they are also used in the biomedical and food industry (2). In this study, an alternative carbonation method to synthesize calcium carbonate particles and control their size and morphology by varying the operating conditions is reported.

2. Methods

$CaCO_3$ particles were synthesized through carbonation (pure CO_2) of a CaO slurry. A Packed Bed Reactor, with a monolith as structured packing, was employed for this study in a setup illustrated in Figure 1. The synthesis was carried out at constant gas and liquid flowrate and stirring. The CO_2 flux was stopped once the pH was less than 10.5, value at which, according to the carbonate equilibria, the CO_3^{2-} formation is not favoured, thus reducing the CCnP saturation. Two zones are individuated: *i*) the crystallization one in the PBR, whence the CO_2 and the calcium solution get in contact and the precipitation takes place and *ii*) the stabilization one in the feed tank, where the pH is maintained high enough to provide a stable environment to the CCnP, since under alkaline conditions growth and agglomeration phenomena of the CCnP are not favoured (1). Then, once the process was finished, the synthesized particles were filtered by vacuum (pore size=0.45 µm) and repeatedly washed with deionized water to eliminate ion excess. By last, the $CaCO_3$ powder was dried at 60 °C overnight and finally their size, morphology and crystal phase were characterized.

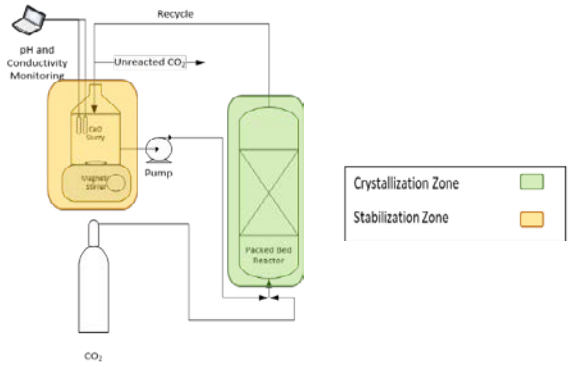

Figure 1. Packed bed reactor experimental setup.

3. Results and discussion

The operating conditions had an important effect on the properties of these particles. Cubic particles were obtained in the most of cases, in which the pH was maintained constant enough during the entire synthesis. The initial CaO concentration had an interesting effect on the particle size. Even if high CaO concentrations mean higher supersaturation levels, and then smaller particles would be obtained. At the beginning of the process, high saturation levels were present, but it led to higher synthesis times, and once the primary particles were formed, growth and agglomeration phenomena were prevalent, since they are favored by particle size and ion concentration respectively. Low liquid and CO_2 flowrates also led to elevated synthesis times, hence larger particles were synthesized. The flow regime, instead, affected the CO_2 absorption, controlling thus, the nucleation and growth rate. Higher liquid and gas flowrates led to smaller particles preparation, since they provide a more effective micromixing leading to a higher nucleation rate. In the cases where the CO_2 flowrate was too high (higher than 550 mL/min) and the pH suffered a progressive change during the synthesis, agglomerates were although formed. Consequently, this had an effect on the morphology of these particles, since hollow and particles with a wide PSD were obtained. Therefore, particles with mean particle size less than 200 nm were synthesized at optimal operating conditions, starting from a CaO slurry 0.015 M and liquid and gas flowrates equal to 300 and 400 mL/min respectively.

4. Conclusions

The size and morphology of calcite particles have been controlled in a carbonation precipitation for the CO_2 conversion. The shape of this particles reflects upon the operating conditions of the synthesis. The pH during the synthesis played a fundamental role, it controlled the agglomeration and growth phenomena. Hence, it had an important effect over the morphology and size. Higher pH values led to cubic calcite nanoparticles. Smaller particles were synthesized by employing higher liquid and gas flowrates, while low flowrates led to larger and agglomerated particles.

Highlights

- Precipitated nanoparticles of Ibuprofen down to 25nm
- Precise simulations of precipitation of Ibuprofen in a T-mixer
- Trend of particle size and shape of PSD are well captured for all Re in simulations

1. Introduction

It is estimated that more than 40% of new drug candidates fall into the Biopharmaceutic Class II and IV characterized by the low solubility of the active pharmaceutical ingredient (API), which results in low bioavailability **[1]**. Manufacturing drug particles in the nanometer range have been found to be a promising method to enhance the dissolution rate and, thus, the bioavailability. In particular, below 50nm the dissolution rate begins to drastically increase compared to the coarse-grained powder in the micrometer range. In doing so, precipitation of API nanoparticles attracted the attention in recent years due to the simple process condition, the easy scale-up as well as the low energy costs involved **[1,2]**. Still, the most challenging task remains on gaining suspensions stable with respect to the particle size distribution and crystallinity at defined process condition **[1,2]**. Numerical modeling of precipitation has been proven to be a useful tool to understand the interaction of the underlying processes for inorganic compounds. However, the transfer to organic compounds, e.g. API's, haven't led to great success so far, primarily due to the influence of the organic stabilizers usually applied. A recently in our group developed stabilization method closes this gap, provides insights into the underlying processes during precipitation of organic nanoparticles and allows to predict the resulting particle size distribution for well-stabilized nanoparticles.

2. Methods

A simple T-mixer is used to mix an alkaline aqueous ibuprofen solution with an acidic aqueous Zirconium chloride solution and to trigger the precipitation of Ibuprofen while Zr-ions stabilize the formed particles. The Villermaux-Dushmann reaction is conducted to quantify the mixing efficiency experimentally. The numerical approach consists of direct numerical flow simulations of the mixing process solving the Navier-Stokes and the convection-diffusion equation. A parameter-free approach is here applied which does not require any turbulence modeling. To describe particle formation, the nucleation and diffusion-limited growth is described by the population

balance equation along Lagrangian trajectories. Details on the mixing and precipitation experiments as well as on the flow simulations can be found in **[3,4]**.

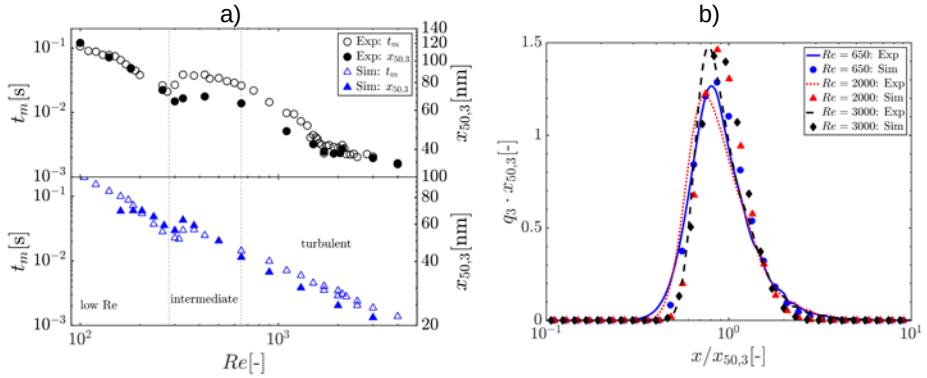

Figure 1. (a) Experimentally measured and computationally estimated mixing time t_m (left y-axis) and median particle size $x_{50,3}$ (right y-axis) as a function of Reynolds number Re. (b) Comparison of normalized particle size distributions at particular Re.

3. Results and discussion

The supersaturation is the thermodynamic driving force of the precipitation, which is here determined by the rate the two fluids are brought in contact with each other. Thus, the primary particle formation steps nucleation and growth are mixing controlled under the assumption of fast chemical reactions. This prevailing view is substantiated in Fig. 1a), which depicts a nearly perfect alignment of the experimentally determined mixing efficiency with the median particle size $x_{50,3}$ as Re increases. To properly simulate the precipitation, the mixing needs to be accurately captured at first, which was achieved in excellent qualitative agreement to experiments in our recent study **[4].** Subsequently, the particle formation induced by the inherent mixing history along each Lagrangian trajectory is simulated resulting in a finally accumulated PSD. With this approach, we are able to predict qualitatively the median particle size over the entire Re-regime considered without any modeling, see Fig. 1a). Note that only known physicochemical constants of Ibuprofen have been incorporated (particle density, molecular weight, diffusion coefficient). The only unknown parameter is the experimentally hardly accessible interfacial energy, which is determined by a model-based approach. The thus determined fixed, single value for all calculated PSD's is in the typical order of known organic substances. Remarkably, the shape of the particle size distributions is very well captured by the simulations in particular at high Re, see Fig 1b).

4. Conclusions

Modeling of precipitation, in particular, of organic nanoparticles is challenging. Our results demonstrate considerable progress and provide the potential for broader applications in future. In the talk, we will outline in detail the applied approach. In particular, we will focus on the interaction of mixing and supersaturation build-up, the prediction of PSDs and scale-up to very high Reynolds numbers and explain the role of the interfacial energy for predictive numerical modeling and simulation.

Rheological study of binary mixtures of powders using interparticular forces

Martin Giraud[1,2], Guillaume Bernard-Granger[2], Cendrine Gatumel[1], Stéphane Vaudez[2], Henri Berthiaux[1]

1 Centre RAPSODEE UMR CNRS 5302, IMT Mines Albi; 2 CEA-Marcoule, DEN/MAR/DMRC/SFMA

**Corresponding author: martin.giraud@mines-albi.fr*

This study has been carried out in order to improve the understanding of the mechanisms that occur during powder mixing operations, which are commonly used in many industrial processes. Up to now, the link between physicochemical and morphological properties of the powders and its flowability is still unclear. Likewise, for a mixture of several powders of different particle properties, the influence of the mass fraction of each powder within the mixture on its resulting rheology is not clearly established.

For this study, alumina (Al2O3), zircon (ZrO2) and yttrium oxide (Y2O3) powders of different grades have been selected in order to get a relevant range of size and shape for the study. The mixtures are prepared in a Turbula® mixer and the flowability of each blends has been assessed by Jenike shear cell yield locus measurements, performed with a powder rheometer.

A model linking the flowability of the mixtures to their composition and the morphological properties of each powder has been investigated using a population dependent Bond number which has been developed in previous studies [1]. This dimensionless number corresponds to the ratio between adhesive interparticular forces and the weight of the particles within the powder. It is then linked to the overall cohesion of the powder bed (Figure 1). The population dependent Bond number is assessed by fine characterization of each powder in terms of size distribution, surface roughness, specific surface area, surface energy and true density.

Defluidization behaviour due to sintering of industrial reactive powders

Domenico Macri[1*], Paola Lettieri[1]

[1]Department of Chemical Engineering, University College London, London WC1E 7JE, UK

*Corresponding author: domenico.macri@ucl.ac.uk

Highlights

- The defluidization behaviour of mixtures of coke and titanium ores were studied
- Early stages of sintering process were experimentally simulated
- Sintered materials were analyzed by optical, chemical and mechanical tests

1. Introduction

Fluidized bed reactors are used in a wide range of industrial chemical processes and they are particularly useful in high temperature systems thanks to their ability to provide high heat transfer rates and rapid solids mixing which lead to isothermal and more controllable conditions. Their applications spread the environmental, chemical, energy and process industries. For example, they are a key technology in the petroleum industry, catalytic chemicals synthesis processes, combustion and gasification of solid fuels (coal, wastes and biomass), metals productions and many more.
Operations below incipient fluidizing conditions in combustion-type operations can lead to particles aggregation and sintering which change the characteristics of the bed and could cause bed defluidization with consequential unscheduled process downtime and additional costs.
However, the details of the physical processes under such conditions are still not well understood. Despite the countless researches that have been done so far, such processes still disclose unrevealed features and challenge the researchers worldwide.
The objective of this work is to assess the influence of operative conditions on the fluidization behaviour of mixtures of petroleum coke and different titanium ores industrial reactive powders.
The fluidization behaviour of several mixtures have been studied at process temperatures ranging from ambient up to 950 °C in a specially designed heated fluid-bed reactor, where the early stages of the sintering process were experimentally simulated.

2. Methods

In order to tackle the problem of assessing the defluidization behaviour of powders at operative conditions, the early stages of the sintering process were experimentally simulated in the fluidization rig for the mixtures of coke, rutile and slag by blowing air into the fluidized bed for a certain time [1]. The effects of high temperature and air flowrate were investigated systematically in different fluidization regimes. Fundamental fluidization tests were also carried out on the spent systems (i.e. after combustion and cooled down to ambient conditions) and compared to the fresh ones. The reactor was then emptied and the aggregates collected for further off-line examinations: mechanical properties evaluation by means of a vibrated plate friability test, optical and chemical composition assessment by SEM/EDX analysis.
Fundamental fluidization tests were also performed using the unique X-ray Imaging technique available at UCL, which enabled to visualize the internal flow pattern inside the metallic reactor and to obtain quantitative information. Simultaneous measurements of local temperatures and

pressure drop across the bed were carried out in order to detect possible aggregation and sintering phenomena.

3. Results and discussion

The tests showed that combination of operative conditions and coke characteristics have a significant role on the formation of the aggregates and on their properties. In particular, the mechanical strength of the aggregates was found to be strongly dependent on the coke particles size and the operating fluidizing regime: they appeared more friable with when larger coke particles size and low air flowrates were employed. The SEM/EDX analysis permitted the inspections of the bridges among particles and the assessment of the chemical composition of the sintered material. The results suggested that only particles of rutile and slag were involved in the formation of the sintered bridge (with a particular enrichment of Al-Si phase in the bond) and no relevant bonding structures involving coke particles were found.

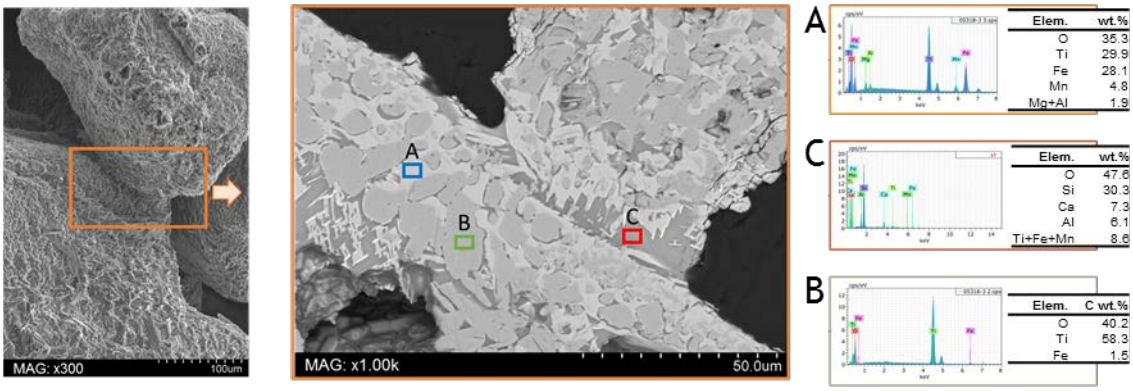

Figure 1. Example of SEM image and EDX spectrum on a sintered bridge

4. Conclusions

Inspections of the fluidization performance of different mixtures of titanium ores and coke showed that a number of factors are responsible for the onset of defluidization due to particles aggregation, such as rutile's nature, coke particles size, operative fluidization regime, etc.

The basis for a fundamental understanding of the investigated industrial process has been delivered by successfully reproducing and controlling the early stage stages of the sintering processes in a small pilot scale fluidized bed at temperature far below the real operative one. Moreover, a clear relationship between the characteristics of the final aggregates and the operative conditions was found.

Highlights

- Hydrophilic and hydrophobic formulation did not alter particle shape and size.
- Lactose-coated glass beads showed a surface roughness incensement.
- The hydrophilic glass bead showed highest, lactose coated bead lowest flowability.

1. Introduction

The study and comparison of formulated powders are a great interest as it can suggest solutions to improve the transport of real powders. The flowability of glass beads was largely investigated in previous studies [1-2]. The dependency of powders flowability to the moisture [3] and formulation [4] is known phenomenon. In fact, particle–particle interactions determine the macroscopic behavior of the powder. Powder flowability is expected to decrease due to liquid bridge formation between two particles dependently to the humidity [5]. Moisture sensitivity depends on hydrophilic and hydrophobic treatments. Furthermore, the friction between particles in granular materials is known to influence particles flowability [6]. By modifying the roughness of the surface, lactose coating may modify friction between particles. The surface roughness is comparable to the one of the particles obtained by lactose agglomeration (having a lactose core) but the Young modulus of particle core influence the collision effect during the flow. Therefore, aforementioned treatments may influence the interactions between particles, consequently powder flowability.
In this study, links between powder surface modification and rheology are investigated. For this purpose, glass beads with 100 µm mean size are employed. In order to study the influence of surface composition, various surface treatments leading to hydrophilic, hydrophobic and lactose-coating are performed on glass beads. Moreover, in order to investigate the influence of powder core composition, agglomerated lactose powders presenting similar mean particle size are also produced by high-shear wet granulation and characterized. Finally, the flowability of powders are studied and compared by performing tests with a FT4 powder rheometer (Freeman Technology) [7]. Furthermore, the TA Instruments AR 2000 Advanced Rheometer is in use to obtain the flow curves of powders. At the final, obtained results from both apparatuses will be compared to make links between the apparent viscosity of the powder depending on its formulation and the flowability measurements provided by FT4 rheometer.

2. Methods

The particle size distributions are determined by laser granulometry with a Mastersizer 3000 supplied with an Aero S dry dispersion unit. FT4 powder rheometer is used in order to study

powders flowability. In this paper, stability and rotational shear cell tests are performed on the powders. Stability test intends to evaluate powder flowability in a low-stress environment, whereas the rotational shear cell test is devoted to analysis of powder flow properties in high-stress conditions. Moreover, TA Instruments AR 2000 Advanced Rheometer is implemented with the objective of studying the rheology of powders. A cylindrical Couette geometry with a vane is used to insure that the powder does not slip on the inner cylinder walls. The angular velocity of the vane is imposed and the corresponding torque is measured by the rheometer. The torque time evolution monitoring ensures that a steady-state flow is established for each value of the rotational speed. Thus, the relation between the shear stress and the shear rate in permanent regime can be determined.

3. Results and discussion

Fig 1 shows the evolution of shear stress recorded at variable decreasing normal stress from 7 to 3 kPa for each sample. At the beginning of each test 9 kPa of pre-shear stress applied by FT4 in order to reach the critically consolidate state. In general, the higher the curve on the diagram, the poorer the flow properties [8]; therefore, according to this criterion, investigated powders can be ranked according to their flowability in shear stress conditions: hydrophilic glass beads ≈ control glass beads > hydrophobic glass beads> lactose-coated glass beads> agglomerated lactose powders.

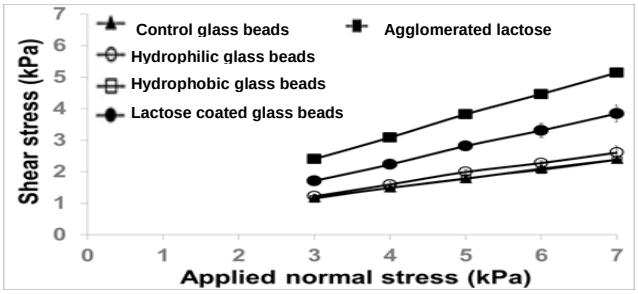

Figure 1. Evolution of shear stress with applied normal stress after pre-shear at 9 kPa applied on 100 µm powder samples. Error bars represent st -andard errors; some were not visible as their size was inferior to the marker size.

4. Conclusions

The size distribution measurement of particles after formulation evidenced that agglomerated lactose powders and lactose coated glass beads presented similar mean particle size but a wider size distribution than the rest of powders. Based on shear cell test of FT4 rheometer, hydrophilic and lactose coated glass beads were more and less flowable powders, respectively. The result of TA Instruments AR 2000 Advanced Rheometer (which is in progress) will be compared with the FT4 results. Besides, the microscale properties of powders will be studied by single particle impact and nanoindentation tests to determine the influence of the surface modification on the deformation and adhesion properties of particles. Also, links between flowability, rheometry and microscale properties of particle-particle interactions will be analyzed. Concerning nanoindentation tests low inter-particle friction and low elasticity expected to lead to good flowability.

Crystal engineering strategies to ensure the quality of particulate products for the food and pharmaceutical industries

Elena Simone[1*]

1 School of Food Science and Nutrition, University of Leeds, Leeds, United Kingdom

**Corresponding author: e.simone@leeds.ac.uk*

Highlights

- Crystal shape and polymorphism of lactose and ortho-aminobenzoic acid were tailored with combinations of solvents and structurally related additives.
- Temperature cycling was used to manipulate crystal shape of succinic acid without affecting its purity.
- Process analytical technology for online monitoring and control of crystallization.

1. Introduction

Crystallization is an important unit operation used in the pharmaceutical, agrochemical and food industries. Crystal size, shape and lattice structure (polymorphism) have a profound effect on the properties of the final particulate product as well as on the efficiency of the downstream operations (filtration, washing, drying, tableting etc.). Crystals can be engineered by opportune choice of crystallization conditions. Here, examples of how these processing conditions can affect crystal polymorphism, purity and size/shape distributions are presented [1-3]. The implementation of process analytical technology (PAT) tools during the development stage of APIs has largely helped in better understanding and optimizing crystallization processes. Specific instrumentation can be used to monitor on-line, in situ, crystal size and shape (focused beam reflectance measurement, FBRM, particle vision and measurement, PVM), polymorphism (Raman, spectroscopy) and liquid phase composition (Attenuated total reflectance, ATR, UV/VIS) [3]. Furthermore, feedback control strategies based on PAT tools signal can be implemented to specifically tailor the characteristics of the produced crystals. This work shows few examples of application of PAT tools for the study and control of crystallization processes.

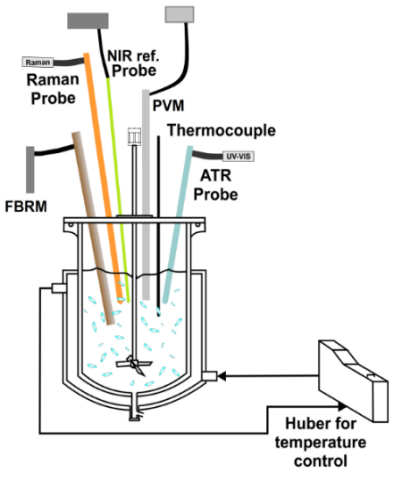

Figure 1. Schematic of the rig used for the experiments.

2. Methods

Three examples of crystal engineering strategies to control crystal polymorphism and shape are shown here. Cooling crystallization experiments were carried out at 400 mL scale in a jacketed vessel equipped with temperature control. Ortho-aminobenzoic acid (OABA), lactose and succinic acid were used as model compounds for the experiments. The shape and polymorphism of OABA were tailored via crystallization in

different solvent mixtures (water and isopropyl alcohol, IPA) and with the addition of a structurally related additive (benzoic acid, BA). Lactose polymorphism and size distribution were controlled via crystallization in water/acetone mixtures. Finally, succinic acid was crystallized from water and its crystal shape was controlled via applying heating (dissolution) and cooling (growth) cycles. The array of PAT tools shown in Figure 1 was used to monitor experiments online, while offline microscopy, X-ray and laser diffraction as well as chromatography were used to measure size, shape, purity and crystal polymorphism of the obtained crystals after filtration and drying.

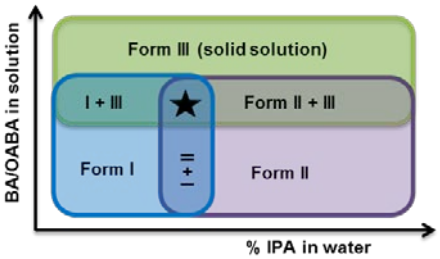

Figure 2. Polymorphic control of OABA.

3. Results and discussion

3.1 Polymorphic control using solvents and additives

Figure 2 shows the results obtained for the polymorphic control of OABA. Increasing the amount of IPA in water induced the formation of the metastable form II while high water concentrations favoured the nucleation of stable form I [2]. Introducing BA generated nucleation of the metastable form III regardless of the solvent used. BA was found to be easily incorporated in form II and III of OABA, generating solid solutions. Lactose crystallization was instead performed in solvent mixtures at different ratios of acetone and water. High concentrations of acetone determined faster nucleation and growth rate but poor control of polymorphism, with β-lactose crystals nucleating together with the desired α-monohydrate form. In water only the α-monohydrate form was obtained but with slow growth kinetic, leading to poor recovery yields [1].

3.2 Shape control using temperature cycling

Temperature cycling was used to modify the morphology of succinic acid crystals in water, exploiting the different rates of growth and dissolution for each specific facet (Figure 3). The shape of crystals moved from plate-like, with a dominant (100) face, to diamond-like. Because of the different facet-specific kinetics of growth and dissolution it was possible to completely eliminate the (100) facet in favour of the growth of the (110), (011), (-110) and (01-1) facets. This strategy allowed shaped manipulation without the introduction of additives of impurities [3].

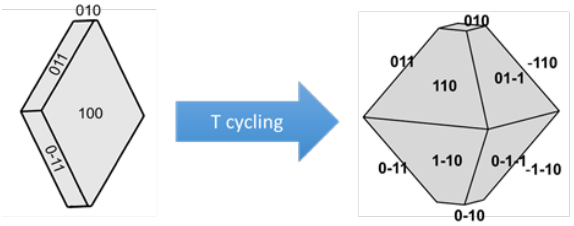

Figure 3. Shape control of succinic acid.

4. Conclusions

In this work different examples of crystal engineering approaches for the design of crystallization processes and their online monitoring and control are illustrated. Crystal properties could be fine-tuned by selecting opportune operating conditions.

Obtaining the True Process Value of the Fragmentation Kinetic Function (FKF) For The Breakage of Silica Flocs in Taylor Couette Flow Via Population Balance Simulation.

Y.K. Leong[1], P.I. Au, J.S. Liu, Y. Wang

1 Department of Chemical Engineering, The University of Western Australia, Crawley, Australia 6009

Highlights

- A method for determining experimental FKF data presented
- Computed and experimental PSD matched.
- FKF data cannot be determined experimentally.
- FKF values very large for small flocs.

1. Introduction

The breakage or fragmentation kinetic function (FKF) of a given father size floc breaking to form two specific daughter size flocs cannot be measured experimentally. Indirectly it can be determined from the FKF model used to solve the population balance equation for floc fragmentation subjected to meeting two conditions: i) the computed and experimental particle size distribution function (PSDF) matched at all fragmentation time and ii) the PSDF data at zero fragmentation time was the input in the computation[1]. The fragmentation of compact polyelectrolyte-bridged silica flocs in a narrow gap concentric cylinder flow cell was investigated in the laminar Taylor vortex flow regime at Taylor number of 26000. A past study showed that the FKF values are smaller for large flocs as they tend to migrate to the low shear region[1]. Monodispersed SiO_2 particles of 0.34 μm were coated with a low Mw cationic PEI and then bridged with a high Mw anionic polyacrylamide flocculant.

2. Methods

This dimensionless PBE expressed in log-form given by[2]:

$$\frac{\partial N(\tau,10^{X})}{\partial \ddot{A}} = t_{scale} k_{F_{max}} v_{max} \int_{X_r = X \oplus X_{min}}^{X_{max}} K_F(10^{X_r},10^{X}) N(\ddot{A},10^{X_r}) 10^{X_r} \log_e 10 \, dX_r - \frac{1}{2} N(\ddot{A},10^{X}) t_{scale} k_{F_{max}} v_{max} \int_{X_p = X_{min}}^{X \leftrightarrow X_{min}} K_F(10^{X},10^{X_p}) 10^{X_p} \log_e 10 \, dX_p . \quad (1)$$

Is solved directly after being converted to ordinary differential equation by MOL. $X \equiv \log_{10} V$, $V = v/v_{max}$, $N = (v_{max})^2 n/m_F$, $K_F = k_F/k_{Fmax}$, $\tau = t/t_{scale}$ and $dV = \log_e 10 \times 10^X dX$. The experimental time scale t_{scale} must be used in the computation so that the simulated and experimental results are

$$S = 0.001 + 0.05e^{-0.8(5+\frac{Log[10^{X_r}]}{Log10})^2} + 7(1 - Tanh[1.13\left(5.45 + \frac{Log[10^{X_r}]}{Log10}\right)]$$

comparable.[1]The FKF used for 200rpm is:

$$K_F(10^{X_r},10^{X_p}) = \frac{S}{S_{max}}\exp[\sigma(10^{X_r})^g](10^{X_p} - 10^{X_{minin}})^h(10^{X_r} - 10^{X_p} - 10^{X_{minin}})^h / (\exp[\sigma]\left(10^{X_r - Log_{10}2} - 10^{X_{minin}}\right)^{2h}),$$

.

Continuous particle size distribution (PSDF) data at zero fragmentation time was the input in the computation to solve Eqn 1 to obtain temporal PSD data.

3. Results and discussion

The discrete and continuous PSD for fragmentation in Taylor Couette flow at 200 rpm are shown in Figure 1(a) PSDF in (b).

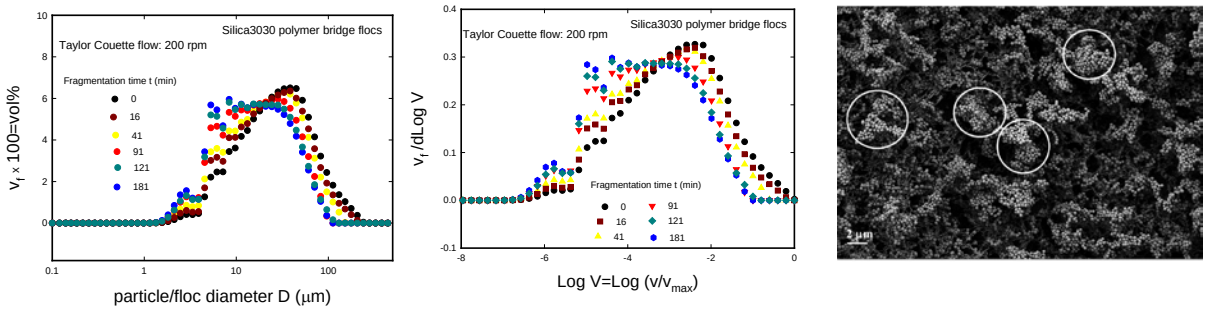

Figure 1. Temporal a) PSD and b) PSDF during fragmentation, and c) compact fragmented silica flocs.

The comparison between computed and experimental PSDF is shown in Figure 2 for dimensionless time τ a) 0 and 1, b) 0.24 and c) 0.68. The agreement are considered good. This means the the FKF data used in computation and some of which are shown in Figure 3 represents the experimental values.

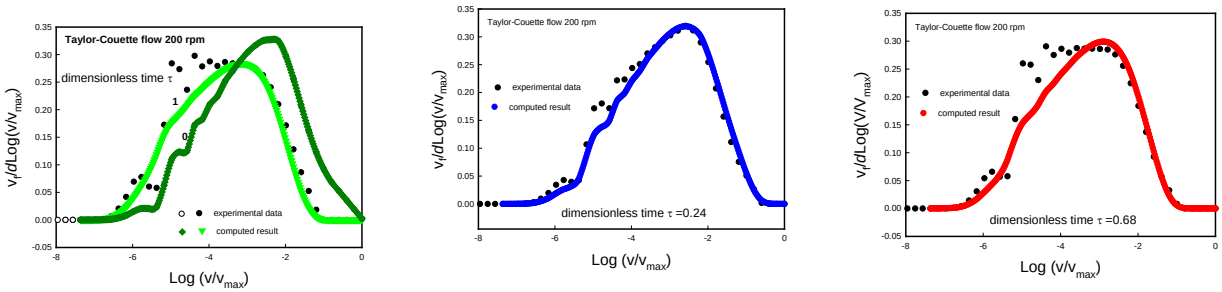

Figure 2. Computed and Experimental temporal PSDF comparison are various fragmentation time.

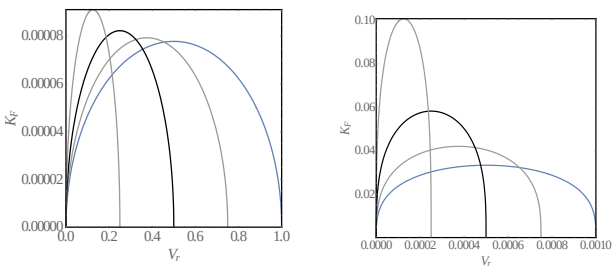

Figure 3. FKF data used in the PBE represent the true process values.

4. Conclusions

Computed and experimental PSDF matched at all fragmentation time. The FKF data used thus represent the true process value.

Shape modification of needle crystals using polymer additives and temperature cycling

Wei li[1], Brahim Benyahia[1], Chris Rielly[1]

1 Department of Chemical Engineering, Loughborough University, Loughborough, Leics, LE11 3TU, UK
**e-mail: w.li@lboro.ac.uk*

Highlights

- Additives combined with temperature cycling helps to produce more equant shape crystals
- Optimized closed-loop temperature cycling can eliminate fines and agglomerates
- Polymer additives affect growth on specific crystal faces
- Seeded and mill-aided processes can further improve aspect ratio of needle crystals

1. Introduction

Crystal products which have a needle-like morphology tend not to compress well into tablets, and hence more equant shaped crystals are preferred for the secondary manufacturing process. Lovastatin has been studied in this work and is an active pharmaceutical ingredient widely used for the treatment of hypercholesterolemia. However, it forms needle-like crystals and is notorious for its poor processability and difficult formulation. High aspect ratio needle crystals often have poor processability for the filtration washing and drying stages [1]. Needle crystals are often brittle, and breakage results in fines and dust in the working environment. In the current work, lovastatin cooling crystallizations were conducted using polymer additives, namely polypropylene glycol (PPG-4000), coupled with temperature cycling profile using a direct nucleation control (DNC) approach [2], to improve the aspect ratio. This high-molecular-weight, high-boiling point polymer additive can block specific fast-growing crystal surfaces through a hydrogen bonding effect [3]. Hence, they modify the morphology, by inhibiting unwanted elongated growth in the length of the crystal and provide a selectively preference for growth on the short sides.

2. Methods

2.1 Materials:

Lovastatin, ethyl acetate, polypropylene glycol (PPG)

2.2 Equipment:

400ml crystallizer, process analytical tools were used to measure the particle counts, particle length, temperature and concentration profile.

2.3 Process:

- Cooling crystallization from saturation temperatures of 35°C to 10°C in the absence and presence of polymer additives was investigated
- DNC approach was applied to produce size and shape modification, using continuously heating and cooling cycles effectively by indirectly control growth and dissolution mechanisms

- Combination of polymer additives and temperature cycling effect were studied
- Different startup and nucleation conditions were studied, including classical seed addition and wet-mill facilitated nucleation

3. Results and discussion

Fig 1 shows PAT data and PVM images for batch cooling crystallizations. The *in situ* PVM images indicated that the aspect ratio was not improved much for crystallizations with linear cooling profiles (Fig 1b) and varying amounts of PPG, although the nucleation time and nucleation rate were suppressed with increasing mass of polymer additives. The particle counts, concentration and temperature time histories showed that an improved DNC method with PPG additives can shorten the isolation temperature cycle time (Fig 1c & e) and reduce the aspect ratio of the crystals. With an optimised temperature cycle process, agglomeration was not observed and fines were removed by dissolution. Furthermore, wet-mill-aided and seeded DNC can be applied for further shape modification of lovastatin crystals (Fig 1d & f).

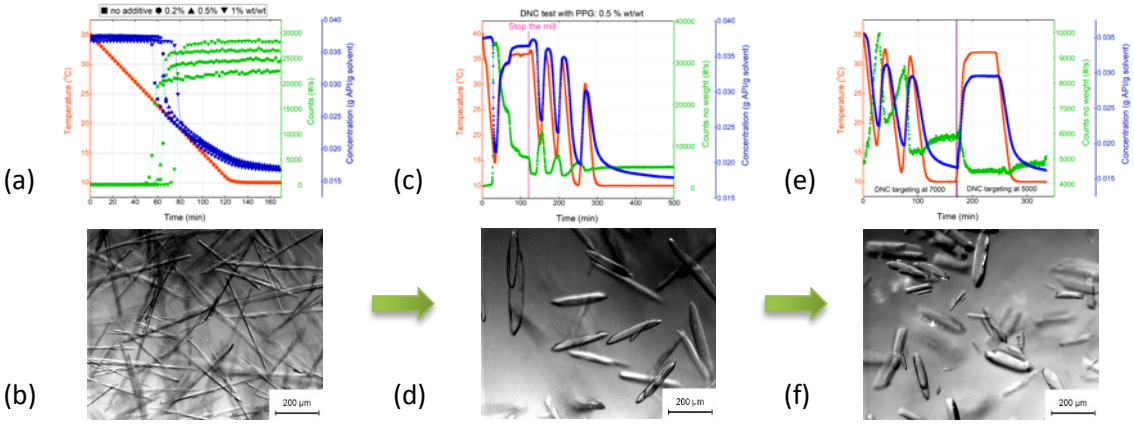

Figure 1. FBRM counts/s — temperature — and concentration — against time profiles and in situ PVM images captured of the final crystals for: (a) and (b) Linear cooling crystallization of lovastatin/ethyl acetate system; (c) and (d) Lovastatin/ethyl acetate/PPG-4000 system with mill-aided DNC T cycling crystallization; (e) and (f) Lovastatin/ethyl acetate/PPG-4000 system with seeded DNC T cycling crystallization

4. Conclusions

Additions of a polymer additive PPG-4000 on the linear cooling crystallization of lovastatin in an ethyl acetate solvent were investigated, resulting in a delay in the start of nucleation with increasing concentration of additives. Application of an optimized DNC approach (with and without polymer additives) was compared with a benchmark cooling crystallization. The aspect ratio was more significantly improved using a combination of temperature cycling from DNC and the presence of the polymer additive. The crystal size and shape distribution can be further improved by different seeding approaches.

Relating crystalline properties with the bulk and surface chemistry of quercetin and its hydrate forms using molecular and synthonic modelling

Panayiotis Klitou[1*], Ian Rosbottom[2], Elena Simone[1*]

1 School of Food Science and Nutrition, University of Leeds, Leeds, U.K.; 2 School of Chemical and Process Engineering, University of Leeds, Leeds, U.K.

fspkl@leeds.ac.uk, e.simone@leeds.ac.uk

Highlights

- Water molecules satisfy hydrogen-bonding in hydrate structures
- Hydrate structures can pack more efficiently
- Hydrate structures can have different physiochemical properties

1. Introduction

Quercetin is a naturally occurring flavonoid which is ubiquitous in the human diet. It is found in many fruits and vegetables and it is known to be an antitumor agent and to exhibit antiallergic, anti-inflammatory and antioxidant activity. [1] Due to the wide range of health benefits, this compound finds use in nutraceuticals and food supplements. [1] Quercetin can exist as an anhydrous, monohydrate and dihydrate crystal form. Usually hydrates exhibit different physiochemical properties, like solubility, stability, morphology and surface chemistry. [2] Understanding these properties and selecting the most appropriate crystal form in terms of thermodynamic and kinetic stability is of critical importance for several industrial applications.

Molecular modelling is an inexpensive and quick way to gain insight into the link between crystal structure and powder properties. This can be achieved by calculating the strength, directivity and dispersive nature of the intermolecular interactions (synthons) within the crystal structure. [3]

In this work, synthonic modelling is used to explore three different hydrated crystalline structures of quercetin: the anhydrous, monohydrate and dihydrate forms, for which the bulk intrinsic and surface extrinsic synthons were examined. The role of water molecules within the three hydrated structures was studied to understand how water affects the packing and conformation energetics of quercetin crystals. This knowledge can then be used to predict physiochemical properties such as stability, and to better understand the mechanisms of nucleation and growth during the crystallization process. Furthermore, the attachment energy model is utilized here to predict the crystal morphology of each form, and by the characterisation of the surface extrinsic synthons, to explore the surface chemistry and predict surface properties such as polarity. [4]

2. Methods

The Habit 98 software (developed in house at the University of Leeds) was used for the calculation of the pairwise intermolecular interaction strengths and lattice energy. [3] This was achieved by summing all the interactions between a central molecule and all the other molecules within a sphere of fixed radius of 30Å around the central molecule. The intermolecular interactions were

calculated using the Momany force-field. [3] All visualization of molecular and crystal packing were carried out in Mercury CSD Version 3.10.

3. Results and discussion

By analyzing the bulk chemistry of quercetin anhydrous, it was found that all key synthons are polar interactions, involving hydrogen bonds and permanent dipole-dipole interactions, while in the monohydrate and dihydrate structures the synthon contributing more to the lattice energy is a non-polar π-π stacking interaction. The hydrogen bonding interactions in the two hydrates are satisfied partly (monohydrate) or exclusively (dihydrate) by interaction with the water molecules.

A conformational analysis was performed and revealed that the quercetin molecules within the anhydrous structure are organized in a less planar arrangement, thus being unable to pack as efficiently and resulting in a lower unit cell density. The quercetin molecules in the monohydrate and dihydrate structures are arranged in a more planar way, due to the fact that quercetin hydrogen bonding is satisfied by the presence of water molecules. Therefore, the presence of water allow quercetin molecules to pack more closely and form the strong π-π stacking interactions, which result in higher unit cell density and greater stability, agreeing with experimental solubility data. [1]

Finally, the attachment energy model was used to predict the growth rate of each face in the three structures and to identify the surface extrinsic synthons contributing to the growth of each facet. The extrinsic synthons were characterised and the surface chemistry of the different faces in each structure was studied, predicting different properties such as face polarity. The attachment energy model was further used to predict the morphology of the structures, illustrated in Figure 1.

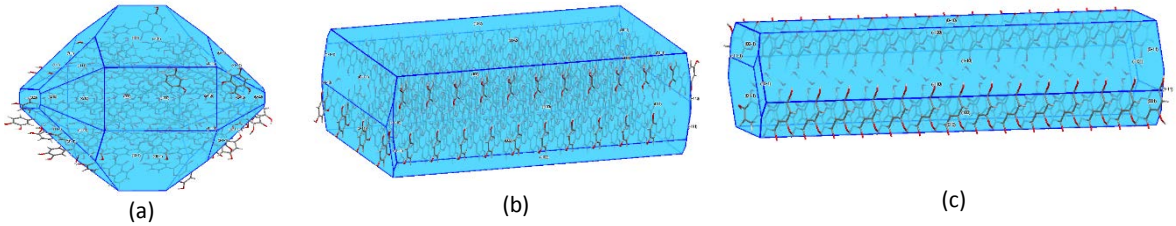

Figure 1. Morphological predictions of quercetin anhydrous (a), monohydrate (b), and dihydrate (c)

4. Conclusions

The presented modelling results show how the presence of water molecules in the quercetin hydrate structures impacts on the type and strength of intermolecular interactions within the crystal, affecting the conformation and packing of the quercetin molecules in each structure. This results in differences in physiochemical properties, such as stability, morphology and surface chemistry. This work shows how synthonic modelling can be used as a predicting tool to better understand the relationship between crystal properties and product quality, leading to a more efficient product formulation and faster development.

Influence of fluid dynamics conditions on Pb-hematite nanoparticles mass transfer coefficient in Rushton equipped stirred tank reactor

Giorgio Vilardi[1*], Marco Stoller[1], Nicola Verdone[1], Luca Di Palma[1]

1 Dept. of Chemical Engineering Materials Environment, Sapienza University of Rome, via Eudossiana 18, Rome, 00184

**Corresponding author: giorgio.vilardi@uniroma1.it*

Highlights

- A CFD model was successfully applied to predict the mass transfer coefficients
- A notable Lead sorption capacity of 38 mg/g has been obtained by nano-hematite
- The coefficients of Sh correlation from predicted and regressed k_L were in agreement

1. Introduction

Only recently it has been recognized that various properties of iron (hydro)oxide, such as structure and stability besides the reactivity, might vary as a function of the mean particle's size [1]. In particular, the structure of hematite, α-Fe_2O_3, when it is of maximum particle's size of 40 nm, becomes similar to that of goethite, α-FeOOH [1]. It has already been demonstrated that when the hematite nanoparticles mean size is close to 40 nm, the surface characteristics of the minerals are similar to those of goethite for approximately 60% [1]. These characteristics are suitable in heavy metals separation processes from wastewater streams, by means of sorption phenomenon. In this work, hematite nanoparticles (nHP) have been synthetized using a Spinning Disk Reactor, according to a previous study [2] and have been employed in a Rushton equipped agitated vessel for the removal of Pb cations in aqueous solution. The kinetics of the process has been evaluated and modelled according to a film-diffusion mass transfer model and the influence on mass transfer coefficient of impeller Reynolds number (Re_I) and clearance (C) were evaluated.

2. Methods

The nHP were synthetized according to a previous work [2]. The particles were characterized by a unimodal size distribution and a mean size of 46 ± 1.8 nm and a pH of zero charge of 8.3. The particles were used for the removal of Pb (50 mg/L) at a concentration of 2 g/L (the optimal concentration and pH were found according to preliminary tests) and a pH higher than the pH of zero charge (pH=9.5) to maintain the particle's surface negatively charged and to favour the sorption of Pb. From equilibrium tests (25°C) using Pb solutions (10-100 mg/L) it has been observed that the Langmuir model was the most suitable one (compared with Freundlich and SIPS) to describe the experimental trend. The regressed isothermal parameter values were b, equilibrium constant, equal to 0.22 L/mg and q_{max}, maximum sorption capacity, equal to 38 mg/g (data not showed). The Re_I was varied in the range 1.4-3.5x10^4, to maintain full turbulent conditions, by varying the impeller rotational velocity (500-1250 rpm). The dimension of the tank diameter, T (m), was 0.123 m, whereas the liquid height, H (m) was fixed equal to T. The impeller diameter, D_i (m), was fixed equal to 0.33T, whereas C was varied as 0.15T, 0.25T, 0.33T and 0.4T (data not showed).

The number of baffles was 4 and their dimension was 0.1T. The tests were conducted with two identical reactors, and at selected time steps, the same liquid aliquot was withdrawn from the two reactors. The former was used to re-fill the first reactor, to keep its volume constant and to avoid the variation of the hydrodynamic field, whereas the second one was used for the analysis. The residual Pb concentration was measured by a Flame Absorption Spectroscopy instrument (Agilent). The kinetic experiments were interpreted according to a mass transfer model reported in a previous work, where also the fluid dynamic model (RANS + k-ε model) of the stirred tank has been described [2]. The regressed liquid film mass transfer coefficient, k_L (m/s), and the simulated ones (obtained from CFD simulations) were used to evaluate the empirical coefficients of the experimental relation between Sherwood, Reynolds and Schmidt numbers, as reported below:

$$Sh = \frac{d_p k_L}{D_{Pb}} = \left[2 + \alpha Re_p{}^c Sc^d\right] \quad (1)$$

$$Re_p = \frac{\varepsilon^{1/3} d_p^{4/3}}{\upsilon} \quad (2)$$

$$Sc = \frac{D_{Pb}}{\upsilon} \quad (3)$$

where ε (W/kg) is the specific power per unit of mass dispersed in the vessel, D_{Pb} (m^2/s) is the Pb bulk diffusion coefficient and ν (m^2/s) is the kinematic viscosity of the solution.

3. Results and discussion

The increase of impeller rotational velocity, i.e. Re_I and turbulence, favored the mass transfer phenomenon and led to a reduction of required residence time in the agitated vessel to reach the asymptote (Figure 1a). The empirical correlation among Sh, Re and Sc numbers was employed as model to fit both predicted and regressed k_L values and the obtained empirical coefficients (α, c and d) were quite similar, considering the accordance among the k_L values (Figure 1b)

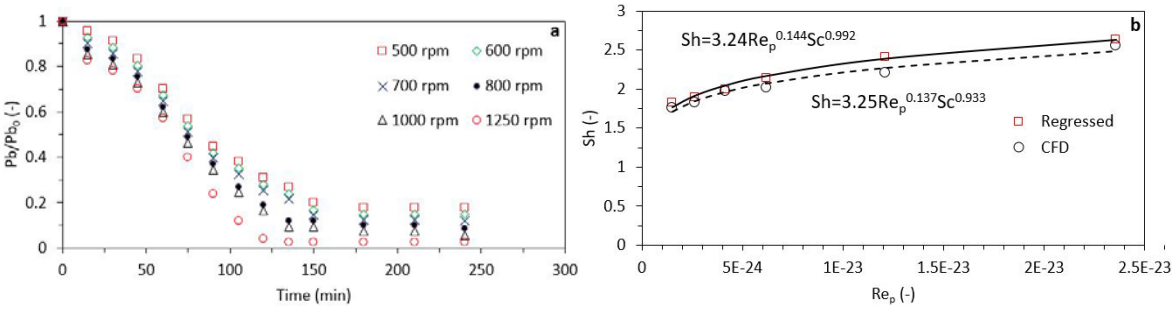

Figure 1. Pb sorption kinetics at different impeller rotational velocities (a) and Sh correlation obtained from CFD predicted and regressed k_L values..

4. Conclusions

The k_L obtained from CFD simulations were close to that obtained from data regression, as well as the empirical coefficients of Sh correlation with Re and Sc numbers. The nanohematite particles were able to sorb a considerable amount of Pb cations in alkaline environment and the process may be intensified by an accurate selection of impeller rotational velocity and reactor geometry.

Highlights

- Using MTMS in the synthesis of mesoporous silica produced a novel material (MS-Asym)
- Increasing the silica to template relative molar ratio gave a hierarchical morphology
- All members of the MS-Asym sfamily possess a similar porous structure with the same pore size

1. Introduction

Porous materials and specially mesoporous silica particles are commonly used in a number of different applications such as petroleum refining, detergents, medicinal applications and separations [1]. MSP are very promising as they are cheap to synthesize and their surface properties can be tuned to suit specific functionalities [2]. The effect of employing the asymmetric methyltrimethoxysilane (MTMS) as the only silica source on the synthesis of mesoporous silica particles has been scrutinised for the first time in our previous work [3]. The resultant synthesis was a novel MSP, which we named MS-Asym. In the current study, we have focused on analyzing the MS-Asym particle's morphology, characteristic sizes and crystallinity, when increasing the silica to template relative molar ratio.

2. Methods

The novel mesoporous silica, MS-Asym, was synthesised using a triblock copolymer, Pluronic P123 ($EO_{20}PO_{70}EO_{20}$) in a highly acidic media, and trimethoxy(methyl)silane (MTMS, Sigma-Aldrich) as a new silica source via a sol gel method [3, 4].

To study the morphology transformation of the samples seven different experiments were conducted. The pH and the amount of Pluronic were kept constant in all the tests. The amount of MTMS was increased to reach the desired MTMS/Pluronic P123 molar ratio from 59 to 590. The produced samples were labelled MS-Asym-1 to MS-Asym-10 according to the relative molar ratio of silica/template. As a result, the silica source concentration increased from 0.3 mol/L to 2.24 mol/L, and the concentration of the template decreased from 0.53×10^{-2} mol/L to 0.38×10^{-2} mol/L.

The products were characterised using SEM to study the external morphology, TEM to investigate the internal structure and ATR-FTIR spectroscopy to confirm the conformation of the bonds. A Malvern Mastersizer was also employed to measure the particle size by laser diffraction.

3. Results and discussion

In the first three samples (MS-Asym-1, MS-Asym-2 and MS-Asym-3), the solid products were not discrete and they formed a structure with the characteristics of continuous solids [3]. However, according to the SEM results shown in Figure 1, MS-Asym-2 and MS-Asym-3 included many tiny spherical particles that were packed together. MS-Asym-4, MS-Asym-6, MS-Asym-8 and MS-Asym-10 were quite similar in shape, and consisted of spherical and rod-like individual particles, completely different from the first three samples.

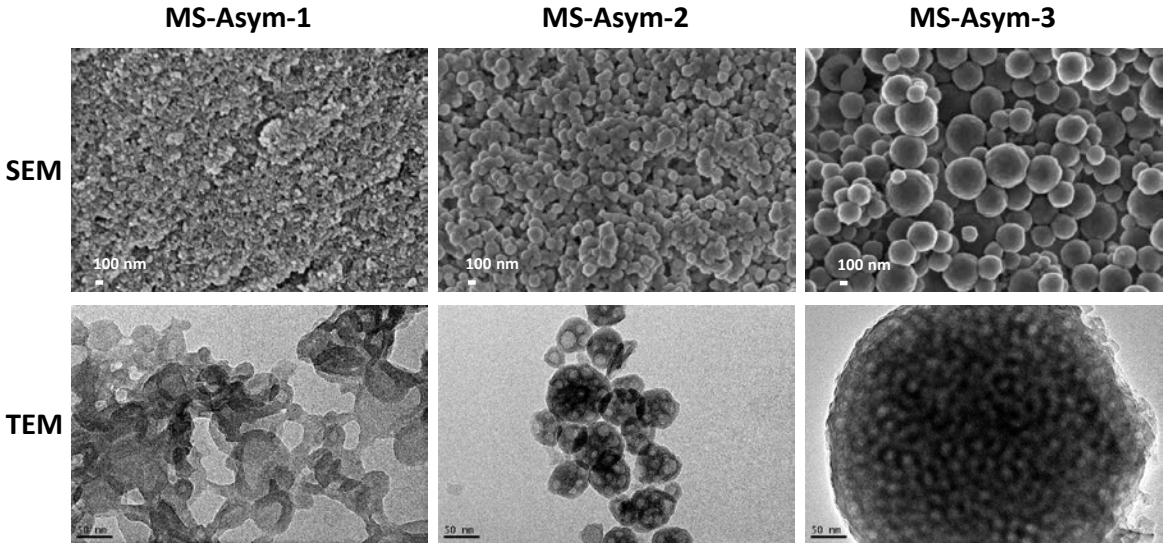

Figure 1 SEM and TEM results of MS-Asym-1, MS-Asym-2 and MS-Asym-3

From the size measurements of these samples demonstrated in Figure 2, it could be suggested that the outer diameter of the particles was mostly controlled by varying the concentration of the silica source. The higher the concentration of MTMS, the larger the characteristic sizes of the produced particles were, which is in accordance with what Neville et al. (2016) observed in the synthesis of nonporous PEI-MTMS particles [5].

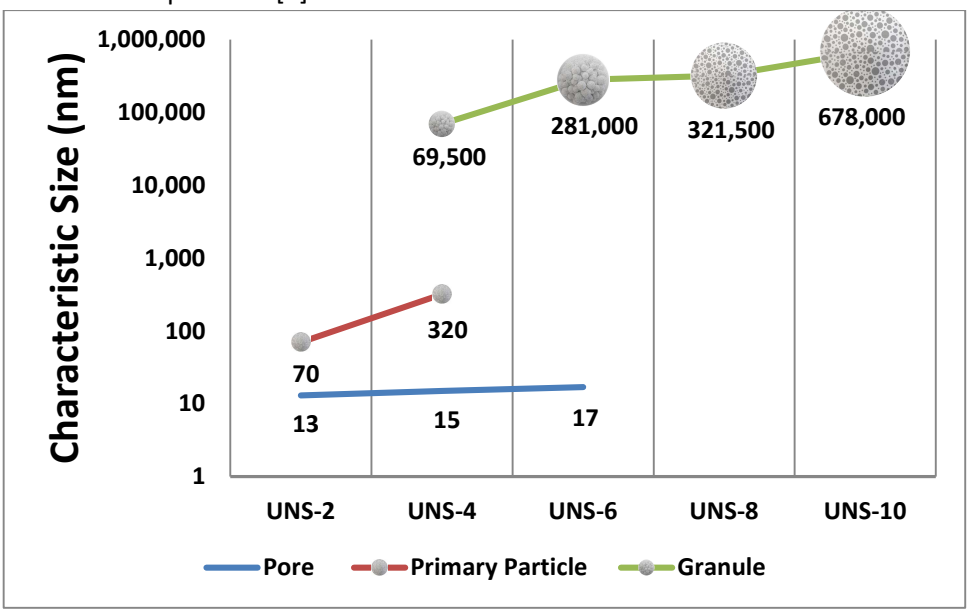

Figure 2 Comparison of the characteristic sizes of the samples

On the other hand, the pore size of all these samples obtained from their TEM images, proposes that all the porous samples from MS-Asym-2 to MS-Asym-6 have a similar pore size range. This similarity could be attributed to their similar process conditions such as pH and temperature as well as the employment of the same template in their fabrication. By further increasing the amount of MTMS and decreasing the concentration of Pluronic, MS-Asym-8 and MS-Asym-10 were produced, which were much less porous than the previous members of the family. MS-Asym-6, MS-Asym-8 and MS-Asym-10 also presented crystallinity, which did not appear in the other samples.

4. Conclusions

Altering the amount of MTMS resulted in a combined change in both MTMS and Pluronic concentration. By considering SEM and TEM results of the samples, a distinct pattern was identified as described in the results section. This study also found that the combined effect of MTMS and P123 concentrations played a crucial role in controlling the particle morphology of MS-Asym mesoporous material. With the increase in the MTMS concentration and decrease in the P123 concentration, the morphology of the spherical-like MS-Asym particles changed from aggregated nanoparticles to micrometre size granules.

The new developed porous silica family offers the possibility to be processed in a shorter time, which is beneficial in commercial applications since it undergoes a faster reaction and makes the project more feasible. It is also large and inert and its density covers a range which is lower than that of water density in MS-Asym-6. These characteristics could open up new horizons to enquire into different novel applications.

Highlights

- 99.8% of cobalt recovery from batteries leachate by precipitation
- Impact of temperature on cobalt precipitation kinetic
- Impact of temperature on particle size distribution
- Optimum precipitation conditions for cobalt recovery

1. Introduction

Fifty metals are considered strategic for industry and essential for global economic and geopolitical issues [1]. It is certain that, due to the communication development, information technologies, and electrical vehicles, demand for strategic metals will become more and more important counting cobalt. Indeed, this metal is present in all the technologies that are becoming essential for the energy and the digital transition. According to the European Commission, cobalt has been recognized as a critical raw material [2]. That is why, it is more important than ever to develop cobalt recovery processes for the coming years. Our current research work focuses on cobalt recovery from Li-ion batteries, by precipitation. After a bibliographical and simulation study, the precipitating agent chosen was the hydroxide ion. Simulation's result allows to determine cobalt precipitation conditions for a recovery of 99.8%. Experimentally, several operating parameters were varied on a solution containing only cobalt (II), results show the high impact of temperature on cobalt hydroxide precipitation kinetic and on particles size distribution.

2. Methods

To perform cobalt (II) precipitation with hydroxide ion: $Co^{2+} + 2\ OH^- = Co(OH)_{2\ (s)}$, the following reactants were used:

- Sodium hydroxide solution: NaOH (1 $mol.L^{-1}$, VWR Chemicals),
- Cobalt (II) sulfate heptahydrate solution: $CoSO_4,7H_2O$ (0.131 $mol.L^{-1}$, Fisher).

The experimental set-up is composed of:

- a double-jacketed reactor of one liter, a thermostatic bath (Julabo F32-EH),
- pH meter (Mettler Toledo)
- Büchner filtration system with 0.45 or 0.22 µm porosity,
- Laser diffraction particle size analyzer (Hydro MS 2000 Malvern)

Experiments were performed at different temperatures: 25°C, 56°C and 60°C. To precipitate 0.0131 mol of Co^{2+}, 0.0262 mol of OH^- are needed, which corresponds to a volume of 26.2 mL of soda (1 $mol.L^{-1}$). The thermostatic bath regulates the experimental media at the desired temperature. After that, all soda volume is rapidly introduced into the cobalt solution. Every 10 minutes, during 3 hours, pH is measured and a sample of the solution is taken for ICP analyses. These analyses allow to determine the cobalt concentration as a function of time and thereby cobalt hydroxide precipitation kinetic. Concerning particle size analyses, samples are analyzed in the same day.

3. Results and discussion

3.1 Temperature impact on particle size distribution

Particles size distributions show that the particle size decreased when the temperature increased. It is due to the larger Gibbs free energy; this energy is highly dependent on solution temperature. The increasing temperature (>50°C) lead to a more important supersaturation and thus to a large number of small particles [3]. Consequently, the median diameter is around 25 µm at 25 °C, d_{50}= 14 µm at 56 °C, and d_{50}= 12 µm at 60°C. According to different research studies [3], the kinetic energy of particles gets higher with increasing temperature, which allow to obtain a better precipitation efficiency [3].

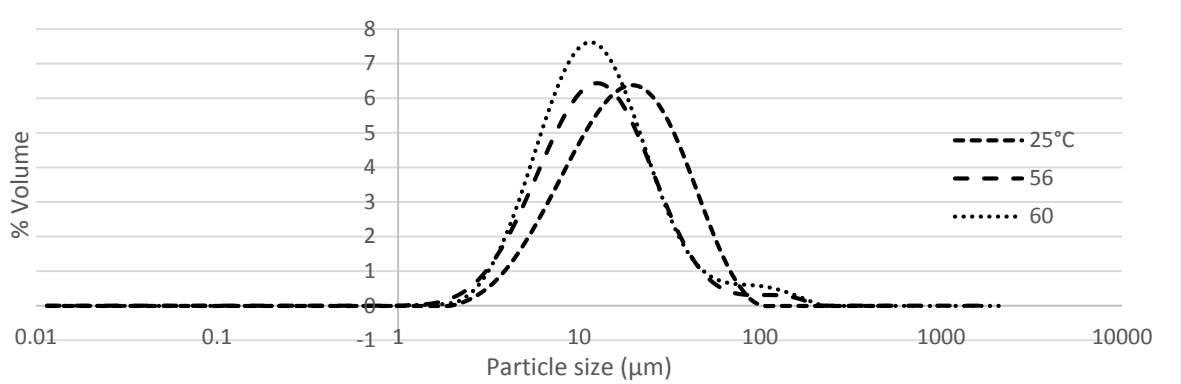

Figure 1. Particle size distribution in function of temperature.

3.2 Temperature impact on cobalt precipitation kinetic:

Temperature impact on Cobalt recovery were investigated at 25°C and 50°C (Figure 2). It appears that, at 25°C, the highest yield of cobalt recovery is obtained. Indeed, at t=28 minutes, 99. 98% of cobalt is in $Co(OH)_2$ form. In comparison, at 50°C, at t= 8 minutes, 99. 73% of cobalt has precipitated. Also, it can be seen a little dercrease of cobalt yield (0.8%) during time. It can be explained by $Co(OH)_2$ oxidation into $Co(OH)_3$ by oxygen from the air.

First of all, at 25°C, under a very high supersaturation effect, cobalt precipitates as $Co(OH)_2$ and reaches in a few minutes more than 99.9% precipitation. Its stabilization is between 16 and 30 minutes. This nearly stabilization amounts to the dissolution of α-$Co(OH)_2$ polymorph and its precipitation in its most stable form β-$Co(OH)_2$. Indeed, Cobalt hydroxides are known to crystallize in two polymorphic forms α and β. The pink colored ß-$Co(OH)_2$ is the most stable polymorph, with a brucite-like structure [4]. This crystallographic form doesn't have intercalated species, unlike the

alpha form. Indeed, the blue-green α-$Co(OH)_2$ is hydrotalcite-like structure, this ionic lamellar structure contains inorganic anions (e.g., NO_3^-, CO_3^{2-}, Cl^-…) and water molecules comprised in $Co(OH)_{2-x}$ monolayers charged positively. Experimentally, α-$Co(OH)_2$ appears first, then dissolves, to allow β-$Co(OH)_2$ precipitation. When this transformation process begins, a concentration plateau that lies between the solubilities of the two forms appears. Which can be explained by the growth of the thermodynamically stable phase β-$Co(OH)_2$, compensated by the less stable phase α-$Co(OH)_2$ dissolution. In addition, it is observed that this plateau is absent at 50°C, which means that α-$Co(OH)_2$ appears and disappears very quickly. Its transformation into β-$Co(OH)_2$ occurs in less than 8 minutes. Thus, temperature accelerates the process of phase transformation.

On the other hand, at 25°C, from 36 minutes onwards, cobalt concentration decreases slowly. This is explained by the gradual transformation of $Co(OH)_2$ into $Co(OH)_3$. In comparison to 50°C, where oxidation occurs more quickly, from 8 minutes and more significantly. Thus, temperature accelerates phases transition from α-$Co(OH)_2$ to β-$Co(OH)_2$. However, this transition occurs without improving cobalt recovery in solution, especially since the oxidation reaction is accelerated at high temperatures. Therefore, it will be more interesting to work at room temperature, in order to obtain a precipitation rate higher than 99.9% within a few minutes. After that, filter immediately afterwards in order to maintain the same precipitation rate.

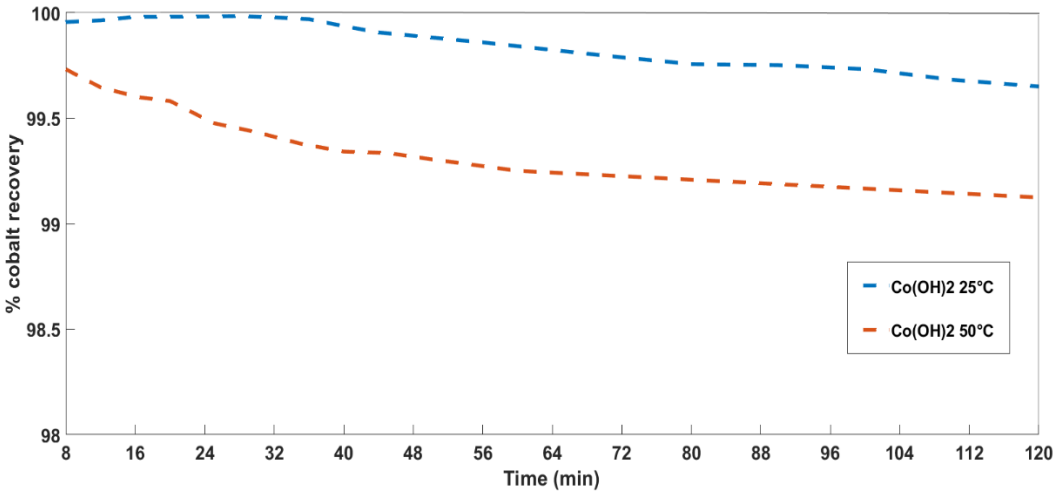

Figure 2: Cobalt recovery in function of time at 25°C and 50°C

Conclusions

This study allows to highlight temperature impact on cobalt hydroxide precipitation kinetic in one hand and to determine optimum precipitation condition in other hand. It was found that temperature increase accelerates phase transition of α-$Co(OH)_2$ into β-$Co(OH)_2$ and the oxidation reaction of $Co(OH)_2$ to $Co(OH)_3$. It has been demonstrated that cobalt recovery is optimal at 25°C with a yield of 99.98%. Therefore, it will be necessary to study synthetic solutions of battery

leachate, containing other metals, such as copper, nickel and manganese and to optimize the operating conditions for cobalt recovery, with high efficiency and good purity.

Highlights

- Goethite particles are stabilized using Zr(IV) salts.
- The suspensions were further processed and a fine and coarse fractions of particles were separated.
- Size analysis was carried out by combining sedimentation- and gas-phase analysis.
- The results match the size distribution obtained from image analysis.

1. Introduction

Goethite (α-FeOOH) is a technologically relevant material, widely used as adsorbent in waste water treatment, as precursor for magnetic drives and as a yellow pigment.[1,2,3] Goethite typically comprise particles with acicular shape, often entangled in macroscopic agglomerates with limited dispersibility and only short time stabilization against agglomeration. The colloidal stability of suspensions is an important pre-requisite to ensure that the properties of the individual particles are extended to their ensembles in liquid phase. To achieve colloidal stability of goethite particles we consider for the first time the use of aqueous solution of Zr(IV) salts as stabilizers and we carry out a comparison with the already known $AlCl_3 \cdot 6H_2O$.

2. Methods

Sedimentation analysis by Analytical Centrifugation (AC) and Ultracentrifugation (AUC) supported by ξ-potential measurements, time resolved UV-Vis spectroscopy and FTIR spectroscopy is used thoroughly to ascertain the stability of the suspensions.

[2] E. R. Encina, M. Distaso, R. N. Klupp Taylor, W. Peukert "Synthesis of Goethite alpha-FeOOH Particles by Air Oxidation of Ferrous Hydroxide Fe(OH)2 Suspensions: Insight on the Formation Mechanism" *Cryst. Growth Des.* **2015**, *15*, 194.
[3] A. Güldenpfennig, M. Distaso, R. N. Klupp Taylor, W. Peukert "Modelling the two-dimensional growth and oriented attachment of goethite nanorods synthesized via oxidation of aqueous ferrous hydroxide slurries" *Chem. Eng. J.* **2018**, *347*, 798.

3. Results and discussion

The colloidal stabilization enabled the separation between the fine and coarse fractions that constitute the particles ensemble. The fine fraction showed a ξ-potential > 50 mV and was found to be stable for more than 70 h at 25 °C. In a previous study, some of us demonstrated that the combination of two analytical techniques, namely AUC and scanning mobility particle size analysis (SMPS), enables an accurate characterization of the length and width of gold and ZnO nanorods.[4] This approach was applied to stabilized goethite particles suspensions, whereby a bi-dimensional size analysis was carried out showing excellent agreement with the results obtained by Scanning Electron Microscopy (SEM) analysis.

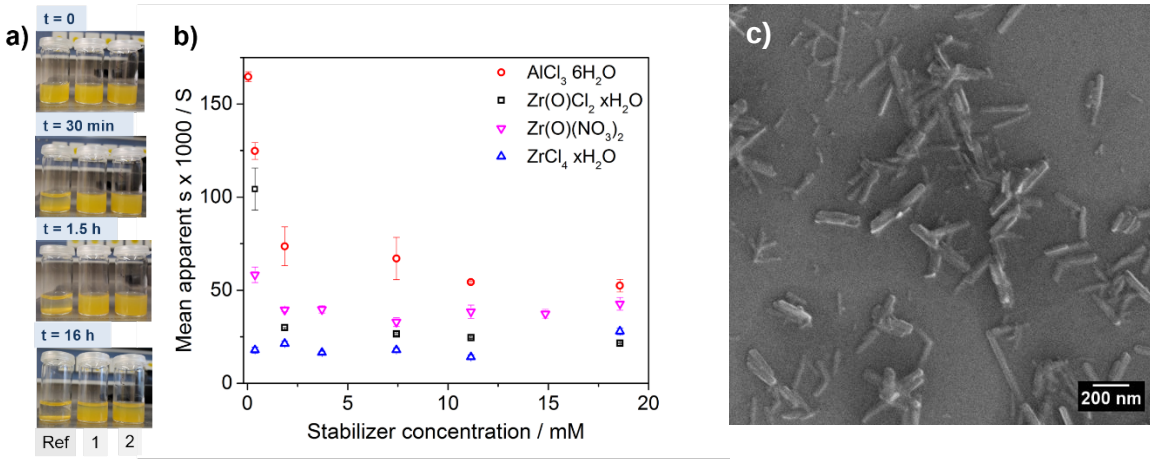

Figure 1. a) Digital micrographs of goethite suspensions in water and Zr stabilized suspensions with Zr(IV) concentration 3.71 mM (1) and 15 mM (2) at different time intervals; b) comparison between $AlCl_3 \cdot 6H_2O$ and Zr salts with different counter ions. [α-FeOOH] = 3.71 mM in all cases. Rods with mean width and length of (25 ± 8) nm and (135 ± 55) nm, respectively, were analyzed; c) SEM analysis of stabilized goethite particles.

4. Conclusions

Excellent colloidal stability of goethite particles with acicular shape was achieved using Zr(IV) salts as stabilizers. The suspensions could be further processed and a bi-dimensional size analysis was carried out by AUC and SMPS to assess the size distribution of the sample, without counting the particles from SEM images.

Phase inversion temperature of polymeric surfactant-based emulsions for the formation of nanoemulsions

Martin Meulders, André Barrizzelli Murino, Véronique Sadtler, Cécile Nouvel*

LRGP Laboratoire Réactions et Génie des Procédés, UMR CNRS-Université de Lorraine 7274, Nancy F-54000, France

** cecile.nouvel@univ-lorraine.fr*

Highlights

- Nanoemulsions were obtained with polymeric surfactants through PIT process
- Cycling the process decreases the droplets sizes and narrows the size distribution
- PIT process heavily depends on the copolymer architecture to achieve nanoemulsions

1. Introduction

Nanoemulsions are remarkable for their high specific area and kinetic stability among others. They have many pharmaceutical or cosmetic applications for their high performances in drug delivery [1] and are often required as an intermediate for the formulation of nanocapsules [2]. Nevertheless, their making requires high mechanical energy input through traditional emulsification methods also called “high energy methods” [3]. Therefore, low-energy methods such as Phase Inversion Temperature (PIT) can be cost-effective alternatives for the production of nanoemulsions [4]. The principle of the PIT relies on the ability of a temperature-sensitive surfactant to shift its overall affinity from the aqueous phase of the emulsion [5] to the hydrophobic one with increasing temperature. Examples of PIT are reported with small commercially available surfactants but almost never for polymeric surfactants [6]. In this work, we have studied the PIT process on a dodecane/water system using various polystyrene-b-poly(oligo(ethylene glycol) methyl ether methacrylate) (PS-b-POEGMA) as surfactants. The influence of different process parameters was investigated to evaluate the potential of such surfactants to produce nanoemulsions.

2. Methods

A two-step synthetic pathway using the Atom Transfer Radical Polymerisation was adapted from the literature [6, 7] to synthesize PS-b-POEGMA copolymers with various molecular weights and POEGMA/PS weight ratios. The copolymers were solubilized at 8 wt% in aqueous solution, which was mixed with dodecane (80 v/v% water and 20 v/v% dodecane) and then used in the PIT process, monitored both by viscosimetry and conductimetry. Emulsification was carried out under a constant temperature rise at 0.5°C/min and under gentle stirring in a rheometer with a helical ribbon, equipped with conductivity and temperature probes (figure 1 a) as set up before in our laboratory [8]. Once the emulsion was inversed, highlighted by a dramatic conductimetry drop and viscosity increase, the system was rapidly cooled with an ice bath and the droplet size distribution was measured by laser granulometry. The procedure was cycled several times.

3. Results and discussion

The synthesis of the PS-b-POEGMA surfactants allowed us to design the molecular weight of each block, resulting in copolymers with various POEGMA/PS weight ratios (from 10 to 17) and total molecular weights ranging from 17 500 to 34 000 g/mol with a reasonable dispersity. The influence of the surfactant concentration, the number of cycles and the surfactant design on the PIT process was studied and compared to small surfactants (Brij30 and various Igepals). The conductivity dropped to zero because of the transition from a conductive oil-in-water emulsion to a water-in-oil emulsion (figure 1 b). Simultaneously, the viscosity increased rapidly due to the switchover from an aqueous continuous phase which was 80% of the emulsion volume to a more viscous oily continuous phase that only represented 20% of the system's volume. The local maximums for conductivity and viscosity can be attributed to a transitional bicontinuous phase. Submicron emulsion could be produced with the polymeric surfactant through the PIT process. Cycling the procedure significantly facilitated the phase inversion resulting in lower droplet sizes (down to 150 nm). The shortest copolymers were the most efficient to achieve nanoemulsions (smaller droplet sizes and fewer PIT cycles) which was attributed to their faster diffusion at the water-oil interface.

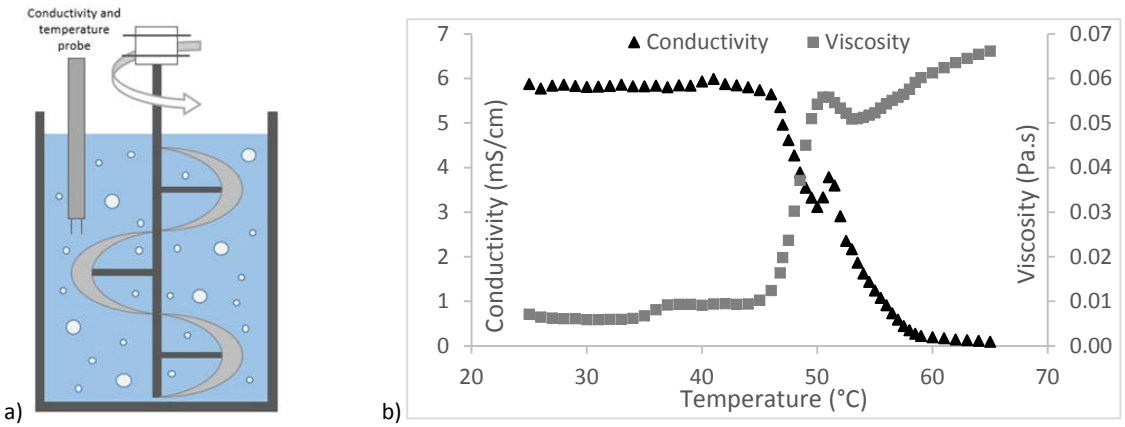

Figure 1. Conductivity and viscosity monitoring of the PIT a) Experimental setup b) Example of results with dodecane/water system using one PS-b-POEGMA surfactant (Mw = 17 500 g/mol, D=1.4).

4. Conclusions

This work has paved the way to the use of polymeric surfactants to produce nanoemulsions through the PIT process. The design of the copolymer (molecular weight, hydrophilic/hydrophobic ratio) has shown to be a crucial parameter to control the performances of the PIT process.

Design And Development of an Innovative Aerosol Generation Setup for Simulating the Inhalation Exposure to Ambient $PM_{2.5}$.

Sina Taghvaee[1], Amirhosein Mousavi[1], Mohammad H. Sowlat[1], Constantinos Sioutas*[,1]

[1]*University of Southern California, Department of Civil and Environmental Engineering, Los Angeles, California, USA*

**Corresponding author: sioutas@usc.edu*

Highlights

- A new method was developed to generate aerosols that are representative of ambient PM.
- Re-aerosolizing the aqueous extracted filters recovered water soluble portions of PM.
- The VACES/aerosol-into liquid collector tandem was able to recover all components of PM.

1. Introduction

Several detrimental health impacts are documented as a result of exposure to ambient particulate matters (PM). While toxicological studies are in need of real-world ambient PM for inhalation exposure assessments, the commercially available aerosols are not good representatives of ambient PM, due to its complex chemical composition. Furthermore, the ambient PM concentrations are not at levels causing acute adverse health consequences. Therefore, the main purpose of this study was to develop an innovative method for generating physically and chemically stable aerosols that are well representative of ambient particulate matters (PM) and can further be used for health exposure studies.

2. Methods

In this research, the ambient PM samples were collected on filters (20 × 25 cm, 3.0 µm pore size, PALL Life Sciences, USA) by the means of a high-volume sampler; followed by aqueous extraction of filters in ultrapure Milli-Q water. In addition to these aqueous extracted slurries, the versatile aerosol concentration enrichment system (VACES)/aerosol-into-liquid tandem technology was employed to capture ambient particles directly into the Milli-Q water. Subsequently, we re-aerosolized the aqueous PM solutions from both methods using commercially available HOPE nebulizers (Model 11310, B&B Medical Technologies, USA). Afterward, the size distribution of nebulized aerosols were investigated under various compressed air pressures of the nebulizer, and dilution air flow rate, using a scanning mobility particle sizer (SMPS 3936, TSI Inc., USA) in conjunction with a condensation particle counter (CPC 3022A, TSI Inc., USA). In addition, the re-aerosolized PM were collected on filters for further chemical analysis. In this regard, the collected PM samples (both ambient and re-aerosolized) were analyzed for their chemical compositions including elemental and organic carbon (EC/OC), water soluble organic carbon (WSOC), polycyclic aromatic hydrocarbons (PAHs), metals and trace elements, and inorganic ions.

3. Results and discussion

Our finding revealed that the water soluble constituents of ambient PM (e.g., water-soluble organic matter, and water-soluble inorganic ions) can be recovered effectively by re-aerosolizing the aqueous extracted filters. However, this protocol was deficient in reconstructing EC, PAHs, and some of the redox-active metals and trace elements as important insoluble components of ambient PM. On the other hand, employing the VACES/aerosol-into-liquid tandem technology for collecting ambient PM directly into ultrapure water enabled us to effectively recover all components (i.e., water soluble, and water insoluble) of ambient PM. For instance as presented in Figure 1, there were great agreement between chemical compositions of ambient $PM_{2.5}$ (collected on VACES) versus re-aerosolized $PM_{2.5}$ (from the direct capturing of PM into the ultrapure water by the means of VACES/aerosol-into-liquid tandem technology).

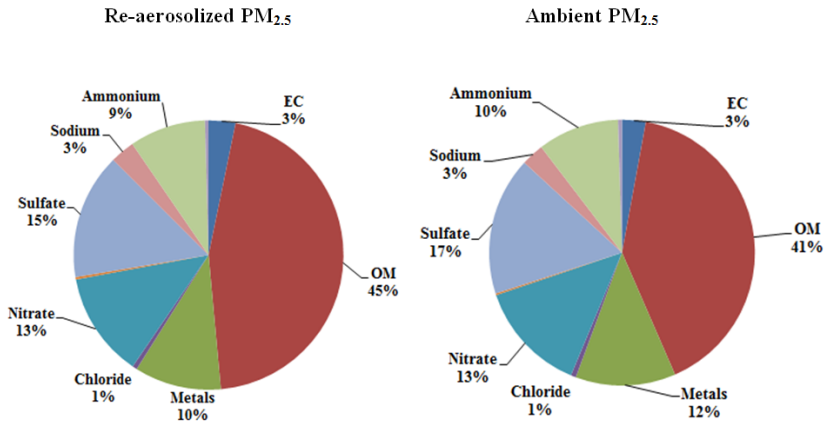

Figure 1. Chemical composition of re-aerosolized versus ambient $PM_{2.5}$

4. Conclusions

Our finding corroborate the superiority of implementing VACES/aerosol-into liquid tandem technology for producing PM solutions; followed by re-aerosolization procedure to generate stable aerosols that are fully representative of ambient PM in terms of physical and chemical compositions. Therefore, this protocol can be implemented to simulate the inhalation exposure to real world ambient PM. .

** grzegorz.tyl.dokt@pw.edu.pl*

Highlights

- A novel closure method for the nonlinear moment-transformed Population Balance Equations has been proposed and applied.
- Gram-Charlier type A densities allow to access the full distribution during simulation.
- The introduced method has been employed to solve PBE for Ostwald ripening problems.

1. Introduction

Population balance equations (PBE) are widely used to predict evolution of the particulate systems. To decrease computation time and incorporate PBE into CFD software one can use methods of moments and represent distributions with averaged values. When, however, nonlinear terms are present in PBE, a closure procedure is required. This is often done by using quadrature methods, which precisely approximate polynomial terms. In other cases an error of approximation can be significant. There is also no simple way to calculate pointwise values.

In this work a new method of closure, based on Gram-Charlier type A expansion [1] with GNT transformation [2], is presented. It allows to robustly retrieve a full distribution in each time step of the simulation and close the nonlinear terms of PBE.

2. Gram-Charlier densities

One of the approaches to retrieve a full probability density function (PDF) from its statistical parameters is an expansion of the searched PDF about another PDF with common mean and variance. A type A Gram–Charlier expansion is made about normal distribution density:

$$f(x) = \phi\left(x, \mu, \sigma\right)\left(1 + \sum_{s=1}^{N} a_S H_S\left(\frac{x-\mu}{\sigma}\right)\right) \tag{1}$$

where $\phi\left(x, \mu, \sigma\right)$ stands for the normal probability density function with a mean value μ and standard deviation σ, a_S are the moment dependent parameters and $H_s\left(x\right)$ are Hermite polynomials of order s. The series in Eq. (1) have to be truncated depending on the number of moments available and required precision. To obtain $f(x)$, being a positive function that integrates to unity, a squared transformation and scaling are applied ([2], [3]). The function given below can be used to execute further integration in nonlinear terms of PB:

$$f(x) = \frac{\phi\left(x, \mu, \sigma\right)}{w}\left(1 + \sum_{s=1}^{N} a_S H_S\left(\frac{x-\mu}{\sigma}\right)\right)^2 \tag{2}$$

$$w = \int_{-\infty}^{\infty} \left(1 + \sum_{s=1}^{N} a_s H_s\left(\frac{x-\mu}{\sigma}\right)\right)^2 \phi\left(x,\mu,\sigma\right) dx = 1 + \sum_{s=1}^{N} a_s^2 s! \tag{3}$$

3. Application to population balance

As a test case for the introduced closure method a simulation of the Ostwald ripening (OR) process has been chosen. Modeling with PBE of the size dependent dissolution, requires calculation of the pointwise values of the PDF. The moment-transformed PBE for OR reads:

$$\frac{dm_k}{dt} = k \int_{x_{\min}}^{\infty} x^{k-1} G\left(x\right) f\left(x\right) dx + x_{\min}^k G\left(x_{\min}\right) f\left(x_{\min}\right) \tag{4}$$

where m_k denotes k-th moment of the PDF, $G(x)$ is a size dependent growth rate such that particles smaller than x_{min} disappear and larger grow ([4], [5]):

$$G\left(x\right) = \frac{\alpha}{x}\left(\frac{1}{x^*} - \frac{1}{x}\right) \tag{5}$$

where x denotes the particle size, $x^* = x_{min}$ and α is proportional to the diffusion coefficient.

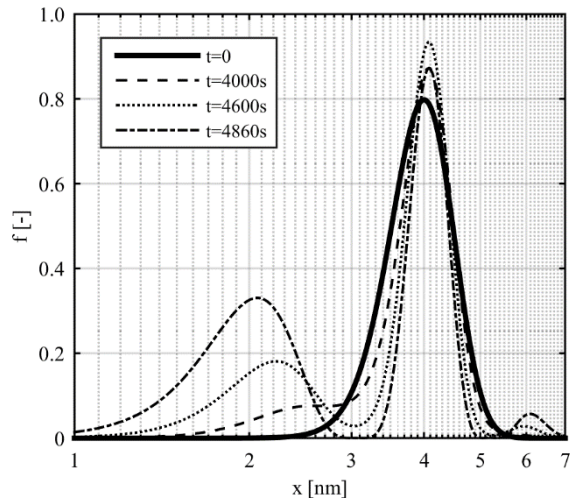

Figure 1. Time evolution of the particle size distribution ($n_0=10^{23}$, $\mu_0=4nm$, $\sigma_0=0.5nm$, $x_{min}=0.5nm$, $\alpha=10^{-30}$, $x^*=4nm$)

4. Discussion and conclusions

A time evolution of the normalized particle size distribution is presented in Figure 1. As one can see dissolution of particles smaller than 4nm results in creation of transient multimodal distributions. Results of simulations agree, at least qualitatively, with experimenal data.
A closure method is robust and can be used ragardless of the type of system simulated, including non-polynomial source terms and application of pointwise values of PDF if necessary.

The authors gratefully acknowledge the financial support from Solvay, France.

Microwave processing of hydrocolloid membranes made with agro-industrial orange waste

Helbert Antonio Portugal Ochoa [1, *], Luis Felipe Miranda Zanardi [1]

1 San Agustin National University, Arequipa, Peru

**Corresponding author: helbertportugal@gmail.com*

Highlights

- Microwaves.
- Orange waste.
- Hydrocolloid membranes.

1. Introduction

The application of microwaves in the processing of different materials has a great potential because the dipolar polarization mechanism associated with it speeds up the heating and also different chemical reactions [1]. On the other hand, the agro-industrial residues of orange have in their composition mainly pectin, cellulose, hemicellulose and lignin [2], which can be used instead of being treated as waste.

2. Methods

Different solutions containing glycerin, pectin and orange waste, according to a mixture design, were homogenized and subjected to microwave radiation (2.45 GHz) for 2 minutes. After the radiation treatment, semi-rigid membranes were obtained, which were evaluated by tensile test (ASTM D638-14). In addition, the molecular structure of both the solutions and the resulting membranes were evaluated using FTIR infrared spectroscopy.

3. Results and discussion

Through infrared spectroscopy, important changes were observed in the hydroxyl group band after exposure to radiation. The presence of glycerin in high concentrations favored the formation of intermolecular hydrogen bonds, which was evidenced in low energy OH bands. On the other hand, the presence of high concentrations of pectin or lignocellulosic residues meant high energy bands, which implied that few intermolecular forces were generated due to the presence of branches in the polymer chains, mainly in the residues. In the mechanical evaluation, the tensile strength and the nominal strain at break were obtained as responses. The strength was greater in the presence of pectin and lower when the proportions of citrus or glycerin residues increased, this because the glycerin tends to increase the intermolecular spaces and weakens the polymer-polymer forces. The strain was more dependent on the presence of residues than glycerin. The higher the residue concentration, the lower the deformation. These results are explained by the weak interaction between glycerin and polymer chains with branches.

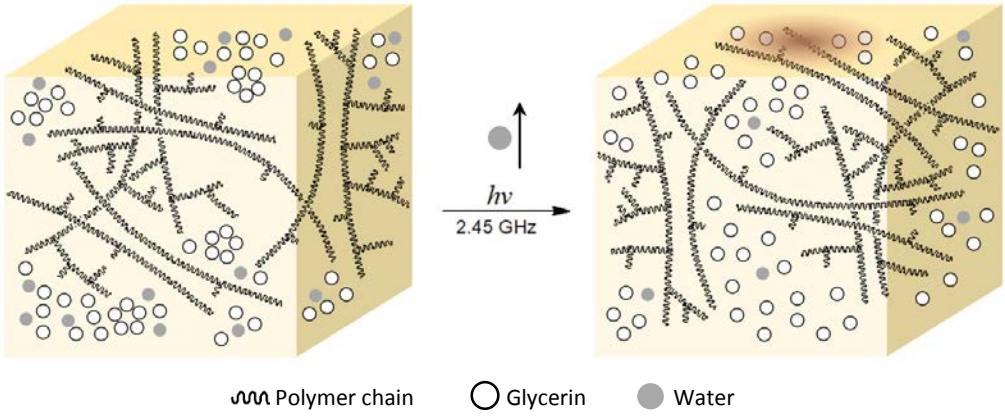

Figure 1. Effect of microwave radiation in mixtures of glycerin and orange waste.

4. Conclusions

Microwave processing of solutions containing pectin, glycerin and orange waste generates hydrocolloid membranes with acceptable mechanical properties because the radiation improves intermolecular forces.

Novel bio-based polybenzoxazine/epoxy materials for self-healing and/or shape memory applications

Aleš Ručigaj, Rok Ambrožič, Matjaž Krajnc

University of Ljubljana, Faculty of Chemistry and Chemical Technology, Večna pot 113, 1000 Ljubljana, Slovenia

Highlights

- Bio-based polybenzoxazine/epoxy (co)polymers were targeted designed.
- The DSC study showed several overlapping curing mechanisms.
- The prepared advanced materials showed self-healing and/or shape-memory potential.

1. Introduction

The growing demand for advanced materials synthesis along with the negative impact of classic petrol-based products on the environment forced both academic and industrial researchers to find new development pathways towards bio-based materials production. Preparation of polybenzoxazines, which are a newly developed class of thermosetting material with excellent thermal and mechanical properties, may be considered as a promising way to unlock different renewable resources, such as natural phenols and amines, and enable preparation of novel smart materials. In this context, unique benzoxazine monomers with designed properties of the final material, such as self-healing and/or shape memory ability, were synthesized from naturally occurring chemicals. To enhanced chain mobility, which should have a beneficial effect on self-healing and shape memory properties, bio-based epoxy resins were introduced and thermally copolymerized with benzoxazine monomers to form a final copolymeric network.

2. Methods

Chemical structure and thermal behavior of newly synthesized benzoxazine monomers were characterized by ^{1}H and ^{13}C NMR technique and DSC analysis, respectively. Once benzoxazine-epoxy (co)polymeric networks were formed by thermally induced ring-opening polymerization, mechanical properties of resulting material were investigated by DMA measurements. Final smart material shape memory and/or self-healing behaviors were quality and quantity studied by visual examinations and by performing DMA cycles and tensile stress tests, respectively.

3. Results and discussion

Initially, novel benzoxazine monomers were synthesized from bio-based phenols (resorcinol, diphenolic acid and cardanol) and amines (octadecylamine and series of polyether diamines), according to the standard procedure. Once benzoxazine monomers were fully characterized, thermal cross-linking and/or (co)polymerization with commercially available bio-based epoxy resin (resorcinol diglycidyl ether) took place. Recently published studies show excellent epoxy-

benzoxazine compatibility through ether linking copolymerization and formation of 3-dimensional structure. The DSC study of the cross-linking process indicates various curing mechanisms, such as thermally stimulated benzoxazine ring-opening, benzoxazine homopolymerization, benzoxazine catalysed epoxy ring-opening and epoxy-benzoxazine copolymerization, might occur. Moreover, by introducing epoxy resin into the polybenzoxazine network, higher chain flexibility, favourable for self-healing and shape memory ability, was formed. Therefore, all tested materials possessed thermally assisted shape memory (Figure 1), at least to a certain extent. In addition, final material properties can be target designed by suitable selection of raw materials. For instance, chemicals rich with aliphatic chains (from cardanol, octadecylamine and polyether diamines) resulted in higher chain flexibility, while chemicals rich with aromatic rings (from resorcinol, diphenolic acid) gave more rigid structure.

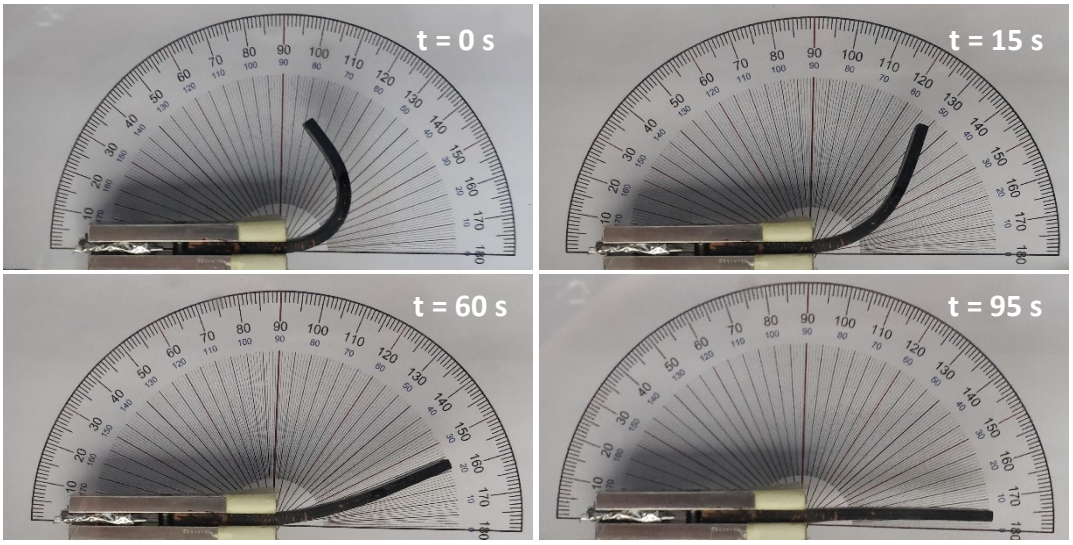

Figure 1. Thermally assisted shape memory effect of benzoxazine/epoxy copolymer based on resorcinol and octadecylamine.

Furthermore, self-healing ability of polybenzoxazines was accomplished by incorporation of additional site groups (COOH) capable of an extra intermolecular and intramolecular hydrogen bonding formation, which enables connection and reconnection between several bonding sections, leading to self-healing effect.

4. Conclusions

Bio-based polybenzoxazine/epoxy (co)polymers, as promising building blocks for advanced materials, were targeted designed, depending on selected starting chemicals. Such an approach represents significant applicative potential, since materials with shape memory, self-healing or even both effects (SMASH) can be optionally prepared.

Incorporation of paper sludge in clay mixtures used for fired-clay bricks manufacturing: understanding the bleaching phenomena issue observed on industrial products

Noémie Courtois[1,2], Isabelle Pochard[2], Jean-Yves Hihn[2], Laurent Tourneret[1]

1 Wienerberger, Laboratoire Central R&D, 25770 Franois, France; 2 Institut UTINAM, UMR6213CNRS, 25000 Besançon, France

Highlights

- Brick manufacturing recycles paper mill sludge produced by waste water treatment.
- Drying and thermal insulation brick properties are improved by PS incorporation.
- PS can be degraded over time by bacterial decomposition process.
- Degradation produce intermediate compounds responsible for bleaching of products.

1. Introduction

Paper manufacturing produces large amounts of sludge residue, which is the final product of their waste water treatment process. Incorporation in clay brick formulation is one of the recycling alternatives for these wastes. Using paper sludge (PS) in bricks manufacturing [1] has two major advantages: due to the hydrophilic effect of vegetal fibers present in sludge, the drying is optimized and porosity is created by the fibers combustion during firing process. However, the organic matter present in PS, particularly cellulosic fibers, can be degraded over time by bacterial decomposition. This can lead to problematic phenomena on brick products like surface bleaching.

2. Methods

Paper sludges used in brick manufacturing are produced by several paper mills, which leads to various properties and compositions. In order to investigate which PS parameters are responsible for surface bleaching, four PS with different compositions, namely PS-1 to PS-4, were studied. The PS composition, principally fiber and calcium hydroxide contents, were determined by loss-on-ignition measured at 400°C and 1050°C respectively. Then, five mixtures were studied: a pure clay mixture used as reference (MR-0) and four mixtures obtained by incorporating the four different PS (MR-PS1 to MR-PS4) in the clay mixture in 88:12 mass clay:paper proportions. The drying property was characterized by the diffusivity coefficient of the ceramic samples, representing the drying speed of the products. This coefficient was determined by measuring the mass and dimensions of the samples in wet state, during drying and in dried state. Porosity of the fired products was evaluated by determining the rate of water absorption by the samples after water immersion for 2h under vacuum at 500mmHg. The surface of the samples (with bleaching problematic or not) were analyzed by IR-ATR spectroscopy between 2000cm^{-1} and 400 cm^{-1}.

3. Results and discussion

PS-2 has the highest fiber content and the lowest calcium hydroxide content, while PS-3 and PS-4 have the lowest fiber content and high calcium hydroxide content. PS-1 is intermediate (Fig 1). The analysis of the clay/PS mixtures shows that MR-PS2 and MR-PS4 have a particularly low diffusivity coefficient ($1.8.10^{-9}$ against 2.10^{-9} m²/s). The porosity is significantly greater when PS is incorporated in clay phases (increase of 4 to 7% between reference mixture and MR-PS mixtures). MR-PS1 presents the greater porosity while the three other MR-PS blends have a similar porosity at 21-22%.

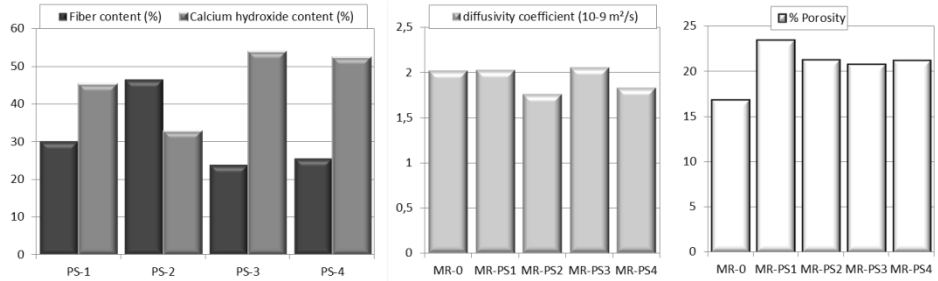

Figure 1. Compositions of the four paper sludges analyzed and properties of the five clay/PS mixtures.

A bleaching is observed on the MR-PS-2 and MR-PS-4 surfaces after drying (not shown). The FT-IR-ATR spectroscopy analysis reveals peaks at 1440 and 1560 cm^{-1} and a small one at 1300cm^{-1} (Fig 2). These vibration modes are absent on the other samples and thus, are characteristic of the compounds responsible for the bleaching.

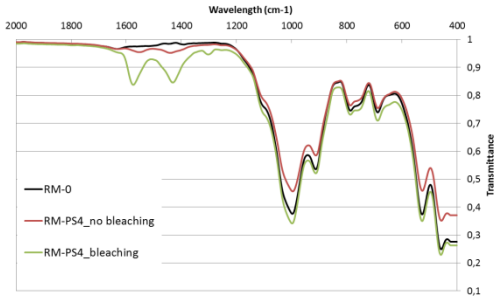

Figure 2. IR-ATR analyses of MR-0 and MR-PS4 with or without bleaching.

These characteristic peaks can be assigned to symmetric C-O stretching vibration, antisymmetric C-O stretching vibrations and symmetric methyl bending vibration of acetate anion respectively [2]. This means that bleaching at brick surfaces is due to the presence of organic compounds with carboxylate anion, like acetate salt. These organic compounds are formed during the bacterial anaerobic degradation of the cellulosic content of the PS [3].

4. Conclusions

The incorporation of PS in fired-clay brick formulation has several benefits. It also can lead to problematic phenomena like surface bleaching. This phenomenon is due to the presence of organic molecules in PS produced by cellulose degradation.

Highlights

- Nanometric hydroxyapatite (n-HAp) was used to stabilize Pickering emulsions.
- Stable Pickering emulsions (PE) were successfully prepared in batch mode.
- NETmix technology allows the production of PE in continuous mode.

1. Introduction

Mixtures of two immiscible liquids – emulsions – are commonly used, and play an important role in several product's formulations. Examples include food, pharmaceuticals and personal care products [1]. Traditionally, their stabilization is achieved by one, or more, chemical emulsifiers, but it's can have limited use due thermodynamic instabilities, and due health problems because start to be associated with allergic reactions and carcinogenicity [1,2].

Pickering emulsions (PE) arise as an alternative to traditional emulsions and are receiving significant attention at industrial and academic level. In fact, the solid particles are able to be positioned in the oil-water interface forming a thicker barrier, acting as an emulsion stabilizers [3]. The "surfactant-free" character made PE more suitable for various applications, particularly in food area [1,3].

Hydroxyapatite (HAp) has been described as a suitable Pickering stabilizer, it tends to stabilize O/W emulsions due to its hydrophilicity [4,5]. Nowadays, previous works are focused in the production of PE using bath processes [1,2]. Aiming at achieving a more feasible industrial process, in this work, the NETmix technology is used for the first time to produce PE in continuous mode with high reproducibility. The NETmix was developed at the Associate Laboratory LSRE-LCM, it consists in a network of static mixing chambers interconnected by transport channels (Figure 1 A and B) [6].

2. Materials and Methods

To produce green PE**,** sunflower oil and water containing dispersed n-HAp were used as oil and aqueous phases, respectively. Two process were performed: *i*) batch mode (Figure 1 C): the mixing system was comprised by a high-speed homogenizing device Miccra D-9, a thermostatic bath and a peristaltic pump, the sunflower oil was injected into n-HAp aqueous phase; and *ii*) continuous mode (Figure B): in this process, both phases are feed into NETmix in a pre-mixed mode, with the total flow rate adjusted according to the desired Reynolds number (Re).

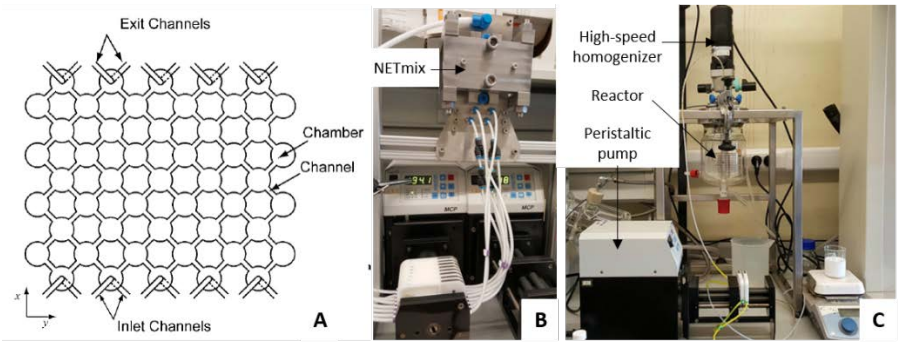

Figure 1. NETmix schematic representation (A). Experimental setup: NETmix (B) and batch (C).

3. Results and discussion

The PE were produced considering the relevant parameters affecting their stability, namely solids content and oil-water ratio. For both, batch and continuous (NETmix), a stable emulsion was achieved with 20-80 as the oil-water ratio and 5 %wt. of n-Hap. In batch mode, the average diameter of the oil droplets ranged between 10-25 µm (Figure 2 A). By cryo-SEM analysis was observed PE droplets with n-HAp layer around oil core (Figure 2 B), the EDS analysis (data not shown) confirmed the presence of these materials. This PE was stable for more than 8 weeks.

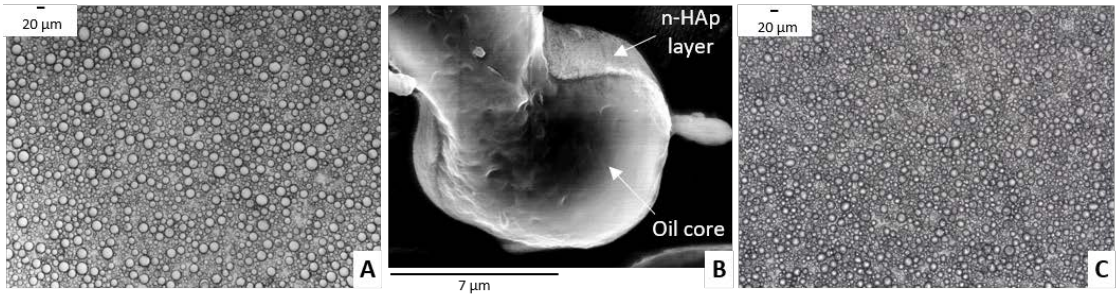

Figure 2. PE images: (A)- optical and (B) – cryo-SEM obtained by batch mode, and (C) – optical obtained using NETmix.

Regarding the production in continuous mode, preliminary results indicate that it is feasible to use the NETmix technology to produce PE. The achieved results are quite promising for Re ~500, the formed PE have average diameters of 5-7 µm (Figure 2 C) being smaller than obtained in batch mode.

4. Conclusions

Stable PE were produced using n-HAp as stabilizers with size distributions ranged between 10 to 25 µm (batch mode) and 5 to 7 µm (continuous mode). Moreover, the NETmix reactor can enable the production of these emulsions at pilot/industrial scale.

Highlights

- Characterization of biogenic particles.
- Wetting properties of coccoliths.
- Size estimations of oblate particles.

1. Introduction

The marine alga *Emiliania huxleyi*, one of the many species of the Coccolithophorida family was cultivated in this study with the intention to produce coccolith particles [1]. Coccolithophores are an extend group of calcifying unicellular algae found in the photic zone of oceans, best known for their ability to produce micron-sized calcareous platelets called coccoliths. Assumed to be responsible for half the existing global amount of calcium carbonate [2] their role in stabilizing the carbonate cycle is considered important as are also the data that have been retrieved from fossil particles for past climate conditions. Depending upon environmental availability, the algae are known to embed various elements in the particles' structure resulting to slight different chemical compositions which enables reconstruction of past temperatures [3]. Coccoliths are composed of radially oriented calcite crystals and organic matter and are the focus of this study. As they are biologically produced it is impossible to reconstruct them synthetically and remain therefore a unique structure of calcium carbonate. The particles are here characterized and efforts are being made to cover a literature gap surrounding their properties.

2. Methods

After recovering intact coccoliths from fresh cultivations the material was characterized chemically (ICP-OES), while particular attention was placed on its surface chemistry (Zeta Potential, FTIR). The above results aided a better understanding of the material's wetting behavior, estimated with the liquid penetration method and the Owens Wendt Rabel Kaelble (OWRK) model [4]. The surface free energy of the material was compared with synthetically $CaCO_3$, chalk and comminuted oyster shells, three broadly used calcium carbonate sources. Further the particular form of coccoliths, resembling that of an oblate disc, helped compare commonly used particle size estimation techniques and evaluate their applicability for non-spherical particle systems.

3. Results and discussion

The surface free energy (SFE) of coccoliths was found to be similar to that of the comminuted oyster shells, with values of 27.6 and 26.03 $mN \cdot m^{-1}$ respectively. The highest SFE was noted for the synthetically produced $CaCO_3$ at 34.7 $mN \cdot m^{-1}$ while chalk showed the lowest value at 16.4 $mN \cdot m^{-1}$. Based on the OWRK model, coccoliths showed the highest polar part of their SFE. In contrast to that the synthetically produced $CaCO_3$ showed the lowest polar part. These findings are particular valuable in all processes where the material comes into contact with a fluid.

In the second part of this study the influence of oblate shaped particles on size measuring techniques was reviewed. By comparing results obtained from an analytical (LUMsizer) and a differential (DCS) centrifuge and a laser diffraction spectrometer (LDS) with microscopic image size evaluations (LM), it was found that LDS results at better representing the true size of the particles.

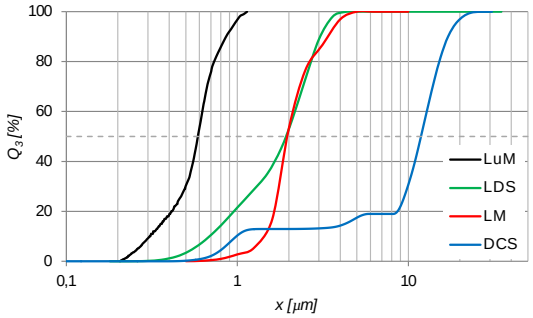

Figure 1. Particle size distribution (Q_3) measured by different techniques for coccoliths.

Figure 1 shows four cumulative distributions measured for coccoliths. The particles are depicted finer with the analytical centrifuge ($x_{50,LUM}$ = 0.79 µm; LumiSizer). The median of the LDS (Helos KR; Sympatec) and LM (Axiotech 100 HD camera; Zeiss) methods was estimated at 1.92 µm and 1.9 µm respectively. As seen from the figure above, the two curves seem to deviate mostly in the finer region with LDS depicting particles finer than they probably are. Continuing with the differential centrifugal sedimentation (CPS) the media was estimated at $x_{50,CPS}$ = 11.87 µm.

4. Conclusions

Through the liquid penetration method, the surface free energy of four calcium carbonate materials could be estimated. The differences in the polar components can be attributed to the presence of organic materials, confirmed also through FTIR analysis, that can stabilize the surface by neutralizing the surface charge.

Considering the particular shape of coccoliths and observing the results presented in **Figure 1** it was concluded that laser diffraction analysis best suited the requirements of the system and represented the distribution of the particles. By comparing the four methods for different shaped particles it could be eliminated that the measuring deviations displayed a measuring inaccuracy.

Removal of pharmaceuticals with supported ionic liquids

Márcia C. Neves*, Maria Santos, Beatriz Rocha, Guilherme Lobo-Sousa, Sandra C. Bernardo, Luciana Rocha, Hugo Almeida, Mara Freire

Department of Chemistry and CICECO-Aveiro Institute of Materials, University of Aveiro, 3810-193 Aveiro, Portugal

Highlights

- Supported Ionic Liquids are efficient adsorbents for pharmaceuticals.
- Sodium diclofenac, ketoprofen, naproxen and acetylsalicylic acid undergo different adsorption processes onto SILs.
- Different ionic structures as counter ions in SILs lead to different adsorption processes.

1. Introduction

The presence of organic pollutants has been shown to have potentially adverse effects on man and the environment. Mainly due to their large worldwide consumption, active pharmaceutical ingredients (APIs) were already found in a wide variety of environmental aqueous samples, in concentrations ranging from ng/L to µg/L. This is due to the inability of current technologies used in sewage treatment plant (STPs) and wastewater treatment plants (WWTPs) to remove such compounds, thus leading to serious environmental and public health concerns after long-term exposures. Therefore, the treatment of water contaminated with these compounds is extremely important.

Ionic liquids (ILs) have a great potential to remove biomolecules from aqueous solutions [1], including pharmaceuticals [2]. Despite the many advantages associated to ILs, their immobilization in materials would overcome some leaching problems. ILs can be immobilized on solid supports by the covalent bonding of the cation, resulting in functionalized materials: supported ionic liquids (SILs). Based on the high potential of SILs in separation/removal techniques and on the health and environmental concerns that we aim to overwhelm, silica based SILs will be investigated to develop an efficient approach to remove pharmaceuticals from aqueous solutions.

2. Methods

SILs were obtained as described in the literature [3]. Silica gel 60 was used as supported for SILs synthesis, namely SilPrMImCl, SilPrNEt$_3$Cl, SilPrNBu$_3$Cl SilPrN(C$_8$)$_3$Cl, SilPrNMe$_2$BuCl (Figure 1). Five additional SILs were prepared from SilPrMImCl by anion exchange with the correspondent sodium salts, namely SilPrMImSCN, SilPrMImN(CN)$_2$, SilPrMImTos, SilPrMImMale and SilPrMImNTf$_2$.

3. Results and discussion

Adsorption kinetics and adsorption isotherms were performed for sodium diclofenac, ketoprofen, naproxen and acetylsalicylic acid with the synthetized SILs. The supported ionic liquid SilPrMImCl

showed to be the most efficient material for the adsorption of sodium diclofenac, ketoprofen and naproxen, being the removal efficiency 91, 51 and 59%, respectively. For sodium diclofenac, the obtained adsorption equilibrium data are well described by the Langmuir or the Freundlich isotherm models, being dependent on the imidazolium supported materials counter ion. A maximum equilibrium concentration of sodium diclofenac in the solid phase of 240 $mg.g^{-1}$ of adsorbent was obtained with SilPrMImCl. Regarding the ketoprofen and naproxen the obtained adsorption equilibrium data are best described by the Langmuir-Freundlich (or Sips) isotherm model and a maximum equilibrium concentration for these pharmaceuticals of 88 and 41 mgg^{-1} was obtained with SilPrMImCl.

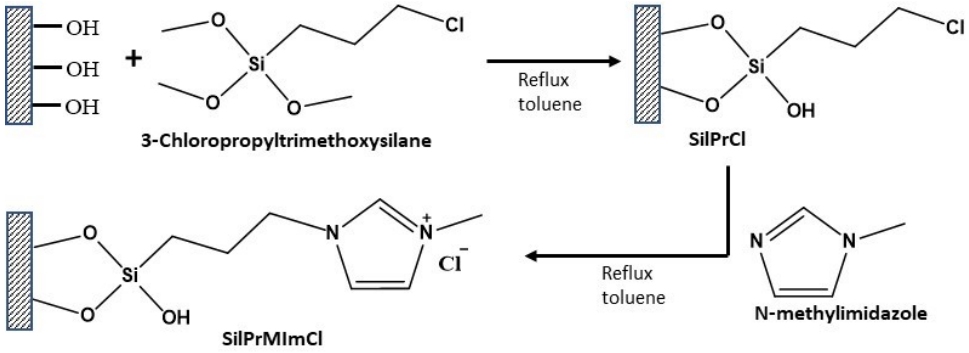

Figure 1- Synthetic route for SilPrMImCl.

In the case of acetylsalicylic acid, the equilibrium concentration of adsorbate in the solid phase decreases in the following sequence of SILs: $SilPrNMe_2BuCl$ > $SilPrNBu_3Cl$ > $SilPrN(C8)_3Cl$. The obtained adsorption equilibrium data are best described by the Langmuir model with a maximum equilibrium concentration of adsorbate in the solid phase of 220 mg of drug per gram of $SilPrNMe_2BuCl$.

4. Conclusions

The synthetized SILs are efficient adsorbents for pharmaceuticals. However, the adsorption mechanisms and maximum equilibrium concentrations depend on the SILs chemical structure and on the drug.

Investigation on the Limiting Oxygen Index of bitumen-organoclay nanocomposites

Miriam Cappello, Giovanni Polacco and Sara Filippi*

Dipartimento di Ingegneria Civile e Industriale, Università di Pisa, Largo Lucio Lazzarino 2, 56122 Pisa, Italy

**Corresponding author: sara.filippi@unipi.it*

Highlights

- Two clays were used to obtain exfoliated or intercalated bitumen nanocomposites
- A reduction of the limiting oxygen index LOI was observed on bitumen mixtures
- TGA analysis showed strong variations in the decomposition kinetic of the bitumen
- Organoclays significantly interact with the binder, modifying its colloidal structure

1. Introduction

Bitumen is a complex mixture of hydrocarbons that are quite flammable and tend to produce smoke and poisonous gases while burning. This is an important aspect in the case of fire events in highway tunnels. Organoclays are well-known fire retardants in the polymer field and have been recently introduced in bituminous binders. The effect of native and organo-modified clays on the fire resistance has been evaluated [1–4], but the chemical-physical interaction mechanism between bitumen and clay has not been investigated yet. Therefore, the main object of this study is to provide a first insight in this direction. For this reason, two organoclays with different degree of interaction with a base bitumen were used in order to obtain both exfoliated and intercalated nanocomposites. The blends were characterized by WAXD, Brookfield viscosity, LOI test and TGA analysis.

2. Methods

The two clays were Cloisite 20A and Cloisite 30B (referred as 20A and 30B) from Southern Clay Products and derive from a sodium montmorillonite by treatment with dimethyl-dihydrogenated-tallow ammonium chloride (20A), and methyl-tallow-bis-2-hydroxyethyl ammonium chloride (30B). Bitumen is a 50/70 penetration grade base bitumen, referred as B, kindly furnished by Eni. Bitumen-clay mixtures were prepared with a high shear mixer Silverson L5T at 4000 rpm, 140 °C for 30 minutes. Wide angle X-ray diffraction (WAXD) was made in reflection mode by a Siemens D500 Krystalloflex 810 apparatus, with a wavelength of 0.1542 nm at a scan rate of 2.0 °/min. Viscosity was measured at 135 °C by a Brookfield viscometer. Thermo-Gravimetric Analysis (TGA) was performed in air using a Q500 by TA Instruments. The LOI test was performed by LOI-Smoke-230, from Dynisco & Alpha Technologies, USA.

3. Results and discussion

From WAXD, after mixing with bitumen, 20A has an intercalated structure with interlayer distance of 4.3 nm and 30B has a prevailingly exfoliated structure (Fig. 1). In the case of polymer nanocomposites, clay exfoliation means high interaction between the matrix and the filler, good

interfacial adhesion, increased viscosity. Moreover, exfoliation improves the flame retardant properties of the materials because the delaminated platelets produce a labyrinth path to oxygen diffusion, thus decreasing the combustion kinetic. Surprisingly, the B/30B mixtures, which have a dominating exfoliated structure, did not show a significant viscosity increasing (Table 1). On the contrary, B/20A mixtures, which have an intercalated structure, showed a high increase in the binder viscosity. Both clays decrease the LOI value (Table 1) and this effect is more pronounced with clay 20A. The TGA derivative weight curves as a function of temperature are reported in Figure 2 for B, B/20A-4 and B/30B-4. The TGA spectra are significantly altered with respect to base bitumen even in the presence of small clay quantities. Moreover, there seems to be a direct correlation between LOI and the weight loss path of the binders.

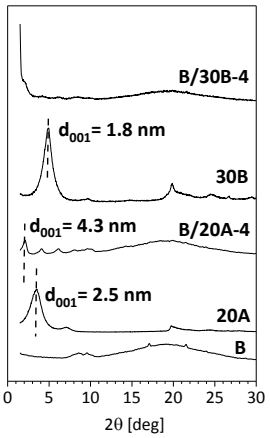

Figure 1. WAXD of B, 20A, 30B, B/20A-4 and B/30B-4.

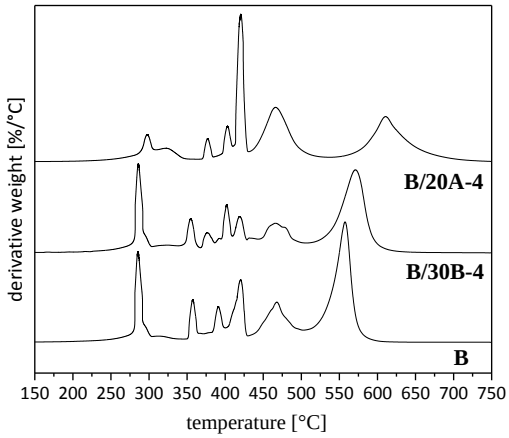

Figure 2. TGA derivative weight curves as a function of temperature for B, B/30A-4 and B/20A-4

Table 1 – LOI, viscosity and TGA data for the binary mixes.

Blend	Clay content (wt %)	LOI	Viscosity (135 °C, cP)
B	0	28	450
B/20A-2	2	26	608
B/20A-4	4	25	2304
B/20A-8	8	22	17000
B/30B-2	2	28	471
B/30B-4	4	29	542
B/30B-8	8	24	850

4. Conclusions

The organoclays significantly interact with the binder, thus modifying its colloidal structure. This effect prevails on the above-mentioned labyrinth-effect related to the presence of exfoliated or intercalated platelets in the bitumen matrix.

Highlights

- A novel zinc phospho-tellurite glass was synthesized for applications in photonic field
- Optical band gap was graphically determined based on optical absorption property
- Metallization criterion in dependency on different physical properties was evaluated
- Electronic polarizability was investigated in correlation with optical basicity

1. Introduction

The present work is focused on the investigation of optical properties, electronic polarizability, optical basicity and other physical features of a novel zinc phospho-tellurite glass, as good candidate for photonic devices. Based on the refractive index and optical band gap, molar refractivity and polarizability have been calculated that, in turn, is decisive for optical basicity [1, 2].

2. Methods

The vitreous material prepared in this work belongs to the 45ZnO $10Al_2O_3$ $40P_2O_5$ $5TeO_2$ system (code Te-5, taking into account the amount of TeO_2 in mol. %) being characterised by a chemical stable composition. The glass has been prepared by a non-conventional wet route of processing the starting reagents followed by melting-stirring and annealing of the glass [3, 4]. In order to prepare a glass having a high optical homogeneity, the melt batch was mechanically stirred aiming to reduce the gaseous inclusions and grooves embedded in the bulk samples. The density of the glass was experimentally determined by hydrostatic method [1, 2], absorption coefficients was plotted based on experimentally optical transmission spectroscopy [1, 2]. The refractive index was measured at λ_D = 589 nm (yellow doubled D line of sodium) by means of the Pulfrich refractometer. Mott and Davis relationship was applied to graphically determine the optical band gap, E_g and, subsequently, polarizability, metallization criterion and optical basicity have been calculated [1, 2]. Other physical properties, such as molar volume, oxygen packaging density, reflexion loss and optical transmission have been calculated [1, 2].

3. Results and discussion

In the Table 1, Te-5 glass properties are presented: glass density (ρ_{glass}), average molecular mass (M_{av}), molar volume (V_M), oxygen packaging density (OPD), refractive index measured at 589 nm (n_D), refractive index measured from dispersion graph (n_{DD}), molar refractivity (R_m), electronic polarizability (α_m), reflection loss (R_L), optical transmission (T) (see Fig.1, absorption coefficient). Table 2 presents: refractive index-based non-bridging oxygen atoms polarizability ($\alpha_{O_2^-}(n)$), band gap-based non-bridging oxygen atoms polarizability ($\alpha_{O_2^-}(nE_g)$), optical band gap (E_g) (Fig.2), refractive index-bazed metallization criterion (M(n)), band gap-based metallization criterion (M(E_g)), Duffy optical basicity (Λ_D), refractive index based-polarizability-based optical basicity ($\Lambda(\alpha_{O_2^-}(n))$, band gap based-polarizability-based optical basicity ($\Lambda(\alpha_{O_2^-}(E_g))$ and Pauling optical basicity (Λ_P).

Table 1. Te-5 glass properties: ρ_{glas}, V_M, OPD, M_{av}, n_D, n_{DD}, R_m, α_m, R_L, T

ρ_{glass} g/cm^3	V_M cm^3/mol	OPD O atom/l$_{glass}$	M_{av} g/mol	n_D	n_{DD}	R_m cm^3/mol	α_m cm^3/mol	R_L	T
2,936	37,95	75	111,45	1,54616	1,54	12,02	$4.75 \cdot 10^{-24}$	0,046	0,912

Table 2. Te-5 glass properties: $\alpha_{O_2^-}(n)$, $\alpha_{O_2^-}(n)$, M (n), M (E_g), Λ_D, $\Lambda(\alpha_{O_2^-}(n)$, $\Lambda(\alpha_{O_2^-}(E_g)$, Λ_P

$\alpha_{O_2^-}(n)$ cm^3/mol	$\alpha_{O_2^-}(E_g)$	M(n)	M(E_g)	Λ_D	$\Lambda(\alpha_{O_2^-}(n)$	$\Lambda(\alpha_{O_2^-}(E_g)$	Λ_P
1.59	1.59	0,6832	0,6832	0,702	0,62	0,62	0,4617

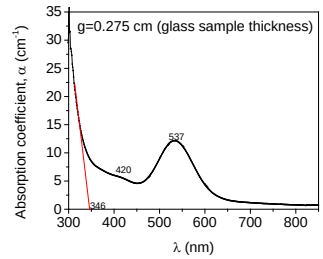

Fig.1. Optical absorption of Te-5 glass versus wavelength

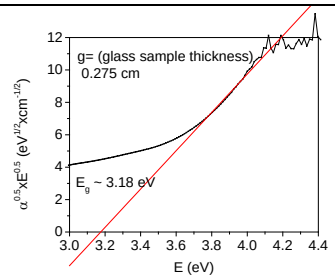

Fig. 2. Graphical determination of E_g for Te-5 glass

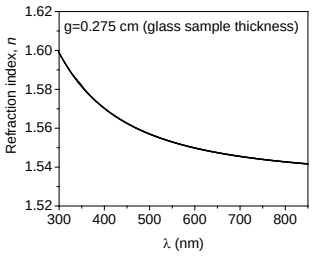

Fig.3. Refractive index dependence on wavelength for Te-5 glass

4. Conclusions

(i) Refractive index measured by Pulfrich refractometer is in a good accordance with the refractive index value determined from dispersion graph; (ii) the metallization criterion reveals an intermediate electrical conductivity vitreous material; (iii) Duffy optical basicity is relative close to refractive index-based polarizability- based optical basicity and to band gap-based polarizability-based optical basicity, respectively, but higher than Pauling optical basicity; (iv) based on optical basicity values it is worth to conclude that Te-5 oxide composition exhibits a relative high tendency to form a vitreous network structure.

Fixed-bed reactors from metal-foam pellets: experiments and CFD models

Gregor D. Wehinger[1], Ginu George[1], Stan T. Kolaczkowski[2],

Didier Beton[3], Leonhard Schmalhorst[3], and Lars Torkuhl[3]

1 Chemical and Electrochemical Process Engineering, Clausthal University of Technology; 2 Chemical Engineering, University of Bath, 3 Alantum Europe GmbH

Highlights

- Comprehensive and validated modeling approach for porous pellet fixed-beds.
- Synthetic bed generation gives realistic bed structure also for porous pellets.
- Porous resistance approach shows good results for pressure drop in full fixed beds.
- Explorative heat transfer study reveals promising characteristics of porous pellet beds.

1. Introduction

During the last two decades, a certain interest has arisen to apply open-cell solid foams as structured catalyst support. Kolaczkowski et al. compared pellets made from metal foams, see Figure 1, with monolith-foam structures in terms of pressure drop and heat transfer performance [1]. In the manufacturing process, different pellet shapes can be realized. The foam pellets showed advantages, especially due to their mixing behavior. However, a systematic investigation of the potentials and weaknesses of open-cell foam pellets applied in fixed-bed reactors is missing up to date.

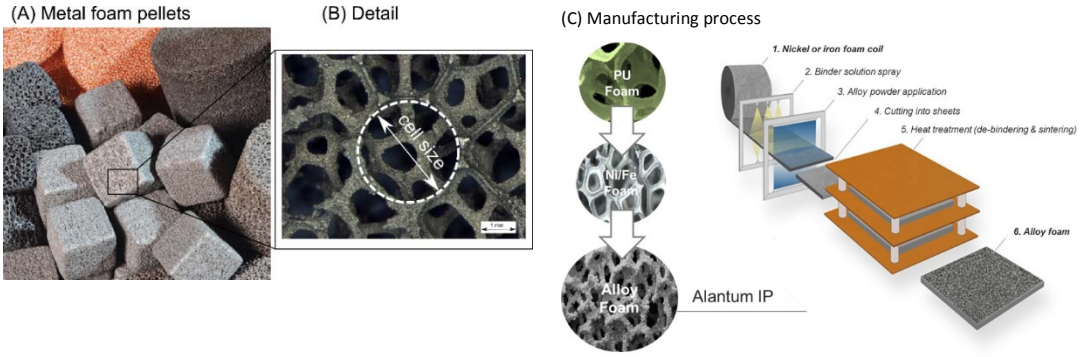

Figure 1: (A) Metal foam pellets with (B) details. (C) Manufacturing process of alloy metal foams.

2. Methods

In this contribution, the established particle-resolved CFD model [2] is transferred to fixed-bed reactors made of open-cell metal foams. The randomly oriented pellets forming the packed bed are captured geometrically. However, instead of resolving the inner structure of the foam, a pseudo-

homogeneous porous CFD-model is applied in order to describe the transport phenomena inside the porous foam pellets. Therefore, a pressure-drop [3] and an effective thermal conductivity correlation [4] are implemented into the model. The interstitial void is described with CFD and coupled with the porous pellet phase. Surface-to-surface radiation is included in the heat transfer simulations. The synthetic generation of fixed beds of foam pellets is validated against experimental x-ray computed tomography (µCT) data. This step is important, since the CFD results are highly sensitive to the underlying bed structure.

3. Results and discussion

In Figure 2, a comparison between µCT scanned structure and a synthetically generated bed is shown. There is an excellent agreement between simulation and experiments. In Figure 2 (D), the specific pressure drop over superficial velocity is illustrated for fixed-bed reactor made of porous cubes and porous cylinders. The agreement is reasonable between experimental data and the CFD simulations, which shows the accuracy of the model. The cubes show a larger pressure drop than the cylinders. Consequently, different pellet shapes are currently explored in terms of radial porosity distribution, pressure drop, and radial heat transfer characteristics.

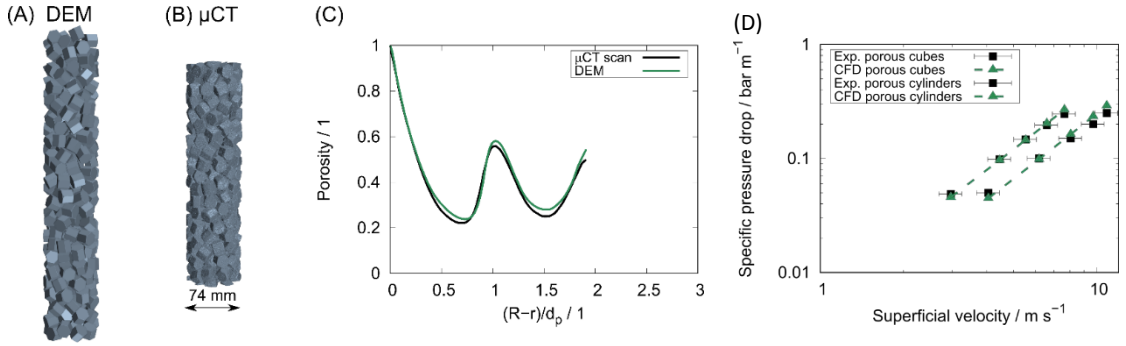

Figure 2. Bed structure in a 74 mm diameter tube with 16x15 mm hexagons. (A) DEM bed, (B) µCT scan, (C) radial porosity over normalized distance from wall. (D) Pressure drop: experiments vs. CFD for porous cubes (10 mm) and porous cylinders (15 mm).

4. Conclusions

We have shown that the synthetic bed-generation method developed in previous works can be applied also for porous pellets. This detailed CFD model was validated against µCT data of the bed structure and pressure drop over a packed bed. This numerical workflow allows the exploration of various novel pellet shapes, since it is independent of geometrical data. In the future, chemical reactions will be included to extend the model to catalytic fixed-bed reactors.

Highlights

- A new generation of improved bituminous binders for paving solutions is being developed.
- Sustainability by developing long lasting materials with outstanding performance.
- Chemical modification of the base bitumen with additives is key to the project.

1. Introduction

The world is growing at a fast pace, a fact with great impact on the use of transport infrastructures and its weathering: more vehicles, heavy transports, roads with poor maintenance, climate change, etc.

Long-lasting pavements are currently a need for the higher demands of society, for the emerging economies where sustainability is a key factor to guarantee continuous growth. During the last decade, environmental aspects such as “life cycle inventory” or “carbon footprint” have gained importance and they have become familiar concepts to both the industry and the society. Therefore, improving durability of structures has become a goal for the paving industry [1, 2, 3].

In this work two strategies towards increasing sustainability of pavements have been studied, both of them focused in the bituminous binder. First, increasing the pavement durability by tuning the composition of bitumen in order to minimize the impact of aging processes and maximize the service life of pavements. Second, incorporating additives from either natural renewable sources or waste materials from other industries with the ability of restoring the damage resulting from aging phenomena (rejuvenating) or preventing it.

2. Methods

A set of model bitumen with different chemical compositions was produced using two different industrial processes (straight run and mild oxidation process) both at pilot and industrial scale. The materials obtained were fully analyzed according the current European Standard (EN 12591) and its chemical composition was determined by Iatroscan analysis (SARA).The materials were aged using two standardized aging methods: Rolling Thin Film Oven Test (which mimics the aging experienced by the binder during preparation of the asphalt mix) and Pressure Aging Vessel (mimicking aging after 10-20 years’ service life). Dynamic shear and bending beam rheological measurements (DSR and BBR respectively) of the materials at different aging stages were used to determine the binder with best performance when aged (and therefore highest durability). Also

Iatroscan analysis was performed in order to determine the chemical structure of the aged bitumen showing the best performance.

The highest performance binder was further chemically modified with additives from renewable sources with antioxidant or rejuvenator effect in order to yield a family of novel binders with improved lifespan and a novel eco dimension. These binders were also fully characterized, aged and rheologically tested in order to characterize its performance and suitability as paving grade binders.

3. Results and discussion

In this work it has been observed that the chemical parameter colloidal instability index of bitumen (defined as the ratio between the asphaltene + saturates and aromatics+resins fractions) is related with the performance if the material in in terms of fatigue (see figure 1). Tuning the manufacturing processes and the origin of the crude oil raw material makes possible obtaining high durability binders. Once the best performance bitumen is selected, its performance during service life was further improved by incorporating vegetal rejuvenators and antioxidants.

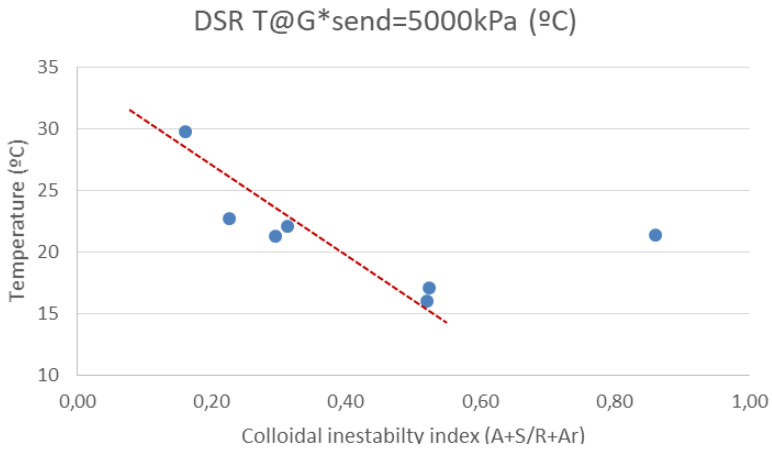

Figure 1. Dependence of fatigue resistance of bitumen on colloidal instability index

4. Conclusions

Improved durability bitumen materials have been manufactured on the basis of physical-chemical parameters. Different types of chemical additives from renewable sources have been assessed in order to improve the long term performance of the asphalt binder.

Abstract

The development of polymers in various industries has been deteriorating due to the depletion in fossil fuels and environmental concerns such as the effect of greenhouse gases, global warming and increasing population. However, vegetable oils have emerged as a worthy replacement for fossil fuels. The need to use non-edible oils is recommended for industrial processes to reduce the dependency on edible oils and hence increasing food security. This investigation uses an affordable process to develop bio-binders for composite materials using non-edible oil produced from castor seed. The oil was first extracted from the castor seeds, purified and then process to yield castor oil-based bio-binders using Epoxidation method. The Epoxidation catalyst was synthesized from of tungstic acid and hydrogen peroxide at 50 - 60 °C. The Epoxidation process temperature varied between 60 and100 °C while varying the catalyst loading and the reaction time. The epoxidized castor oil showed 70% binder yield with 1H NMR spectra showing peaks of an epoxy group at 3.0 – 3.2 ppm; and the epoxy peak was also observed using FTIR at 830 cm-1.

All in One - Advanced technologies for complex low-cost microfluidic devices in glass, silicon and quartz

Highlights

- Multi level laser etching in glass silicon and quartz [Calibri 10].
- 3-D shaped nozzles with six levels in the bottom and the top layer
- Hermetically sealed electrical connectors through the glass

1. Introduction

The controlled generation of liquid micro droplets with uniform characteristics will be one of the future key technologies in research and in industrial production. The Little Things Factory covers the whole portfolio to set up new functionalities for microfluidic systems in glass and we describe recent innovations in this field.

We will show, what are state of the art manufacturing methods to make chips out of glass or quartz with different levels and different types of structures in one setup. Figure 1 shows an example of such a multilevel structure, with grids of posts and cavities, mixing structures and additional structures for detection.

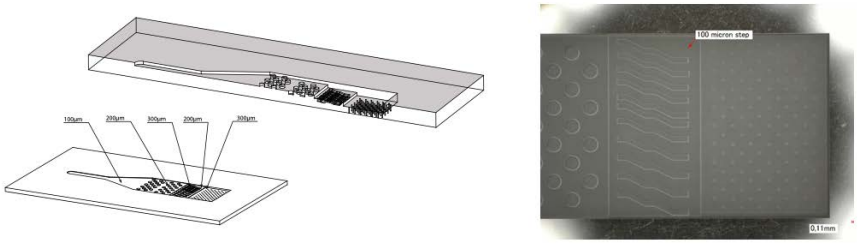

Fig. 1: Multilevel structure with five different levels and various types of structures realized in glass

2. Advanced methods of droplet generation

Figure 2 shows a prototype of the flow focusing chip (FFC). This chip was designed to modify the droplet diameter over the flow ratio and to create swarms of droplets. The FFC consists of a droplet generator combined with a reaction zone. The droplet generator of this chip consists of two 3-D laser etched nozzles, and the microchannels inside the inlet and outlet nozzles have been etched to different levels into the bottom as well as the top glass layer. In this work, six different levels have been applied to define the inlet and outlet nozzle structures in the bottom and the top glass layer.

3. Results and discussion

For a flow rate of 1,6µl/min the pressure loss in the central line was measured to 3.3bar, for the lines for the sheath flow to 2.6bar. The droplet size measured for different mixing ratios can be seen in figure 2. We will present how the droplet size can be modified by changing the flow rate in the central line or for the sheath flow and what happens when changing from Toluene to Cyclohexane.

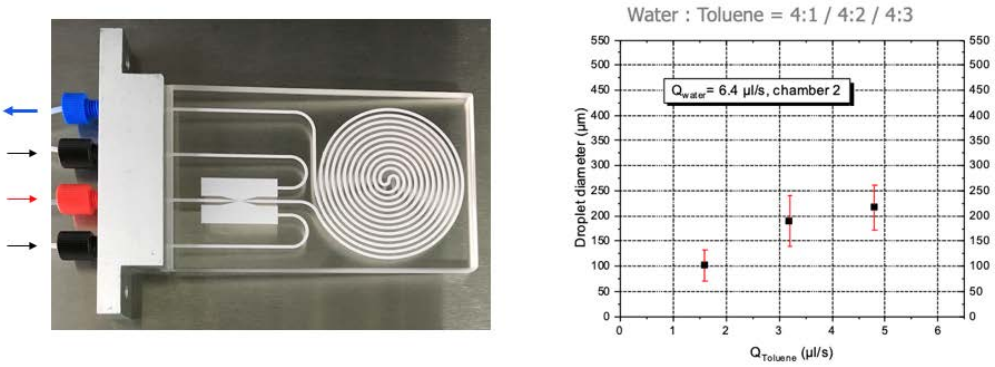

Fig. 2: Flow focusing chip with a droplet generator on the left and the reaction zone on the right. The right picture shows the measured droplet size for different mixing ratios of Toluene and Water

Through Glass Vias (TGV)

We will introduce new possibilities to combine microfluidics with hermetically sealed electrical connectors for various applications that needs electrodes in contact with fluids or electrodes isolated from fluids. The connectors are made of highly conductive silicon to have hermetically sealed feed troughs with a conductivity in the range of 0.01 to 0.02 Ωcm. Figure 3 show possible layouts (left side) and an example how to integrate such a TGV into a fluidic application. So, one can use the two orders of magnitude higher thermal conductivity of silicon compared to that to glass to have different temperatures on the chip, or one can heat or cool a fluid or run the chip on different temperature levels.

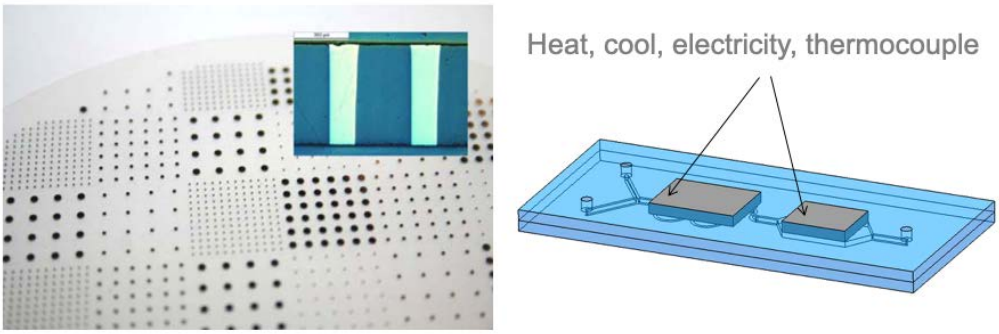

Fig. 3: TGV in glass and cross section (above) and integration in a fluid chip (below)

The conductive silicon could be in contact with the fluid, or not, just ending close to a channel or besides, so the silicon is isolated by a layer of glass to use the electric field. Possible applications may be the steering of fluids, catching cells, electrophoresis or electro kinetic actions. So, integrating a TGV in a fluidic device gives access to digital microfluidics.

Formation of $BiFeO_3$ and $LaPO_4$ nanoparticles during heat treatment of hydroxides co-precipitated in an impinging jets microreactor

O.V.Proskurina[1,2], R.S. Abiev[2,3*], M.O. Enikeeva[2], A.A. Sirotkin[2], V.V.Gusarov[1]

Highlights

- $BiFeO_3$ nanoparticles were obtained using an impinging jets microreactor.
- The synthesized $BiFeO_3$ particles about 20 nm in size are single-crystal.
- $BiFeO_3$ nanoparticles obtained without impurities of other phases.
- $LaPO_4$ nanoparticles were obtained using an impinging jets microreactor.

1. Introduction

Synthesis of nanocrystalline $BiFeO_3$ without admixtures of other compounds is a great challenge. It is hindered by the fact that reducing the number of impurity phases $Bi_{25}FeO_{39}$ and/or $Bi_2Fe_4O_9$ requires, as a rule, an increase in temperature and/or duration of heat treatment of the initial reagents, which leads to the growth of particles of the target product. In recent years, the impinging jets method has begun to attract attention as a tool for nanoscale particles synthesis [1-4]. It was shown [4] that the use of the impinging jets microreactor can significantly lower the synthesis temperature and reduce the crystallite size of the $CoFe_2O_4$ nanopowder. This fact was associated with a high rate of energy dissipation in the collision volume of impinging jets resulting in perfect mixing of reagents, which is a characteristic of this method.

The objective of this work was to study the possibility and conditions of using the method of impinging jets for co-precipitation of hydroxides to obtain single-phase powders based on nanocrystalline $BiFeO_3$ and $LaPO_4$.

2. Methods

A homemade glass microreactor with nozzles of 0.55 mm and 0.65 mm inner diameter was used. A mixture of $Bi(NO_3)_3{\cdot}5H_2O$ and $Fe(NO_3)_3{\cdot}9H_2O$ water solutions in HNO_3 was prepared as a first liquid. The second liquid was KOH water solution. Two jets of the liquids with velocities of 17.5 m/s and 12.5 m/s correspondingly were collided in the reactor. Co-precipitation products were then heat treated in air at 420°C-600°C within 15 minutes. X-ray diffraction, scanning (SEM) and transmission (TEM) electron microscopy, energy dispersive X-ray spectroscopy (EDS), Mössbauer spectroscopy and IR spectroscopy were used for characterization of co-precipitated and heat treated products.

3. Results and discussion

The Bi:Fe atomic ratio in the initial sample and in the samples after heat treatment according to EDS data remains at the same level Bi:Fe = (52 ± 2):(48 ± 2). After heat treatment at 420°C, reflections characteristic of bismuth orthoferrite appear on the diffraction pattern. The tendency described above is also maintained during heat treatment of co-precipitated hydroxides at temperatures of 440 and 600°C. Nanocrystalls of $LaPO_4$ having rhabdofan structure and sizes of 2-3 nm have been formed by use of the impinging jets microreactor (without additional heat treatment).

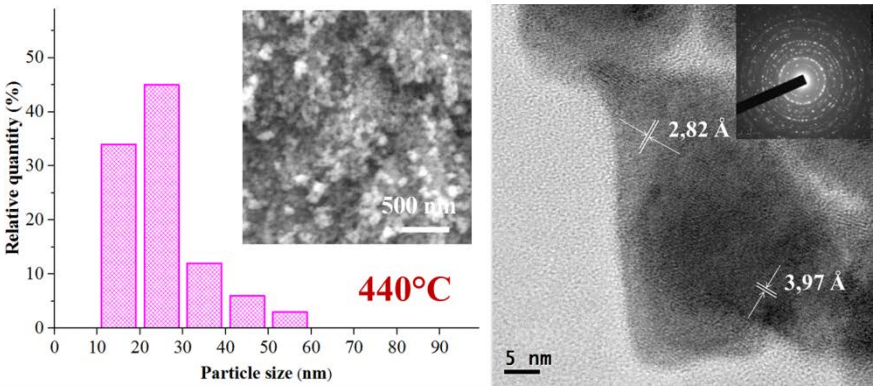

Figure 1. Left: size distribution of BiFeO3 particles obtained by heat treatment at 440°C.The inset shows SEM micrograph. Right: TEM micrograph of the particles. The inset shows selected area electron diffraction pattern

4. Conclusions

By heat treatment of hydroxides co-precipitated in an impinging jets microreactor, nanocrystalline bismuth orthoferrite was synthesized. It was shown that the formation of $BiFeO_3$ nanoparticles without admixtures of other phases with a narrow crystal size distribution and an average crystal size of about 20 nm is possible after heat treatment at 420-440°C of hydroxides co-precipitated in an impinging jets microreactor. The nanoparticles of $BiFeO_3$ obtained under these conditions were single-crystal. It was shown that the sizes of the formed bismuth orthoferrite nanocrystals were consistent with the sizes of the nanoparticles that can be formed in microvortices having a minimum Kolmogorov scale that are formed during the collision of the jets of reagent solutions in the microreactor.

Using the microreactor approach, a suspension of $LaPO_4$ nanoparticles with the structure of rhabdofan was obtained, which turned into a sol after some time, and then into a thixotropic gel. The size of $LaPO_4$ nanocrystalls in the gel according to X-ray diffraction data was 2-3 nm.

The authors acknowledge the partial financial support of this work in the form of RFBR grant 18-29-12119.

Highlights

- Crystal growth kinetics of six different API's in methanol have been studied.
- Experimental desupersaturation data is modeled using empirical and mechanistic equations.
- Solid-liquid interfacial energies and mean diffusion distances have been estimated.
- The relevance of bulk diffusion study suggests surface integration as the limiting-step.

1. Introduction

Crystallization is the bottleneck unit operation in the separation of solids in the pharmaceutical industry and it can be envisaged as a two-step process: nucleation and crystal growth. Both steps contribute to the final particle size distribution of the crystallization outcome but are insufficiently understood. The nature of the solute-solvent intra and intermolecular interactions influences both nucleation and growth. It is hence expectable that molecules with a relative ease of nucleation in a given solvent will also show a growth facility. Very often, however, nucleation experiments do not allow for separating the effects of the steps of new particles formation from those of pure growth because the nucleation outcome can only be evaluated when the solids have grown to a certain size [1]. The process of crystal growth comprises the diffusion of molecules from the bulk phase to the crystal surface and their subsequent integration into the crystals lattice. There are several mechanisms that can describe the surface integration step, e.g. the Burton Cabrera Frank (BCF) or screw dislocations mechanism, and Birth and Spread (B+S) or two-dimensional nucleation mechanism [2]. Additionally, empirical power law equations are useful because they can be applied in a wider range of supersaturations. This study focuses the growth of six different active pharmaceutical ingredients (APIs) in the same solvent aiming to shed light to some fundamental physicochemical aspects influencing the crystal growth kinetics.

2. Methods

Isothermal seeded desupersaturation experiments in methanol were carried out in the range of temperature 288-303 K and supersaturations below 1.32, for Acetaminophen (AAP), Carbamazepine (CBMZ), Piracetam (PCM), Fenofifrate (FF), Phenylbutazone (PBZ) and Risperidone

(RIS). The seed size was 100-180 µm and the stirring speed 250 rpm. The crystallizer (Easymax402, Mettler Toledo) was equipped with an *in-situ* IR probe (ReactIR15) to monitor the liquid concentration at any time and a FBRM probe (Particle track G400) to track the number of counts and their size distribution. After growth experiments, the crystals were harvested, dried and characterized by PXRD, SEM and in a particle size and shape analyzer (G3 morphology).

3. Results and discussion

The crystallographic habit of all the API studied is similar except for PBZ where a needle shape-like habit is distinguished. Experimental desupersaturation data was modeled using power law equations (Fig.1a), BCF and B+S theories. The fitting of power law equation was remarkably good and the involved parameters suggested that the growth is mainly surface integration controlled for the studied API's within the explored experimental conditions. The BCF model provided faintly better fitting than the B+S one being therefore more likely this mechanism to govern. At the same supersaturation and temperature (Fig.1b) the crystal growth rates decreased in the order PCM>FF>AAP> PBZ>RIS>CBMZ. From the B+S model, the estimated solid-liquid interfacial energies (γ_{sl}) and mean surface diffusion distances ranged 0.82-1.55 mJ/m^2 and $6.66\cdot10^{-9}$-$6.52\cdot10^{-8}$ m, respectively. γ_{sl} values are comparable to those determined by nucleation experiments [3] but do not follow the relative growth order mentioned, suggesting that there are more factors at play. Interesting and coherent correlations between growth rates, solubility, molecular volume, mass transfer coefficients and crystal lattice energies have been found, which allows for rationalizing the crystal growth kinetic behavior observed.

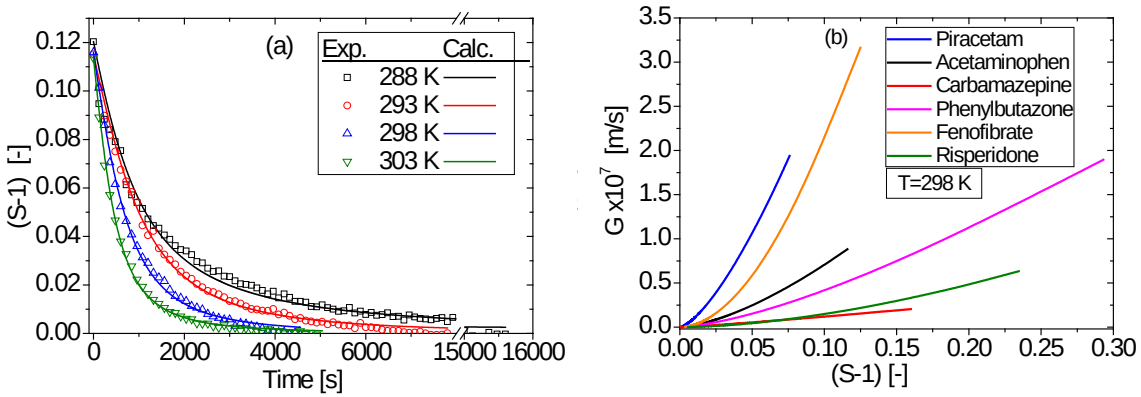

Figure 1. (a) Example of the fitting provided by power law equation for AAP experiments at different temperatures. (b) Comparison of growth rates obtained at 298 K for the different API studied.

4. Conclusions

The power law equation and the BCF model provided the best fit to the experimental desupersaturation data for the six API's studied in methanol. The crystal growth rates decreased in the order PCM>FF>AAP>PBZ>RIS>CBMZ, which can be correlated to fundamental physicochemical properties as solubility, mass transfer coefficients, molecular volume and crystal lattice energies.

Charge-based agglomeration of submicron particles with potential for selective separation in grinding processes

Christoph Peppersack[1], Arno Kwade[1] and Sandra Breitung-Faes[1]

1Institute for Particle Technology, Technical University of Braunschweig, Braunschweig, GER

**Corresponding author: c.peppersack@tu-bs.de*

Highlights

- Top-down synthesis of submicron suspension with high quality standards
- Selective agglomeration in binary particle mixtures
- Separation of wear particles from wet grinding processes

1. Introduction

Within the top-down synthesis in stirred media mills, wear (abrasion) of the mill components, primarily the grinding media, is a major challenge in terms of lowering the product quality. A direct mechanical separation of the wear particles during/after the grinding process cannot be accomplished easily, as these usually have particle sizes similar to the product components.
The (hetero)agglomeration of submicron particle suspensions, induced by electrostatic particle-particle interactions, is a known process in literature. On the contrary, a selective agglomeration of certain components from a mixture of different materials has not been studied extensively yet. In this context, the principle of electrostatically induced agglomeration of submicron particles was investigated in a first step using zirconium dioxide suspensions as an exemplary wear component, since it is one of the most frequently used grinding media material. This study compares different agglomeration mechanisms with regard to their agglomerate size, strength as well as the yield of agglomerated particles. Subsequently, selective agglomeration of zirconium dioxide particles in a binary mixture with either an organic or inorganic material was evaluated. Here, this will be briefly described in its feasibility for anthraquinone as the organic material example.

2. Methods

For the data shown here, anthraquinone (product component, ρ = 1.31 g/cm^3) and zirconium dioxide (wear component, ρ = 5,68 g/cm^3) were chosen as materials. Using a stirred media mill (PML 2, Bühler AG), these substances were first ground in water to a defined particle size ($x_{50,3}$ = 0,3 µm for anthraquinone, $x_{50,3}$ = 0,3 µm for zirconium dioxide). To induce selective agglomeration of zirconium dioxide particles, the anthrachinone suspension was first mixed with a certain amount of agglomeration additive. Subsequently, the zirconium dioxide suspension was added in order to imitate the generation of wear. The final suspension had a mass concentration of anthraquinone equal to 4 %-w/w and of zirconium dioxide equal to 0.2 %-w/w. To analyse the success of selective agglomeration, samples of the suspensions were centrifuged for 5 minutes at different RCF values. Then, a defined volume was taken from the supernatants, which was first dried at 110 °C and then burnt out in a muffle furnace at 600 °C to decompose the organic material. After each heating step, samples were gravimetrically analysed in order to obtain both the loss of anthraquinone (product) and the loss of zirconium dioxide due to centrifugation.

3. Results and discussion

Figure 1. shows the percentage losses of anthraquinone (product) and zirconium dioxide in the supernatant obtained by centrifugation due to different RCF values with and without agglomeration additive. If the curves without additive are considered first, it can be seen that the zirconium dioxide particles can only be separated by higher centrifugal forces in larger quantities. However, this is associated with an undesired product loss, since anthraquinone particles are also centrifuged with the corresponding centrifugal forces. This effect would be enhanced if the centrifugal forces were increased or the centrifugation time extended.
In comparison, the curves with agglomeration additive show that a considerably higher proportion of zirconium dioxide could be separated from the suspension at significantly lower centrifugal forces (approx. 50 %-w/w at RCF = 380). This also ensures that almost the entire product material remains in the suspension because the centrifugal forces are too low to cause sedimentation of the anthraquinone particles. For this reason, it can be assumed from the results that the addition of the agglomeration ingredient resulted in selective agglomeration of the zirconium dioxide particles. This assumption can be supported by particle size analyses and SEM/EDX images (not shown).

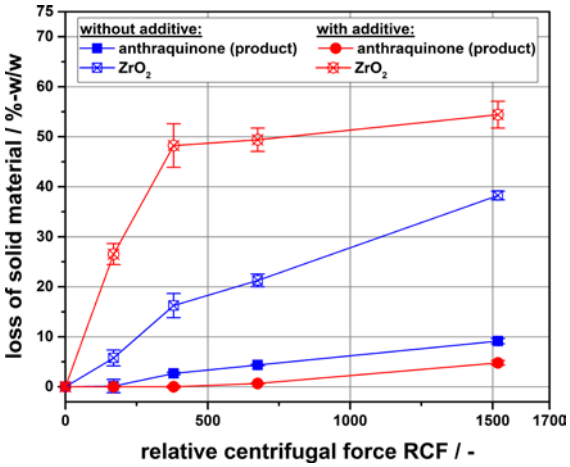

Figure 1. Gravimetrical analysis of selective agglomeration / separation

4. Conclusions

A promising method to selectively agglomerating the wear components is presented. It was shown that zirconium dioxide particles could be separated out of binary mixture with anthraquinone. Multiple variables in order to increase the yield of agglomeration are currently under investigation. The attained knowledge about an efficient, selective agglomeration can be used to remove the wear components from the product suspension in a suitable separation process. Hereby, this ensures that wear-free, submicron suspensions can be produced using a top-down process.

Scalable production of nanostructure materials via atomic layer deposition: a way to reduce the demand for scarce materials

J.Ruud van Ommen[1]

1 Delft University of Technology, Chemical Engineering dept., TU Delft Process Technology Institute, Delft, the Netherlands

**Corresponding author: j.r.vanommen@tudelft.nl*

Highlights

- Applying nanostructured materials can strongly reduce the use of scarce elements.
- Atomic layer deposition is a scalable process to make nanostructured materials.
- Several examples of the use of atomic layer deposition will be shown.

1. Introduction

Nanoscience holds the promise to deliver a plethora of solutions for several grand challenges, such as abundant sustainable energy, clean drinking water and personalized pharmaceuticals. However, many of such solutions never find practical implementation, since they require scarce materials or involve poorly scalable production processes. A marriage between chemical engineering and nanoscience – scalable nanotechnology – can tackle these problems: it is possible to make scalable processes, while strongly reducing the demand for scarce materials. In some cases, novel nanostructured materials can make the use of critical elements even superfluous. Atomic Layer Deposition (ALD) is a versatile and scalable technology for making such nanostructured materials.

2. Methods

We typically take a dry, powder-form substrate that we want to treat with ALD (nanoparticles, micron-sized particles, graphene platelets, …) [1] and load some grams of it into a glass column (typical sizes are 2.5 cm diameter, 50 cm high). The powder is fluidized in an upward nitrogen flow with a superficial gas velocity of typically about 5 cm/s. We deploy ALD by alternatingly adding the two required precursors to the nitrogen flow, e.g. trimethylaluminum and water for alumina, or trimethyl(methylcyclopentadienyl)platinum(IV) (IV) and oxygen for platina, while maintaining intermediate periods without precursor for purging. The alternating addition of the two precursors is repeated until the desired film thickness or cluster size has been reached.

3. Results and discussion

In heterogeneous catalysis, noble metal clusters on ceramic or carbon supports are widely used. Ideally speaking, all metal clusters have the same size, tailored for the targeted reaction. In practice, this is impossible to reach with the production techniques the catalyst industry currently uses, such as wet impregnation and spray-drying. Using ALD, it is much better possible to create a much narrower size distribution of noble-metal clusters [2] (see Fig. 1.a). This can be used to make either

catalysts with a much higher activity or a much lower noble metal loading. Either way leads to a strong reduction in the use of noble metals.

In thin film solar cells, currently often scarce materials such as indium and gallium are used. Here, using ALD alternative routes are possible than not just minimize the use of such scarce elements, but enable a completely different approach by using abundant elements such as copper, zinc and tin [3]. Another alternative might be to move to completely different technology, and apply quantum dot films that are stabilized using ALD overcoating for high-end PV applications [4].

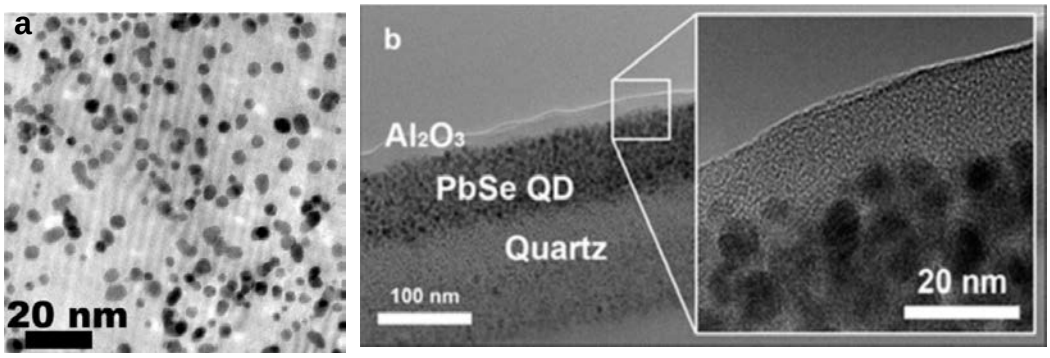

Figure 1. (a) TEM image of platinum nanoclusters deposited on graphene using ALD [2]; (b) Cross-sectional TEM image of a quantum film, in which a protecting alumina overcoating made by ALD is visible [4].

A third sector where materials scarcity plays an important role is the production of Li-ion batteries. The most pressing need for the Li-ion industry to move forward is a strong reduction of the amount of cobalt that is required [5]. Using atomic layer deposition, we can make more stable cathode materials, reducing the amount of cobalt required. However, this will need large amounts of powders to be coated. Most likely the batch-wise operation of fluidized beds is less suitable to achieve this: our continuous pneumatic transport reactor [6] will be a more attractive option for such a large-scale process.

4. Conclusions

Atomic layer deposition (ALD) can be used to provide powdered substrates with a thin film or with nanoclusters of the required materials. The high degree of control makes ALD perfectly suited to produced nanostructured materials that can be applied to strongly reduce the use of critical materials; the scalability of the method makes a smooth translation to industrial practice feasible.

Synthesis of eco-friendly amino acid biosurfactants and characterization of interfacial properties for cosmetics and household products

JongChoo Lim, SeonHui Jo, DaNan Yea

Department of Chemical and Biochemical Engineering, Dongguk University-Seoul, Korea

**JongChoo Lim: jongchoo@dongguk.edu*

Highlights

- Amino acid biosurfactants were prepared from readily biodegradable coconut oil.
- Newly synthesized biosurfactants possess superior interfacial properties.
- Synthesized biosurfactants are nontoxic, non-irritating, mild, and biodegradable.

1. Introduction

Currently, most of the surfactants widely used in various areas of industrial applications are prepared from petroleum base. These synthetic chemical surfactants have been known to be non-biodegradable, irritating, not mild and also detrimental to aquatic organisms. Strict environmental restrictions and rising recognition for the requirement to preserve the environment have leaded to growing attention in biosurfactants as a potential substitute to petroleum based surfactants. Biosurfactants have been known to possess merits over petroleum based surfactants in uniqueness, variety, selectivity, convenience of production, mildness and high efficiency even at harsh operation conditions such as high temperature and extreme high or low pH. Amino acid based biosurfactants are frequently used in detergents, household products, cosmetics, pharmaceuticals, personal care products, food ingredients, and so on due to their extremely low toxicity and excellent biodegradability [1]. In this work, 2 types of anionic amino acid based biosurfactants such as potassium cocoyl glycinate CGK and sodium cocoyl glycinate CGN were synthesized using nontoxic and readily biodegradable coconut oil derived from natural resources.

2. Methods

The structure of the resulting products was elucidated by FT-IR, ^{1}H NMR, and ^{13}C NMR spectroscopies and environmental compatibility such as biodegradability and acute oral toxicity was evaluated. The interfacial characteristics of the synthesized surfactant including surface tension, critical micelle concentration, interfacial tension, wetting property, emulsification activity, viscosity and foam property have been examined. Biodegradability, acute dermal irritation, acute eye irritation and acute oral toxicity have been measured for the newly synthesized surfactants in order to investigate environmental compatibility for cosmetics application. Detergency tests were also carried out with synthesized amino acid biosurfactants to examine the possible uses in detergent application.

3. Results and discussion

The measurement results of interfacial properties for the newly synthesized biosurfactants indicated that the prepared surfactants have excellent interfacial properties. Detergency test has been performed with newly synthesized surfactants by using an agitation/mixing type detergency tester at room temperature. The results suggested that the newly synthesized surfactants show moderately good detergency. Acute oral toxicity (LD_{50}) measurement showed that newly synthesized surfactants are very mild compared with conventional nonionic and anionic surfactants used in detergent and cosmetic formulations such as polyoxyethylene (9) lauryl ether (PLA) and dodecylbenzene sulfonic acid (LAS). The primary biodegradability of newly synthesized surfactants has been found to be greater than 95%, suggesting that newly synthesized surfactants are acceptable for cosmetic and detergent applications. Both acute dermal irritation and acute eye irritation tests revealed that surfactants are mild. In particular, the prescription test in shampoo formulation prepared with synthesized biosurfactants indicated better sensory feeling and excellent foaming ability compared with conventional surfactants used such as silicon. The patch test also indicated no irritation during 48 hours, indicating potential applicability in cosmetic and household products.

4. Conclusions

In this study, 2 types of anionic amino acid based biosurfactants such as CGK and CGN were synthesized using coconut oil and the structure identification of the CGK and CGN was carried out by FT-IR, ^{1}H NMR, and ^{13}C NMR spectroscopies. The interfacial properties of CGK and CGN surfactant systems have been evaluated such as CMC, static and dynamic surface tensions, emulsification activity, wetting property and foam property. The results suggested that both CGK and CGN surfactant systems possess superior interfacial properties. Washing test carried out with a Terg-o-tometer indicated relatively good detergency when comparing with surfactants employed in detergent formulation. Acute oral toxicity evaluation indicated that both CGK and CGN surfactants are nontoxic compared with PLA and LAS. Both acute dermal irritation and acute eye irritation tests showed that both CGK and CGN surfactants are non-irritating and very mild and the primary biodegradability of CGK and CGN evaluated using an activated sludge test KSM 2714 has been found to be 99% in both surfactants. In particular, CGK surfactant can be considered as a strong candidate for the potential applicability in detergent products formulation since CGK surfactant is very effective in lowering interfacial free energy, nontoxic, non-irritating, mild, and readily biodegradable.

Rheology and Draining Properties of Model Dry Powders in a Hopper: Effect of the Vibrations and Opening Geometry.

Arthur Pascot[1]*, Sébastien Kiesgen De Richter[1], Salaheddine Skali-Lami[1]

1 Laboratoire d'Energétique et de Mécanique Théorique et Appliquée, University of Lorraine, UMR 7563
**Corresponding author : arthur.pascot@univ-lorraine.fr*

Highlights

- Vibrations change the structure and rheology of the flow in a silo
- Vibrations prevent arches but tend to decrease the flowrate of the silo
- A law can be drawn between flow rate, geometry and vibrations parameters

This study is conducted in the framework of the "PowderReg" project, funded by the European programme Interreg VA GR within the priority axis 4 "Strengthen the competitiveness and the attractiveness of the Grande Région / Großregion".

1. Introduction

Granular materials are encountered in many fields, be it in Nature (sand castles, lava flows, avalanches…) or in industry (cosmetic powders, cereals, concrete flows…). Understanding the behaviour and flow properties (localization, jamming, aging…) of those materials is a major issue in rheology and fluids mechanic, mainly due to the complexity and multiscale aspect of the flow. Their comprehension is however important in order to optimize systems involving granular flows, such as hopper discharge.

2. Methods

The present work focus on the flow of dry powders in a quasi-2D silo (the depth allow only one layer of particle) when external vibrations are applied. The powders used are mainly spherical glass beads with a diameter around 1 mm. Numerical simulations using DEM [1] (Fig. 1.1) and experiments (Fig. 1.2) were performed in order to study the impact on the flow of the silo opening geometry and vibrations parameters.

For the geometry, various opening sizes between 4.5 to 18 particle diameters were tested, with opening angles ranging from 0 to 60°. For the vibrations, different amplitudes (10-5000 µm) and frequencies (15-600 Hz) were tested.

Experimentally, a scale follow the mass drained (measure of the flowrate) while the flow is recorded with a camera in order to determine the velocity fields (by PIV [2]) and the particle trajectories (by tracking) around the opening.

3. Results and discussion

We focus in particular on the effect of the vibrations on the flowrate, jamming properties (formation and destruction of arches) and local rheology of the flow. We show that, while vibrations

can prevent arches formation, they also tend to decrease the flowrate. Therefore, we also propose an adimensional law linking the flowrate and the different parameters including vibrations properties, based on the Beverloo law [3]. The goal being, in the framework of the “PowderReg” project, to size a 3D silo alimenting with different powders a full scale demonstrator of an industrial chain.

Facile Synthesis of GO-Exfoliation/Goethite Functional Material and It Application in the Adsorption Of Cu(II).

Sidi Zhu[1]

1 School of Chemical Engineering, Nanjing University of Science and Technology, Nanjing 210094, Jiangsu, China.

**Corresponding author: sdzhu@njust.edu.cn*

Highlights

- GO-exfoliation/goethite functional material was first reported.
- The new material has higher adsorption capacity for Cu(II) than goethite.
- It can be used in a wide range of pH from 4 to 9.
- It is harmless to environment and has a good application foreground.

1. Introduction

It is widely recognized that Cu(II) has harmful effects on the environment and human health. The removal of Cu(II) from wastewater has become a hot issue in the world. The methods of removing Cu(II) have adsorption[1], ion exchange[2], chemical precipitation[3], etc. Among them, adsorption is a fast and relatively cost-effective technology for water treatment[4]. This work aims to prepare a new adsorption material to effectively remove Cu(II) from aqueous solution.

2. Methods

In this research, graphene oxide (GO)/goethite functional material was synthesized through a facile method. It consisted of the following steps. (1) The Hummers method was used for the preparation of GO-exfoliation[5]. (2) Goethite was prepared using a method based on the report of Atkinson[6]. (3) The functional material was synthesized via the ultrasonic method in aqueous solution with GO-exfoliation and goethite as precursors.

Adsorption experiments: the adsorption of Cu(II) onto the material was analyzed vs. temperature, adsorption time, pH values, as well as the associated adsorption isotherms. Then XRD, BET and TEM were used to explore the characteristics of the material.

3. Results and discussion

The results showed that GO has high surface areas and abundant oxygen-containing function groups. It can be used as an adsorbent in water treatment but difficult to be separated from water due to its hydrophilicity. The degree of GO-exfoliation was important for the adsorption capacity. The active functional material made it easier to be separated from water. The analytical results showed that the material has excellent adsorption efficiency than GO and goethite alone. The proportion of GO and goethite also played a key role for its adsorption capacity. This adsorption processes were rapid as occurred within the first 10 minutes and reached equilibrium in about 30 minutes. Adsorbent with a high removal capacity was important in the performance

of adsorbing Cu(II). The calculated adsorption capacity was 125.47mg/g for Cu(II), which decreased with increasing adsorption time. The material had good adsorption capacity in a wide range of pH from 4 to 9. Pseudo-second-order adsorption kinetic and Langmuir adsorption isotherm were applied to study Cu(II) adsorption process[7]. The main adsorption process is chemical adsorption. So the functional material would be useful for the purpose of environmental protection in design.

4. Conclusions

The results prove that the new material possesses high potential for the removal of Cu(II) in wastewater. GO, using as a kind of two-dimensional support, plays a key role to help the material to remove Cu(II). In addition, GO can be readily obtained from cheap natural graphite in large scale. As precursors are environment-friendly, it can practically usable for Cu(II) separation from water.

Particle Size Control of Recovered $Mg(OH)_2$ in Concentrated Brine Discharged from Sea Salt Manufacturing Process

Highlights

- A morphology of $Mg(OH)_2$ is affected to stirring rate.
- A crystallinity is expected to change by stirring rate.
- The amount of $Mg(OH)_2$ depends on reaction time.

1. Introduction

Concentrated brine discharged from sea salt manufacturing process in Japan contains of value metal resources. The brine after recovering potassium chloride by cooling crystallization gives removed potassium bittern(RPB) as by-product. A part of RPB has been wasting to be hard to recover their resources, however, it is concerned with environment load. Combining their recovery increasing and to decrease environmental load are required, then Mg^{2+} is focus on as a representative resource. When Mg^{2+} is obtained from concentrated brine by reactive crystallization, $Mg(OH)_2$ would be produced to add a precipitator as primary product. However, the method gives a task to be slow on dry and filter process due to small crystal size of $Mg(OH)_2$. There have been many studies to increase a crystal size. For example, they are suggested kinds and addition method of precipitator. Otherwise, main cause of secondary nucleation in industrial equipment occurs from the stirring, there are hardly suggestion by the study to be controlled the crystal size.

The purpose of this study is to grow a $Mg(OH)_2$ crystals by the stirring conditions. For reagent, $MgCl_2 \cdot 6H_2O$ and $Ca(OH)_2$ were used by material and precipitator. Both reaction times and stirring condition are operation factors.

2. Methods

2.1 Material and operation

$Mg(OH)_2$ was precipitated by adding 6.0 mmol $Ca(OH)_2$ powder to 300 ml for 0.5 M $MgCl_2$ solution. The precipitate was filtered and washed third with 3 ml distilled water, dried at 60 ℃for 24 hours. The product was identified by X-Ray Diffraction (XRD) and a morphology was observed by Scanning Electron Microscope (SEM). The XRD pattern of $Mg(OH)_2$ is based on the JCPDS No. 07-0239.

2.2 Reaction time and stirring rate

Mixer (SM-101, AS ONE Co.) is equipped with 3-blades propeller (d = 55 mm). The reaction time was considered at 301 rpm from 60 min to 300 min, the precipitates were identified at constant time. The stirring rate was considered at 180 min from 301 rpm to 496 rpm. Their products were

compared with SEM images and XRD patterns.

3. Results and discussion

Fig. 1-(A) shows the XRD patterns of a precipitates to be altered reaction time. When the reaction time was 60 min, the characteristic peak of $Ca(OH)_2$ at $2\theta = 32°$ is detected. However, when reaction time was more than 120 min, the peak of $Ca(OH)_2$ could disappear. The peaks intensity of $Mg(OH)_2$ gradually increased as diminishing peaks intensity of $Ca(OH)_2$, the amount of $Mg(OH)_2$ is expected to increase.

Fig. 1-(B) shows the XRD patterns of a precipitates to be altered stirring rate. Pay attention at $2\theta = 38°$, the intensity of $Mg(OH)_2$ was stronger as slowing the stirring rate. This phenomenon is considered that decrease of the stirring rate is hard to occur the contact nucleation, then the crystal size is expected to grow. Otherwise, Fig.2 indicated the SEM images at their conditions. From the Fig.2-(a) and (b), the aggregation of primary particle was observed a ellipse-like morphology for secondary particle, however, Fig. 2-(c) cannot check a primary particle. A gap in secondary particle by distorted shape of primary particle is expected to decrease the crystallinity. Consequently, to be the slower stirring rate may facilitate the crystallinity and size of $Mg(OH)_2$.

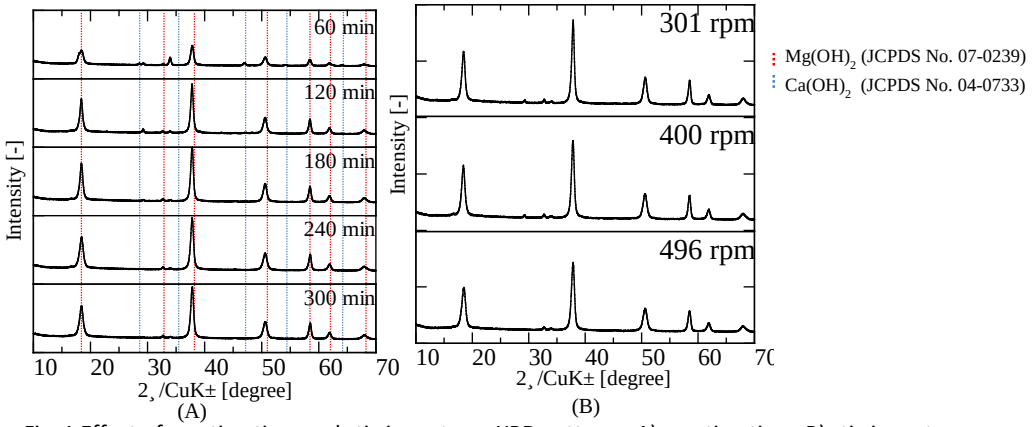

Fig. 1 Effect of reaction time and stirring rate on XRD patterns, A) reaction time, B) stirring rate

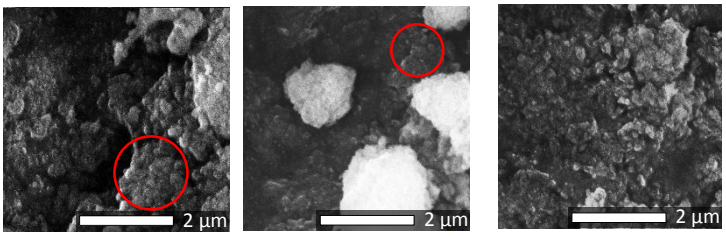

(a) **(b)** **(c)**

Fig. 2 Morphology of the products by changing the stirring rate, (a) 301 rpm, (b) 400 rpm, and (c) 496 rpm

4. Conclusions

This study was carried out to increase a crystal size of $Mg(OH)_2$ by reactive crystallization. The stirring rate and reaction time is considered to affect for the crystal size, their precipitates are identified and observed by XRD and SEM. From the XRD patterns, the amount of $Mg(OH)_2$ and crystal size were changed by operation conditions. From the SEM images, the crystallinity and the crystal size of $Mg(OH)_2$ are expected to increase at the slower stirring rate condition.

Highlights

- Porous magnetic CLEAs (pm-CLEAs) of porcine pancreas lipase (PPL).
- High effectiveness factor and high thermal and operational stabilities.
- Easy recovery using external magnetic field and good reusability.

1. Introduction

Cross-linked enzyme aggregates (CLEAs) is an immobilization technique that does not require solid support, allows the use of semi-purified enzymes, and the biocatalyst has higher volumetric activity [1,2]. However, they present some problems, such as low mechanical resistance, difficulty of recovering and intraparticle diffusion limitations [2,3]. In this context, this work evaluated some strategies in the preparation of CLEAs of porcine pancreas lipase (PPL) to reduce these problems, such as: modification of the PPL surface with hydrophobic aldehyde, co-aggregation with protein feeders (soy protein (SP) and bovine serum albumin (BSA)), use of silica magnetic nanoparticles functionalized with amino groups (SMNPs) to aid the CLEA separation, and the use of starch as a pore forming agent.

2. Methods

The PPL surface was modified with dodecyl aldehyde (DDA) at a PPL:DDA mass ratio of 1:1 for 3 h at 25°C and pH 10 (100 mM sodium carbonate buffer) under 150 rpm stirring. After, sodium borohydride (1 mg/mL solution) was added to the solution and the reaction proceeded for 0.5 h. The modified enzyme was dialyzed at 4°C for 16 h. The aggregation/precipitation step was carried out by adding 3 mL of ethanol to 1 mL of modified PPL solution (5 mg/mL) prepared in 5 mM sodium phosphate buffer pH 7.0, containing 7.5 mg of BSA (or SP), 7.5 mg of SMNPs, and starch (0.8% w/v). The reaction proceeded for 0.5 h at 4°C under 150 rpm stirring. Glutaraldehyde was added to the suspension (5 μmoles of glutaraldehyde/mg total protein) and the cross-linking reaction proceeded for 15 h at 4°C under 150 rpm stirring. The precipitate was recovered by magnetic separation, washed, and resuspended in 3 mL of 5 mM sodium phosphate buffer pH 7.0. α-amylase (100 μL) was added in order to wash away the starch by hydrolysis at 25°C for 2 h. Porous magnetic CLEA of PPL (pm-CLEA) was physically and morphologically characterized, and applied in the hydrolysis of tributyrin at 40 °C, pH 8.0 for 4 h under 500 rpm stirring [4].

3. Results and discussion

The experimental strategies adopted in this work produced pm-CLEAs of PPL with immobilization yield (IY) around 100% and recovered activities (RA) between 67 and 81% for pm-BSA-CLEA and pm-SP-CLEA, respectively, suggesting that the proteins fedeers and nanoparticles reduced mass transfer problems in the CLEA supramolecular structure [4].

The highest activities for free PPL (32.2 ± 0.65 U/mg protein) and pm-SP-CLEA of PPL (24.13 ± 0.35 U/mg protein) were obtained at pH 8.0, while for pm-BSA-CLEA of PPL (19.14 ± 0.13 U/mg protein) was at pH 9.0. The pm-CLEAs of PPL were more thermally stable than the free enzyme, exhibiting maximum activity at 50°C, with pm-BSA-CLEA achieving 20% catalytic retention at 70 °C. The free PPL showed maximum activity under 500 rpm stirring, while the activities of the immobilized enzyme increased continuously within the range evaluated (250 to 1250 rpm). The pm-SP-CLEA and pm-BSA-CLEA exhibited high stability at 40 °C and pH 8.0, retaining approximately 50 and 80% of activity, respectively, after 10 h of incubation, while free PPL was inactivated after 2 h. These results suggest that pm-CLEAs have a fraction of PPL molecules more cross-linked to the nanoparticles, where stabilization effects should be higher due to the higher rigidity of this material compared to a protein, resulting in improved thermal stability to the immobilized enzyme.

The morphological characterization of pm-SP-CLEAs and pm-BSA-CLEAs using scanning electron microscopy (SEM) showed the presence of non-uniform and porous in the structure of the cross-linked PPL due to the hydrolysis of the starch molecules by the α-amylase, which could explain the high effectiveness factor (around $\eta = 0{,}65$), mainly for pm-CLEA of PPL prepared in presence of SP and SMNPs.

The hydrolysis profiles of tributyrin as a function of the time showed that the free enzyme rapidly loosed its catalytic activity, reaching yields of 36 and 52% for free PPL and pm-SP-CLEA, respectively. After five 4 h-batches, the hydrolysis yield of tributyrin decreased only 7% (from 52% to 45%), confirming the high mechanical and operational stability of pm-SP-CLEA.

4. Conclusions

Porous magnetic CLEAs co-aggregated with soy protein and magnetic nanoparticles showed good catalytic properties and performance/reusability in the hydrolysis of tributyrin. The strategies used in this work allowed reducing problems of low mechanical and operational resistance, improvements in intraparticle mass transport, and ease of recovery and reuse of the biocatalyst.

Highlights

- The titania particle size can be controlled by milling condition.
- The porosity of the particle film prepared by EPD increased with used particle size.
- The film prepared from small-sized particles collapsed easily during drying process.
- The proposed force balance model could explain these conflicting phenomena.

1. Introduction

The particle film fabricated by depositing titania nanoparticles (NPs) is widely utilized for novel functional materials, such as the electrode of solar cells and lithium ion batteries, and water purification as photocatalysis. The major processes of making the particle film are the screen printing method, the spin coating method, the dip-coating method, and the electrophoretic deposition method (EPD) [1]. EPD has many superior features compared with other methods where the homogeneous films can be obtained on any forms of substrates, and easy control of the film thickness is achieved by adjusting the applied current and time. When the titania particle films are applied to use for the novel functional materials, the internal structure of the films is one of the key parameters to improve their abilities. However, the experimental conditions of EPD to control the internal structure of the film have not been discussed enough, although several studies have been pointed out to improve the performance of solar cells. In this paper, the effect of the titania particles size used for EPD on the internal structure, especially the porosity, of the film was reported.

2. Methods

The commercially available spherical P-25 NPs (Evonik) was used as the titania NPs for EPD. P-25 particle powder was dispersed into dehydrated-ethanol with acetylacetone by using the milling apparatus (HFM02, Ashizawa Finetech) with alumina beads. The particle size in the sample suspension was controlled by milling operation conditions. All the EPD experiments were carried out under DC constant current maintained by a potentiostat (AMEL 7050). The EPD electrodes were staged on a polyvinyl chloride plate with a 10-mm round hole and the distance between electrodes was 15 mm. The film thickness was measured with a surface profile meter (DEKTAK 150, Veeco). The weight of the deposited NPs was determined by the colorimetric method. The porosity of the thin film of particle deposition was calculated from the measured weight and thickness of film with the density of titania.

3. Results and discussion

When milling period increased, the particle size decreased, and then the mobility of particles during EPD and the electro conductivity of the suspension increased slightly. We found that the denser packed particle films were obtained by using the suspension with smaller-sized particles, and the local porosity of the film was increased with film thickness, as shown in Figure 1.

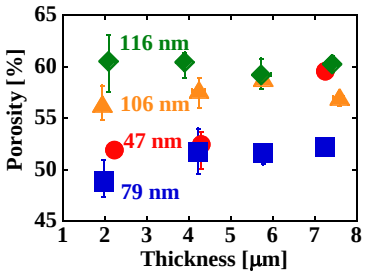

Figure 1. Effect of particle size on porosity of particle layer deposited by EPD.

Those phenomena could be explained that the new surface of titania particles was created due to break the aggregated particles during milling procedure, and then the surface charge density of titania particles and the counter ions in the medium increased as decreasing particle size. However, the total charge of individual particles increased with particle size, because the particle surface area increased more comparing with decreasing the surface charge density when particle size increased. This could be concluded that larger size particles with high total charge were repulsed strongly each other, and the porosity of the film prepared from those particles increased comparing with the case using small size particles, as a result. Therefore, changing the particle size is one of the effective methods to control the internal structure of the titania particle film fabricated by EPD.

However, the particle film prepared from smaller sized particles collapsed easily during drying process after EPD operation, in spite of the dense packed film. We proposed the force balance model for this phenomenon using van der Waals (F_v) and electrostatic (F_r) interactions between particles with the Coulomb force (F_E) from the electric field. The surface distance between particles was calculated, where the attraction forces (F_v + F_E) and the repulsion force (F_r) were balanced, and also determined its balanced force strength. In the case of small-sized particles, the surface distance was short, that means particles were packed closely. And the force strength at the force balanced point was weaker comparing with the case of large sized particles, that is particle adhesion force was weak. This calculation could explain the dependencies of the porosity of particle-deposited layer and the collapsed phenomenon at drying process on particle size of suspension.

4. Conclusions

In this study, the preparation of thin films of titania NPs by applying EPD from ethanol suspensions of different particle size led to the following findings: the porosity of deposition layer increased with particle size, but the strength of the deposition layer prepared from larger-sized particles was stronger than the case using smaller-sized particles. The proposed force balance model could explain those findings.

Stability of polyurethane adhesives and rigid foams produced with industrial biomass by-products

Lukas Jasiunas*, Linas Miknius

Department of Organic Chemistry, Kaunas University of Technology, Kaunas, Lithuania

**Corresponding author: lukas.jasiunas@ktu.edu*

Highlights

- Polyurethane products were synthesized at significant levels of renewable content
- Comparable physical properties to commercial analogues were achieved
- Biopolyol blending shows promise at lowering isocyanate demands
- The products will be evaluated in terms of their stability, flammability and fire toxicity

1. Introduction

Multiple hydroxyl functional group containing compounds, commonly known as polyols, are currently produced from fossil resources, food competing or virgin feedstocks. Representing a significant portion of the polyol-isocyanate system in polyurethane production, their synthesis has to improve in order for humanity to advance into a more sustainable production of value added polymers. Previously produced renewable biopolyols are studied in the production of polyurethane wood adhesives and rigid foams [1].

Sugar beet pulp (residue from sugar production), hemp stalk hurds (residue from cannabidiol and hemp fibre production) and digested sewage sludge (waste water treatment residue) are the studied biomass feedstocks. The three represent by-products of well-established and upcoming industries. Crude glycerol (biodiesel production residue) is incorporated directly as the renewable low cost solvent for the liquefaction process. Finally, commercially available isocyanates are used as the second major component in the polyurethane product synthesis.

2. Methods

A two-step thermochemical liquefaction process, carried out at mild temperatures (110-170 C) and atmospheric pressure, was chosen to investigate the cumulative effects offered by homogeneous base and acid catalysis in batch biomass liquefaction. The stability of the produced wood adhesives (renewable content of 82-87%) and rigid foams (renewable content of 28-39 %) will be assessed in terms of thermal degradation (DTG, TGA-FTIR), fire properties and fire toxicity (Micro Combustion Calorimetry, Cone Calorimetry and Steady-State Tube Furnace), chemical resistance (water uptake and dimensional stability) and biodegradability (via soil burial tests).

3. Results and discussion

The objective of this work is to study the possibility of producing polyurethane products of high renewable content suitable for commercial applications by incorporating locally available biomass by-products. Furthermore, the effect of initial feedstock moisture (ranging from dry to as received) and particle size (from <0.2 mm to 0.5-1 mm fractions), parameters not studied extensively in previous research, are analysed in order to contribute to the knowledge base of direct and industry-friendly polyurethane synthesis. Finally, biopolyol blending is studied as an alternative mode of improving product properties at low isocyanate levels.

The novel findings on such product performance will aid in determining their feasibility. Thermal stability and pyrolytic-oxidative decomposition analyses will add clarity to how such composites compare in terms of fire safety and toxicity with their fossil-derived analogues. Finally, biodegradation adds yet another aspect to how sustainable future materials will have to be handled.

4. Conclusions

Polyurethane wood adhesives and rigid filler foams were successfully synthesized including various amounts of biopolyols. The products show comparable mechanical properties to their commercial counterparts. Meanwhile, the utilisation of biopolyol blending may have significant industrial benefits due to lower isocyanate demands. The products will also be evaluated in terms of their thermal and bio-stability, flammability and fire toxicity.

Highlights

- Enhanced solvent extraction was used to extract antioxidant compounds from mango leaves.
- Supercritical antisolvent process was an efficient method to obtain co-precipitated extract with fluorescein.
- Temperature, pressure and CO_2 flow rate had remarkable effects on particle formation.

1. Introduction

The use of polyphenols from natural resources as fruits, vegetables and nutraceuticals is increasing due to beneficial health effects. In fact, polyphenols possess diverse biological activities as antioxidant, antimicrobial, antidiabetic and anti-inflammatory properties [1]. Otherwise, fluorescein is a fluorescent organic substance which has important optical properties in solution. This characteristic allows it to be used as a marker [2] with interesting active ingredients to be able to track the substance in the organism. In the study reported here, the SAS technique (Supercritical Antisolvent process) optimization was carried out to obtain the co-precipitation of mango leaves extract and fluorescein microparticles. Organic solution containing the solute of interest is sprayed through a nozzle to generate drops of solution into a vessel containing CO_2 at supercritical conditions. During mixing, $scCO_2$ is quickly dissolved in the organic solution, causing the precipitation of solutes by antisolvent effect. Afterwards, scCO2 efficiently extracts the organic solvent, allowing to obtain completely solvent-free products.

2. Methods

2.1. Preparation of mango leaves extract

The extraction of antioxidant compounds of mango leaves was performed by enhanced solvent extraction. The ethanolic extract was obtained using the best conditions of pressure, temperature, CO_2 flow rate and solvent flow rate from previous studies [3]. The extract was obtained at 200 bar and 80 °C with 50% CO_2 – 50% Ethanol:50% water ratio.

2.2. Particle co-precipitation with the SAS process

The SAS technique was used to co-precipitate microparticles of mango extract and fluorescein. A pilot plant built by Thar Technologies® (SAS200) was employed for this purpose. A factorial of mixed levels desing ($3*2^2$ + 2 central points) was used to determinate the effect of pressure, temperature and CO_2 flow rate on the co-precipitation of mango leaves extract and fluorescein microparticles. The response variable used as control was the particle size. The conditions of the factorial desing were: temperatures of 35 and 55 °C; pressures of 150 and 200 bar; and CO_2 flow rates of 10, 20 and 30 g/min. In all the experiments, the concentration of the extract and fluorescein was 24 mg/ml and 6 mg/ml respectively.

3. Results and discussion

Most of the experiments in this work led to the successful co-precipitation of mango leaves extract and fluorescein together. The obtained particles from the extract were spherical, while fluorescein particles were precipitated with an irregular morphology, as show in Figure 1. In general, an increase in the values of the studied parameters led to an increase in the amount of precipitate in the tests performed.

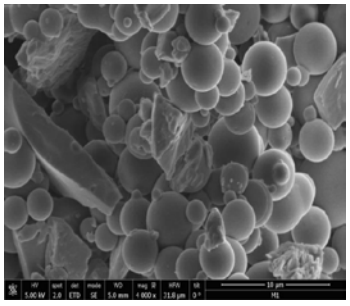

Figure 1. SEM Image of mango leaves extract with fluorescein microparticles

In reference to particle size distribution, it has been observed that the particle size of mango extract tended to decrease when pressure was decreased from 200 bar to 150 bar, obtaining particle diameters in the range of microns. In all cases, an increase in temperature led to a decline in both particle size. A decrease in CO_2 flow rate led to a smaller particle size in the case of fluorescein, but it happens in the opposite way to the mango leaves extract particles.

4. Conclusions

Microparticles of fluorescein with mango leaves extract have been obtained by a SAS process. Parameters that have a marked effect on particle size and size distribution have been evaluated in order to obtain the smallest particles possible. The experiments were successful in most cases. Higher temperature and lower pressure are recommended to obtain smaller particle size.

Electrochemical dissolution behavior of WC-Co in different electrolytes during micro wire-electrochemical machining

Abhijeet Sethi[1], Biswesh Ranjan Acharya[2], Partha Saha[3]*

1,2,3 Department of Mechanical Engineering, Indian Institute of Technology Kharagpur, West Bengal - 721302, India

**Corresponding author: psaha@mech.iitkgp.ernet.in*

Highlights

- Micro tool fabrication by micro wire-electro chemical machining process
- Study of electrochemical dissolution behavior of WC-Co in aqueous electrolytes
- Potentiodynamic polarization analysis through linear sweep voltammetry

1. Introduction

Micro tools, due to their versatility in creating profiles like micro holes, micro channels, micro gears, micro nozzles, micro grooves etc., have become the cornerstone of the micromachining industry [1]. The high hardness and the superior properties like high toughness and high rigidity of tungsten carbide cobalt alloy (WC-Co) have established it as an ideal material to be used as micro tools [2]. Electrochemical machining (ECM) easily dissolves hard metals with advantages like negligible tool wear, no machining force, no thermally induced stress, excellent surface quality and low roughness [1]. One of the most important factors in any electrochemical process is the selection of suitable electrolyte for successive electrochemical dissolution of work material. Therefore, attempts have been made in this study to investigate the performance of different electrolytes to find out their suitability in successive anodic dissolution of WC-Co using a cylindrical WC-Co rod of 510 µm initial diameter for fabricating micro tools, which are required for subsequent micro machining operations.

2. Methods

The electrolytes under this investigation were alkaline aqueous potassium hydroxide (KOH), neutral aqueous potassium nitrate (KNO_3) and acidic aqueous perchloric acid ($HClO_4$). To study the electrochemical dissolution behaviour of WC-Co in the above electrolytes, experiments were conducted by two processes: one is micro wire-electrochemical machining (WECM) and the other one is linear sweep voltammetry (LSV). The experiments in case of micro WECM process were conducted at three levels of a parameter keeping other parameters constant. Among the input parameters only electrolyte concentration and applied voltage were varied, one at a time. The electrolyte concentrations taken into consideration were 0.05 M, 0.15 M and 0.25 M and applied voltage 5 V, 10 V and 15 V for low, mid and high level respectively. The product oriented analysis like material removal rate (MRR) and average surface roughness (Ra) of the machined surface obtained through micro-WECM process were carried out. Furthermore, the electro chemical behaviour of WC-Co in three different electrolytes has been analysed by obtaining polarization curves from linear sweep voltammetry (LSV) where the voltage is varied from -1 V to 1 V at a rate of 0.05 V/s.

3. Results and discussion

As WC-Co is metal matrix composite of a hard phase (WC) enclosed in a binder phase (Co) its electrochemical dissolution needs to be homogenous for greater dissolution efficiency [3]. During the micro tool fabrication process through micro WECM, large amount of sludge is generated on the WC-Co alloy surface whose energy dispersive spectroscopy (EDS) study reveals the presence of tungsten, cobalt and oxygen. From figure 1 it can be found that the MRR in the alkaline electrolyte KOH is very poor, a higher MRR is obtained in case of neutral solution of KNO_3 at all levels, however, the MRR in case of $HClO_4$ is even higher in comparison to KNO_3. Figure 2 shows the comparison of average surface roughness of the machined surface. In case of neutral KNO_3 electrolyte the Ra values are found to be 0.469 µm,0.358 µm and 0.383 µm at low, mid and high level of parameters, respectively, which are lower in comparison to alkali and acidic electrolytes. The potentiodynamic polarisation curves (figure 3) obtained from linear sweep voltammetry show passivation in case of KOH electrolyte and the current density is very low in comparison to neutral and acidic electrolytes. In case of both KNO_3 and $HClO_4$, WC-Co alloy shows active dissolution and maximum current density is obtained in case of $HClO_4$, which confirms the higher MRR obtained in case of micro wire-ECM.

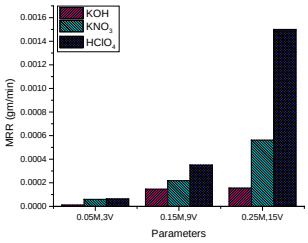

Figure 1. Relationship between material removal rate (MRR) and the level of process parameters for KOH, KNO_3 and $HClO_4$ electrolyte

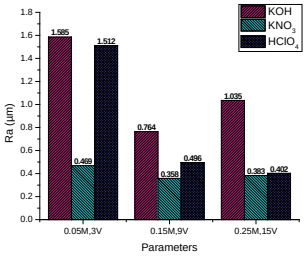

Figure 2. Relationship between material removal rate (MRR) and the level of process parameters for KOH, KNO_3 and $HClO_4$ electrolyte

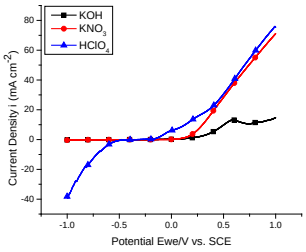

Figure 3. Linear sweep voltammetry (LSV) for WC-Co alloy in different electrolytes

4. Conclusions

The acidic electrolyte $HClO_4$ produces a higher MRR in comparison to both alkali KOH and neutral KNO_3 electrolytes at all levels of parameters. However, neutral electrolyte KNO_3 shows homogeneous dissolution of both WC and Co as the average surface roughness (Ra) values are found to be 0.469 µm, 0.358 µm and 0.383 µm at low, mid and high level of parameters, respectively, which are lower in comparison to alkali and acidic electrolytes. The potentiodynamic polarisation curves obtained from linear sweep voltammetry show better current density as evident for $HClO_4$ in comparison to KOH and KNO_3, which confirms the higher MRR obtained in micro WECM.

Highlights

- steady-state operation of continues Fluidzed Bed Layering Granulation
- robust formation of tailor-made particle properties
- model-based process control with multiple input multiple output controller

1. Introduction

An important class of particle formulation processes is the fluidized bed layering granulation (FBLG). It is widely applied in processing industries to gain high-quality granules. In brief, a solid containing liquid is sprayed onto a bed of fluidized particles. Since the fluidization medium is a heated gas, the liquid phase of the injection evaporates while the solid remains on the particles surface inducing a layer-wise particle growth. On the large scale FBLGs are operated continuously. This allows the formulation of particles with uniform characteristics under steady state conditions.

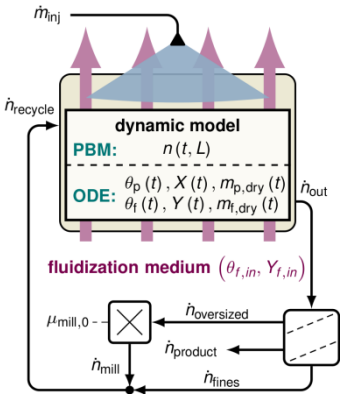

Figure 1. Structure of the dynamic model as presented in [4].

It is well known from previous studies that particle properties depend on the process conditions. For instance, Rieck et al. [1] showed by means of experiments that the thermal conditions of the FBLG process determine the porosity of the particle shell and, in consequence, the apparent particle porosity and density. As Litster and Ennis [2] pointed out, most of the other particle properties, e.g. particle strength, flowability, and dissolution behavior depend on the shell or apparent particle porosity and particle size. Therefore, constant thermal conditions are essential for the production of tailor-made particles. As was shown by Neugebauer et al. [3], the application of feedback controllers is promising to improve the performance of particulate processes. Scope of the present contribution is the development and validation of a multiple input multiple output MIMO control strategy which is capable to control both, particle size and porosity.

2. Methods

The present contribution is based on the dynamic model of FBLG presented in Neugebauer et al. [4]. The model consists, as depicted in Figure 1, of two bi-directional coupled sub-models: The first, a population balance model, represents the growth of the particles; the second considers the

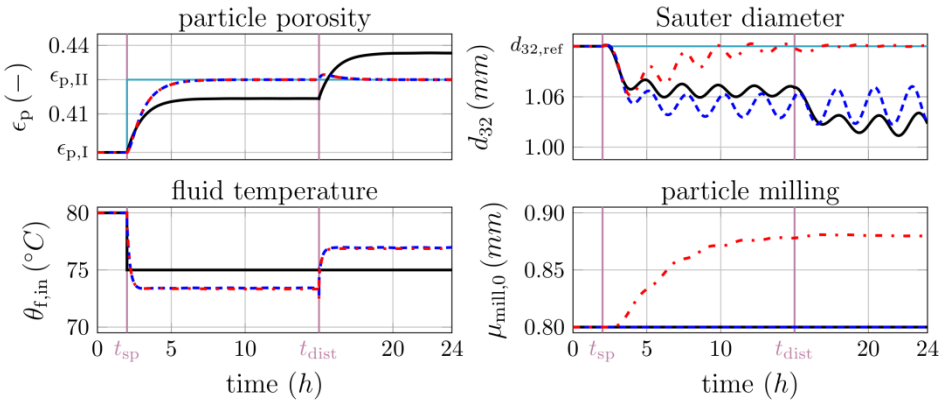

Figure 2. Simulation results according to different configurations: open-loop (black solid line), SISO (blue dashed), and MIMO control strategy (red dash-dotted).

thermal conditions within the granulation process. In the present contribution, the dynamic model is extended to account for (a) the dynamics of the temperature $\theta_{f,in}$ due to the heating and (b) the influence of particle porosity ε_p on the breakage behavior during milling. Afterwards, the resulting model is linearized in the vicinity of a given reference point. By means of the root-locus method two decentralized PI controllers are designed. The first controls ε_p by adjusting $\theta_{f,in}$, the second stabilizes the particle size distribution – here the Sauter diameter d_{32} is used as a representative - by actuating the mill $\mu_{mill,0}$.

3. Results and discussion

To study the influence of different operating parameters on the process dynamics and product properties the following scenario is defined: at t_{sp} = 2 h the set-point of ε_p is increased, whereas a process disturbance, in specific an increase of $Y_{f,in}$, appears at t_{dist} = 15 h. The corresponding simulation results are presented in Figure 2. As indicted by the open-loop results, the manipulation of $\theta_{f,in}$ and $Y_{f,in}$ induce variations of ε_p. However, a proper adjustment of ε_p is challenging as it depends significantly on both parameters. This issue can be overcome, as illustrated by the simulation results, by the application of the first controller: By actuating $\theta_{f,in}$ the particle porosity ε_p can be driven to its new reference value. In addition, the process disturbance at t_{dist} = 15 h can be rejected. On the contrary, a change of ε_p results in variations of the breakage behavior of particles. In consequence, as monitored by d_{32}, self-sustained oscillations of the particles size distribution can occur. As those highly undesired oscillations provoke variations of bed mass and mass flows they might result in a process break-down. To stabilize the particle size distribution, the control strategy is extended by the second controller. Referring to the simulation results presented in Figure 2, the application of the overall control strategy guarantees both, a stable process regime as well as constant product properties.

Highlights

- Novel polymer gel electrolytes (PGEs) are prepared and characterized
- The PGEs are used for successful application to various photo-electrochemical applications
- The PGEs showed the merit of easy cell fabrication as well as high ion conductivity
- Durability of the photo-electrochemical cells is largely enhanced by employing the PGEs

1. Introduction

Polymer gel electrolytes (PGEs) have been widely investigated and utilized in various electrochemical applications such as lithium secondary batteries and dye-sensitized solar cells (DSCs) because they possess moderate ion conductivity and high physical stability [1,2]. They have also been developed for the application to electrochromic devices (ECDs). Recently, ECDs have been attracting much attention owing to their use as a smart window. A smart window or a smart glass can effectively control the light transmission properties for the purpose of proper lighting or heating etc. The PGEs as one of the key components of the ECDs can dominate the major characteristics of transmittance and colored time etc. Especially, the ion conductivity and volatility of the PGEs should be optimized for the fabrication of efficient and durable ECDs. In addition, efficient injection process of highly viscous PGEs during the fabrication of large area ECDs should also be considered. In this work, therefore, we have developed the PGEs which can be easily loaded as a film and then in-situ polymerized through UV irradiation. Moreover, we have developed and characterized novel PGEs consisting of ionic liquid and thermo-responsive polymer. We expect that the PGEs could also be applied to various photo-electrochemical devices such as DSCs for the efficient energy harvesting from solar irradiation.

2. Methods

Various solvents including sulfolane, propylene carbonate (PC), diethyl carbonate (DEC), ethylene carbonate (EC), γ-butyrolactone (GBL), dimethylformamide (DMF), N-methyl pyrrolidone (NMP), dimethyl sulfoxide (DMSO), and dimethylacetamide (DMAc) were used for preparing the PGEs. Several acrylate monomers and polyethers were employed for the formation of the interpenetrating polymer network (semi-IPN) in the PGEs. The ionic conductivity was measured using a 4-point probe cell connected to an impedance analyzer. The PGEs were also employed for

the fabrication of ECDs and DSCs and their photo-electrochemical performances were systematically investigated.

3. Results and discussion

In this work, the optimal composition of the PGEs has been systematically investigated. For example, we have evaluated the effect of a solvent on the optical density of an ECD cell as shown in Figure 1. The optical density of an ECD is shown to largely affected by solvent properties such as donor number, dielectric constant and, viscosity. Through several analytical investigations, we could determine the optimal composition of the PGEs. The more detailed results will be presented at the conference.

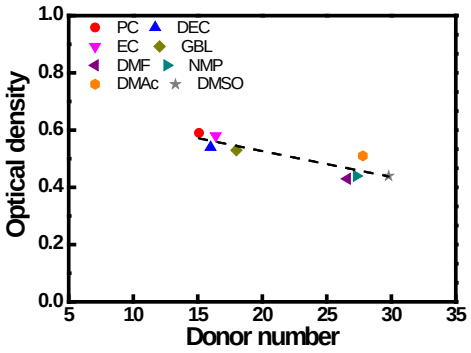

Figure 1. Relationship between solvent property (donor number) and optical density of ECD.

4. Conclusions

In this work, we have prepared novel PGEs for the successful application to various photo-electrochemical applications such as ECDs and DSCs. The prepared PGEs showed the merit of easy cell fabrication as well as high ion conductivity. In addition, the durability of the photo-electrochemical cells was shown to be largely enhanced by employing the PGEs.

This work was financially supported by the Environmental Industry Advancement Technology Development Project of Korea Environmental Industry & Technology (KEITI) funded by Korea Ministry of Environment (MOE) (No. 2017000140002/ RE201702218).

Highlights

- The height of liquid marbles increased and reached a constant value as the core liquid volume increased.
- Drying rate of liquid marble was dependent upon the core liquid solution in the liquid marble.
- Surfaces of the liquid marbles were not fully coated with the microparticles.

1. Introduction

Liquid marble is a non-stick drop coated with micro- or nano-scale particles demonstrating extremely low friction when rolling on solid substrates. Liquid marbles can be obtained easily by rolling water drops on a solid substrate covered with hydrophobic powder layer or by mixing a hydrophobic powder in water [1]. Liquid marbles have great potential in a wide range of applications such as water quality testing and micro bioreactor etc. [2, 3]. Stearates, salts of stearic acid included in animal fat, have insolubility in water and no toxicity, and are used in thickener as a food additive and an anti-adherent for the manufacture of medical tablets. In this study, preparation of liquid marbles (LMs) using stearate microparticles (SMs) and their properties for microreactors are investigated.

2. Methods

For preparation of LMs we used calcium SMs. It has peaks at 5 µm and 100 µm in the size distribution. Aqueous solutions were dropped by syringe onto a substrate surface covered with a layer of calcium SMs. Slight tilting of the covered substrate surface caused the drop to roll and become coated with calcium SMs. The height and drying rate of prepared LMs were measured. The weight of LMs was recorded with time by electronic balance in a low temperature & humidity test chamber at 35˚C and 40 % (RH) of humidity. The drying rate of the LMs was calculated from the weight data. The initial surface of LMs was observed by optical microscopy.

3. Results and discussion

At small core liquid volumes of the LMs they were spherical, but as the volume increased it changed to a puddle shape. The heights of LMs at various core liquid volumes are shown in Fig. 1. As the liquid volume increased, the height of LM increased and reached a constant value (H_{max}). The drying rates of LMs containing each core solution calculated from the weight data are shown

in Fig. 2. The drying rate of LMs was dependent upon the core liquid solution of LMs. The obtained drying curves of LMs were similar with general drying curves of wetted powders. Drying rate of liquid marble was dependent upon the core liquid solution in the liquid marble. The drying rate of the LMs prepared with 0.1 M $MgCl_2$ aqueous solution is the lowest.

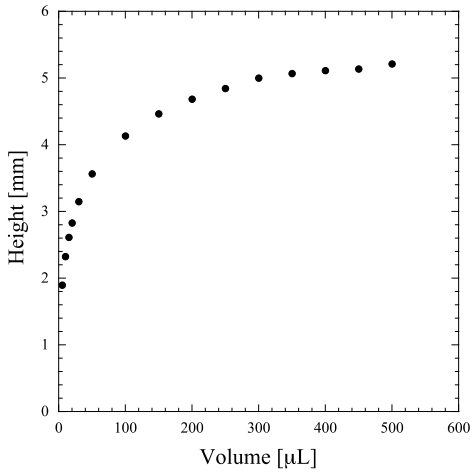

Fig. 1 Relationship between core liquid volume and height observed from side in the preparation of liquid marble.

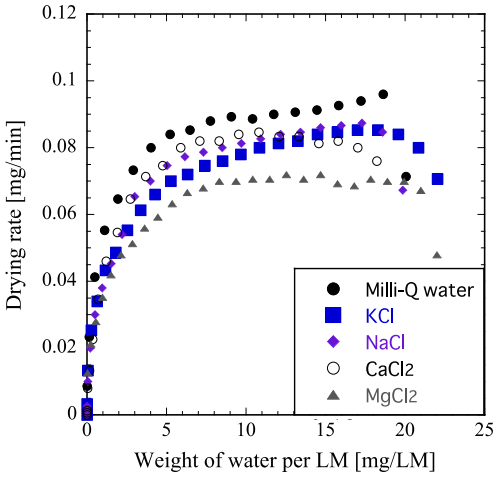

Fig. 2 Relationship between drying rate of LM and weight of core liquid per LM. Salt conc. = 0.1 M.

Fig. 3 shows a microscopic image of the surface of LMs prepared with $MgCl_2$ aqueous solution before drying. The initial surfaces of the LMs were not fully coated with SMs, indicating that gas or vapor can be transported through the surface of LMs.

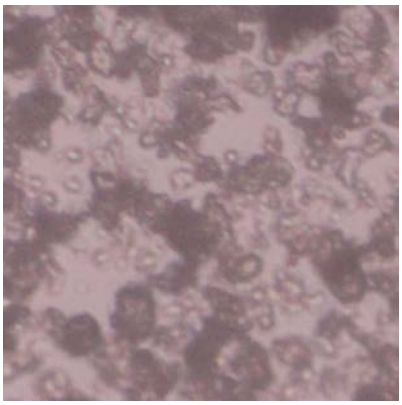

Fig. 3 Microscopic image of surface of SMs LMs prepared with 0.1 M $MgCl_2$ aqueous solution.

4. Conclusions

Preparation of LMs using SMs and their properties for microreactors were investigated. At small core liquid volumes of the LMs they were spherical, but as the volume increased it changed to a puddle shape. The heights of LMs at various core liquid as the liquid volume increased, the height of LM increased and reached a constant value (H_{max}). The drying rate of LMs was dependent upon the core liquid solution of LMs. The initial surfaces of the LMs were not fully coated with calcium SMs, indicating that gas or vapor can be transported from surface of LMs.

Preparation of UV-curable biodegradable functionalized polyesters

T. Cernadas[1], F. M. M. Gonçalves[1], P. Alves[1], Sónia P. Miguel[2], I. J. Correia[1,2], P. Ferreira[1]
1 CIEPQPF, Department of Chemical Engineering, University of Coimbra, Portugal; 2 CICS-UBI, University of Beira Interior, Covilhã, Portugal

Highlights

- Photocrosslinkable biodegradable copolymers were developed based on unsaturated polyesters;
- Photocrosslinking was achieved with a UV exposure time of 2.5 minutes;
- Flexible materials at room and physiological temperatures were obtained;
- According to the obtained results, the materials are suitable for biomedical applications.

1. Introduction

Traditional methods of wound closure are suturing and stapling, but they are associated with pain, wound infection and low aesthetic results. As a result of these shortcomings, medical tissue adhesives are considered an attractive alternative since, besides wound closure, they can accomplish other tasks, such as haemostasis and the ability of sealing air leakages [1,2]. The most used surgical glues nowadays are the fibrin based adhesives [3] and cyanoacrylates [4]. Fibrin based adhesives present several problems, e.g. immunogenicity and risk of blood transmission diseases such as HIV and BSE [3]. Cyanoacrylates have been reported to degrade in aqueous media to produce formaldehyde, which causes inflammation and has got carcinogenicity potential [5]. Other options are now being considered, and among them, photopolymerizable/photocrosslinkable adhesives are the most promising.

The study and development of new biocompatible materials to be applied as UV-curable adhesives is extremely important to grant the preparation of matrices with controlled properties (such as mechanical, biological and thermal) with a fast curing rate when in contact with living tissues. Unsaturated polyesters (UP) present some interesting characteristics to be used in this application due to their inherent biodegradability (ester linkages), potential biocompatibility and to its internal carbon-carbon double bonds that allow them to be photopolymerized forming crosslinked networks [6].

2. Methods

Photocrosslinkable biodegradable copolymers were developed based on unsaturated polyesters (prepared from PEG modified with fumaric acid) and lactic acid oligomers (oligoLA) functionalized with 2-isocyanatoethyl methacrylate (IEMA® by BASF).

During this work, three stoichiometric proportions between the UPs and oligoLA were tested, which, after the addition of a biocompatible photoinitiator (Irgacure® 2959 by CIBA), allowed to obtain flexible, resistant and uniform matrices after 2 minutes and 30 seconds of UV irradiation. The prepared materials were then further characterized, by water sorption capacity evaluation,

determination of gel content, dynamic contact angles measurements, hydrolytic degradation in vitro, as well as thermal characterization (TGA and DMTA). ATR-FTIR and 1H NMR analyses were performed to allow a follow-up of the synthesis, functionalization and photocrosslinking reactions. Finally, their biocompatibility using human dermal fibroblasts (hFib) and antibacterial activity when incubated with Escherichia Coli and Staphylococcus Aureus were evaluated in vitro.

3. Results and discussion

ATR-FTIR and 1H NMR analyses allowed to confirm the reaction between the OH groups of PEG with the COOH of fumaric acid. Also, the bands and peaks correspondent to the C=C bonds were detected in both spectra proving the chemical functionalization of the materials.

Dynamic contact angles determination showed that incorporation of unsaturated polyester leads to more hydrophilic matrices.

It has been found that the rate of degradation of the matrices is closely related to the crosslinking degree and the swelling capacity. In other words, more hydrophilic materials with a lower gel content tended to degrade more rapidly, as did the adhesive composed mainly of UP.

Thermal analysis indicated that the films are stable at physiologic and room temperature. Despite the increase in Tg after curing, this fact does not compromise the film's flexibility since its value remains lower than physiological and room temperatures.

In cell viability studies, the results obtained were satisfactory for two of the three developed adhesives, with cell viability values of around 100% even after 7 days of incubation. The exception was the adhesive containing the highest amount of the oligomer functionalized, which, in turn, recorded values of 50% at the end of the same incubation period. Also, antibacterial activity in the presence of Escherichia Coli and Staphylococcus Aureus was assessed, and inhibition halos were visualized around the materials, allowing to conclude that they present antibacterial activity.

4. Conclusions

The adhesives resulting from the copolymerization of UP and oligoLA functionalized have been shown to be resistant, flexible and with adequate viscosity before a possible application and thermally stable, with very satisfactory crosslinking times.

Considering the obtained results, it is possible to affirm that the UV-curing surgical adhesives developed in this work may come to take a prominent place in the bioadhesive market.

Highlights

- Co-spray drying process is used as an encapsulation tool.
- Operating parameters affect the loading of mesoporous silica nanoparticles.
- Ibuprofen is present in different states and location is revealed.

1. Introduction

Nanosystems for biomedical applications present a great interest as therapeutic tools for the controlled release of active substances [1]. In this context, Mesoporous Silica Nanoparticles (MSN) are relevant drug carriers due to their biocompatibility [2] and high specific surface. Several processes may be used for drug loading [3]. Spray drying, currently used in the industry to dry a product, has a good potential for encapsulation [4], [5]. In this work, ibuprofen (poorly water-soluble molecule) is loaded inside the MSN by co-spray drying. Some properties after loading and their end-used properties can be modified depending on formulation parameters (Ibu/Si weight ratio (R=Ibu:Si), silica concentration, solvent) and process parameters (suspension flow rate, drying gas temperature, drying time, dispersion conditions, spray mesh size).

2. Methods

MSN with controlled properties (pore and particle diameter) were first synthesized with a semi-continuous sol-gel process. Then, the drug loading was performed using the Nano Spray Dryer B-90 (Büchi) [6]. An ultrasonic processor was used to facilitate the drug dissolution and the MSN dispersion. Several characterization techniques allowed improving the knowledge of the properties of the MSN and of the final carriers. Microscopic techniques (TEM, SEM) reveal the aspect of the material. The use of physico-chemical characterizations gives access to many information about the final product: DLS (MSN diameter), SAXS (porous organization), N_2 adsorption (specific area, pore diameter). The combination of different solid-state (SS) techniques informs about the physical state and the drug-silica interactions (TGA, XRD, SS NMR). Complementary and multi-scale characterization techniques permit a real understanding of the parameters influence on loaded-particles properties.

3. Results and discussion

As an example, the results for the influence of the Ibu:Si weight ratio are presented here. The presence of crystalline ibuprofen on dried powder from R=40:60 to 100:0 was shown with XRD patterns and confirmed by TGA (which quantifies the amount of crystalline and amorphous solid). SS NMR revealed information about its mobility (solid or liquid-like) and its interaction with silica

according to the Ibu:Si ratio. SEM and TEM observations suggested a conservation of the MSN matrix, but the MSN agglomerates did not have the same shape according to the Ibu:Si ratio, and the crystals shown by XRD seemed to be outside of the pores at R=75:25 (Figure 1). The pore and crystal sizes confirmed the impossibility for crystalline ibuprofen to be inside the pores [7]. SAXS and N_2 adsorption gave a decreasing trend of peak intensities (SAXS), surface area, pore volume and pore diameter (N_2 adsorption) as the Ibu:Si ratio increased, suggesting a loading of the active substance inside the pores of the MSN.

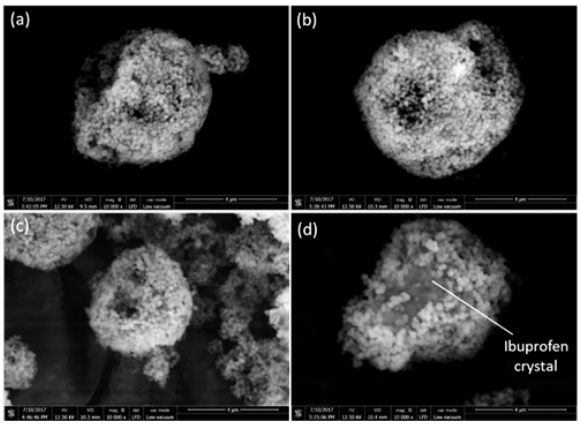

Figure 1. SEM images (x10k) of agglomerates with different R: 0:100 (a), 25:75 (b), 50:50 (c), 75:25 (d)

Sample (R=Ibu:Si)	Specific area ($m^2.g^{-1}$)	Pore volume ($cm^3.g^{-1}$)	Pore diameter (nm)
MSN	777	0.727	3.08
20:80	477	0.357	2.19
35:65	80	0.098	2.19

Table 1. Structural information determined by Nitrogen Adsorption

The combination of all these characterization techniques indicates links between the ibuprofen location (in or out of the pores) and its physical state (crystalline, amorphous, liquid-like). The other operating parameters had also an effect on the size of the particles and the ibuprofen loading.

4. Conclusions

The plentiful techniques permit to reveal that the drug is loaded firstly in the pores, and has been found in different states which are related to the localization inside the system (inside or outside the pores of the MSN). The Ibu:Si ratio influences drastically the agglomerate structure and the physical state of the substance. Afterwards, the effect of the parameters on the end-used properties like drug release kinetic will also be studied.

A conceptual design of Cr(VI)-free anti-corrosion solutions for aerospace applications

Bhavya Goyal[1], Gabriela Hadiwinoto[1], Kleopatra Papamichou[1], Yuyang Tian[1], Zerui Zhang[1*], Pieter Swinkels[1]

1 Delft University of Technology, Faculty of Applied Science, Van der Maasweg 9, 2629 HZ, Delft, The Netherlands

**Corresponding author: Z.Zhang-9@tudelft.nl*

Highlights

- Chromium free anti-corrosive coating for the aerospace industry
- Rare earth metals as corrosion inhibitors and silyl ester as a healing agent

1. Introduction

The high standards of the Aerospace Industry often push the limits of science and one of those times is the protection of aircraft against corrosion. Currently, the coating of an aircraft is made by hand-spraying and the paint itself contains hazardous compounds, with Chromium (VI) to be the most infamous one. This process is not only harmful to the environment but creates major health issues to the painters and raises a lot of concerns. Chromium (VI) salts are very effective and provide a "self-healing" active corrosion inhibition to aluminium substrates. This carcinogenic and toxic compound is banned in the EU and is only permitted in situations where there are no good alternatives, such as in aircraft corrosion prevention. This work provides two Cr-free conceptual designs as the anti-corrosive solutions to be used in the aerospace industry. The two concepts try to mimic the two properties of Chromium (VI) in a safe way: corrosion inhibition and self-healing.

2. Methods

The Delft Design Map (DDM) was systematically followed to frame and organize the designs [1]. Design requirements were identified by translating the needs of stakeholders and the design specifications are generated and evaluated using House of Quality (HoQ) to determine the important features of the final product which were the basis of our design concepts. The corresponding manufacturing process is partially proposed and assessed via safety, health, environment, economic, technology and social (SHEETS) analysis.

3. Results and discussion

The first conceptual design concept proposes the use of rare earth metals as corrosion-inhibitors which work by creating effective protective barriers. Cerium salts, with which researchers have been experimenting for years, oxidize only once and the protective layer they create is not permanent [2]. Long-term protection, therefore, requires the continuous release of these inhibitors. For these, the proposed idea is borrowed from the biomedical community and includes the encapsulation and controlled release of the corrosion inhibitor by macroporous silica particles [3].

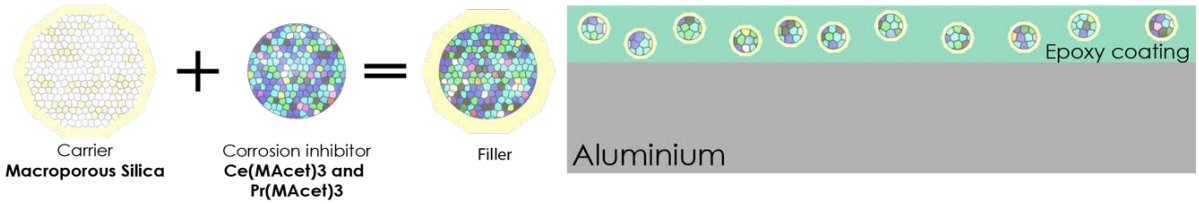

Figure 1. Corrosion inhibitors carried by macroporous silica.

The second conceptual design concept is oriented in the direction of actively protecting the surface of the aircraft against any kind of damage, by the use of "self-healing" materials. The idea is to prevent corrosion that is caused by cracks on the coating of the aircraft, by automatic repair of these cracks. The repair of these cracks can be promoted by silyl ester as a healing agent that can form an adhered-to-the-metal hydrophobic barrier system [4]. Relatively similar to the first concept, the self-healing agent is protected in microcapsules until the moment of action [4].

The preliminary analysis of the two designs shows promising results and a lot of margin for completion. This work can be seen as a thoughtful exploration of the alternatives to the problem of Chromium (VI).

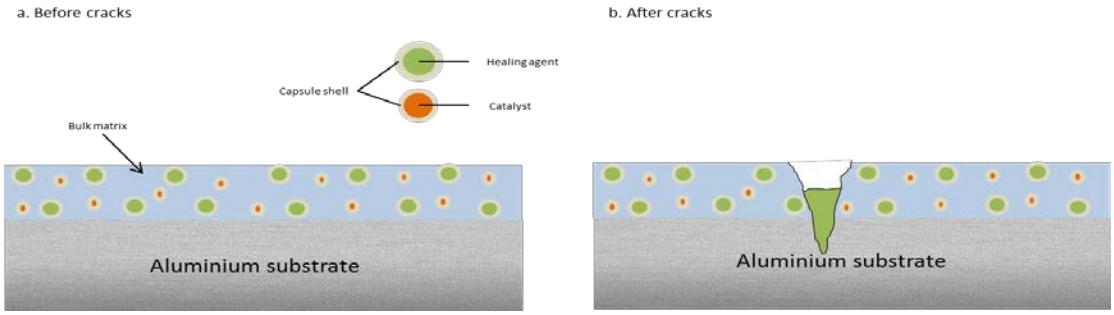

Figure 2. Capsule-based self-healing coating

4. Conclusions

The conceptual designs exhibit possibilities of providing adequate anti-corrosive properties without compromising the structural integrity of an aircraft. In terms of application and maintenance, they facilitate an easier and less hazardous process. However, the thickness of such a coating can exceed acceptable limits and add extra weight, creating issues with the aerospace industry. Therefore, it is proposed to focus on more research in order to combine the two concepts and eliminate their disadvantages.

Selftuning adaptive control for convective drying of particulate solids

Robert Dürr[1,*], Carsten Seidel[2], Christoph Neugebauer[2], Andreas Bück[3]

1 MPI for Dynamics of Complex Technical Systems, Sandtorstraße 1, D-39106 Magdeburg, Germany;

2 Otto von Guericke University, Universitätsplatz 2, D-39106 Magdeburg, Germany;

3 Friedrich Alexander University, Cauerstraße 4, D-91058 Erlangen, Germany;

**Corresponding author: duerr@mpi-magdeburg.mpg.de*

Highlights

- Convective drying of particulate solids
- Model-based controller design
- Automatic adaption of controller parameters
- Guaranteed product quality under varying drying conditions

1. Introduction

Drying, the removal of a liquid from a solid material represents one of the most important operations in the chemical, pharmaceutical and food industries. Besides mechanical liquid removal, thermal drying is extensively applied: Here, a moist solid is heated resulting in subsequent phase change of the liquid into vapor and removal of the vapor from the solid. Thermal dryers are usually categorized by the respective method of heat supply, e.g. contact dryers and convective dryers. Considering the latter, characteristic evaporation rates depend on the moisture content as seen in Fig. 1. Within the second drying phase evaporation rates result from an complex interplay of thermal and moisture fields in the particle [1]. This coupling can be described by the concept of normalized drying curves. Given experimental data, such a curve can be fitted and used for further model-based control design and process intensification. However, such an appropriately designed controller may not be able to keep the desired quality of the product, e.g. moisture content of the dried solid, in presence of external influences like seasonal or local variations in the properties wet solid. Such deviations come along with unforeseen variations of the drying kinetics, i.e. shape variations of the normalized drying curve, and manifest for example in over-/underdrying of the product as well as on-set of unwanted reactions. As an alternative to robust control design techniques which use a fixed controller in order to cope with the described variations [2], adaptive controllers employing online-tuning can be applied to guarantee the desired product specifications [3].

2. Methods

Within this contribution convective conveyor belt drying of baker's yeast is considered which can be described by a set of nonlinear ordinary differential equations [2]. To cope with variations in the drying conditions a self-tuning adaptive controller is applied. Its basic structure is seen in Fig. 1: An approximate simple model of the process is identified online from process measurements via recursive least-squares estimation. The simplified model is used for adaption of the parameters of

the controller which is applied to the complex process . This procedure is also known as adaptive pole-placement.

3. Results and discussion

The selftuning regulator's performance is validated in a parametric study for several scenarios, including uncertainty of the shape of the normalized drying curve as well as disturbances of the solids and gas inlet temperature. The adaptive controller is applied to the nonlinear process and compared to the performance of a nominal PI-controller with fixed tuning parameters. The simulation results in Fig. 1 indicate that the latter is outperformed by the adaptive controller.

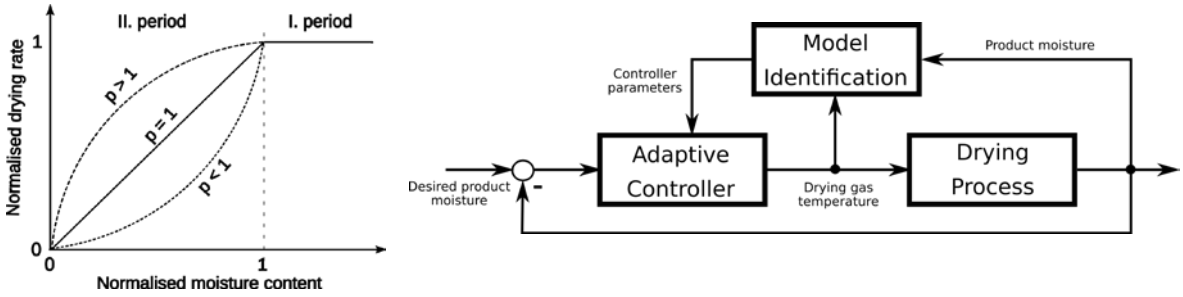

Figure 1. Normalized drying curve (left) and applied adaptive controller structure (right)

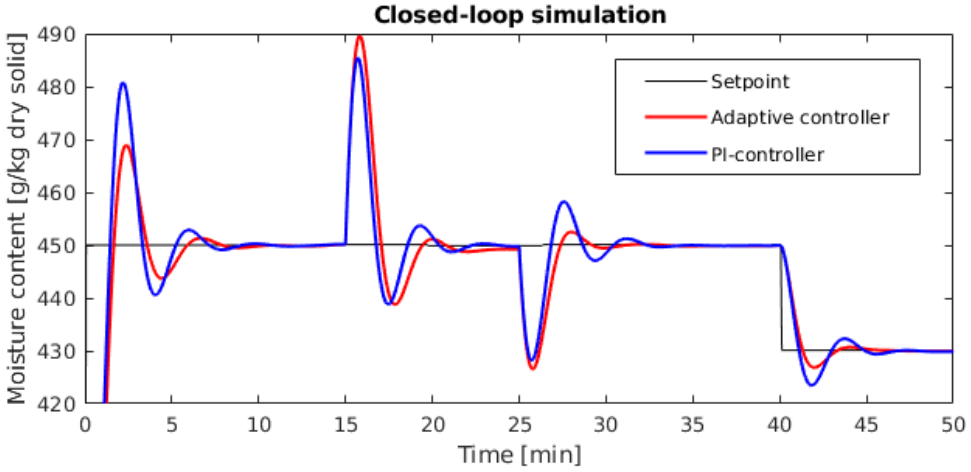

Figure 2. Simulation results adaptive controller and PI-controller for non-nominal process conditions: Disturbance in the gas inlet moisture content (t>15min) and solids inlets moisture content (t>25min)

4. Conclusions

The presented results indicate that the presented self-tuning controller represents a suitable method for control of convective drying processes under unforeseen changes in the material's drying characteristics.

Highlights

- Long chain polyamide as hard segment and amino-terminated polyether as soft segment.
- The thermoplastic elastomer is lightweight.
- Microphase separation of the copolymer is observed.
- The thermoplastic elastomer can be used as permanent antistatic agent.

1. Introduction

Thermoplastic polyamide elastomers (TPAEs) are block copolymers with hard blocks consisting of polyamide segments, and the soft blocks consisting of polyether segments usually including poly(ethylene glycol) (PEG), poly(propylene glycol) (PPG) or poly(tetramethylene glycol) (PTMG)[1,2,3]. The hard and soft segment are linked with ester group where thermodynamic incompatibility between the two segments results in a microphase separated morphology[4].

2. Methods

Thermoplastic polyamide elastomer was synthesized using PA1212 oligomer (Average molecular weight is from 1000 to 5000) and Jeffamine@ED2003 (or Jeffamine@D2000) via a "two-step" melt polycondensation. The TPAEs were characterized by FT-IR, ^{1}H-NMR, WAXD, DSC, DMA, TGA. Meanwhile, the inherent viscosity, density, rheology and dielectric properties of the TPAEs were determined.

3. Results and discussion

The hard and soft segment are linked with amide group (Figure 1a). The Jeffamine@ED2003 crystal melting peaks are observed within 0-40 ^{o}C which are lower than the reported T_m (43 ^{o}C) (Figure 1c). Two distinct glass transitions of TPAEs have been observed (Figure 1d). This result is attributed to the Jeffamine crystallization being confined by the PA1212 hard domains during cooling, a typical characteristic of microphase separation in elastomeric copolymers. The volume resistivity of the TPAEs decreases as increasing frequency and the values are between 10^5 and 10^{12} Ohms·cm (Figure 1e). The density of the synthesized TPAEs is 1.01-1.06 g·cm^3.

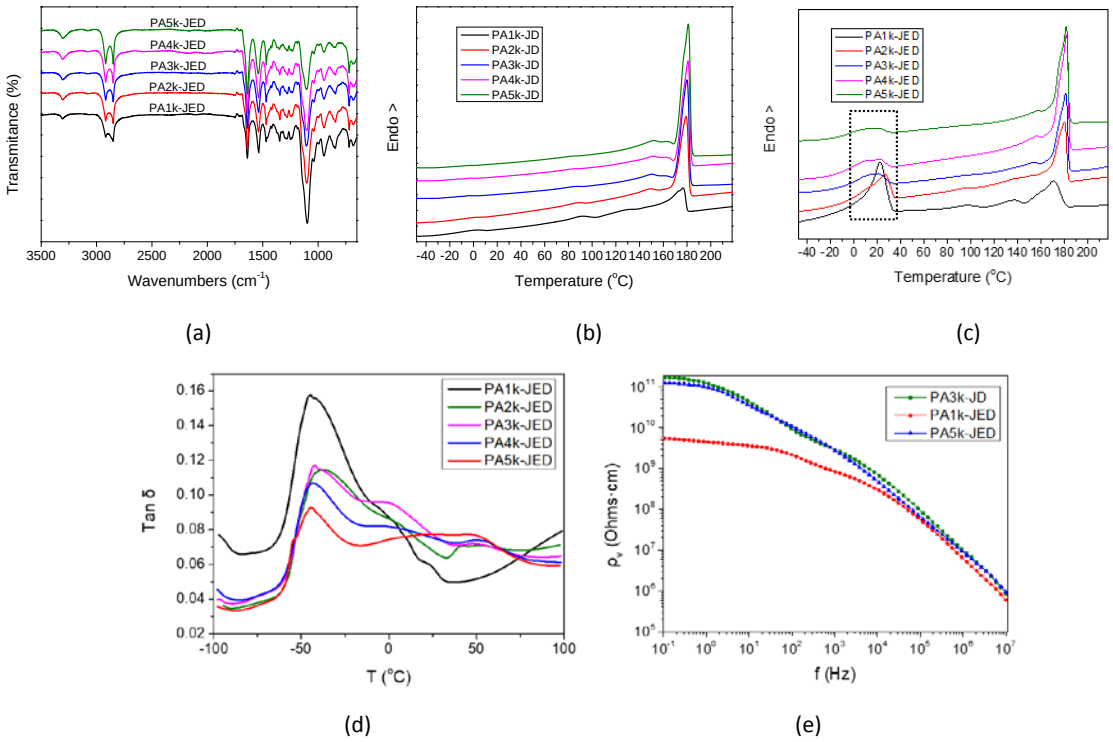

Figure 1. (a) FT-IR spectra of PA1212-co-Jeffamine@ED2003; (b) DSC thermographs of PA1212-co-Jeffamine@D2000; (c) DSC thermographs of PA1212-co-Jeffamine@ED2003; (d) DMA results of PA1212-co-Jeffamine@ED2003; (e)Dielectric properties of TPAEs

4. Conclusions

The hard and soft segment are linked with amide group rather than ester group, resulting in good resistance to hydrolysis and organic solvent. The typical characteristic of microphase separation is observed. The density of the synthesized TPAEs is 1.01-1.06 g·cm^3. The TPAEs can be used as permanent antistatic agent.

Correlation of Powder Performance on Rotary Tablet Presses and Standardized Methods for Flowability

Maren Zimmermann, Kalaiarasi Sathiyaseelan, Markus Thommes

TU Dortmund, Laboratory of Solids Process Engineering, Emil-Figge-Str. 68, 44227 Dortmund, Germany

Highlights

- A quantitative classification of flowability is possible with a ring shear cell.
- The ff_c value correlates with the flow rate through a feed frame.
- Mass flow through a funnel does not predict powder performance on rotary tablet presses.

1. Introduction

In tablet manufacturing powder flow is frequently the rate limiting step as it directly influences several product quality attributes [1]. An insufficient powder flow may cause variations in tablet weight and dose which have to be minimized due to high quality requirements according to legal binding guidelines (e.g. European Pharmacopeia) [2]. Most rotary tablet presses contains feed frames consisting of rotating paddles in order to overcome challenges in powder flow. For the measurement of powder flowability various methods are known which are standardized to ensure comparability. These measurement procedures are used to qualitatively rank powder flowability and rather investigate the performance of powder in tablet manufacturing [3]. The aim of this study is the investigation of the correlation between flow behavior in a rotary tablet press and standardized measurement procedures for the evaluation of powder flowability.

2. Methods

Powder flow experiments were conducted on a feed frame (Fill-O-Matic, Fette Compacting, Schwarzenbek, Germany). The flow rate was measured on an external scale (MSA20201S-000-D0, Sartorius, Göttingen, Germany) (Figure 1). A ring-shear cell (RST-01, Dr.-Ing. D. Schulze Schüttgutmesstechnik, Wolfenbüttel, Germany) with a predefined shear stress (σ = 1000 Pa) was used to determine powder flowability. Flowability was also specified via the tap density (Tap density tester TD1, Sotax, Aesch, Switzerland), the angle of repose and the flow rate through a funnel (Powder flow tester PF1, Sotax, Aesch, Switzerland).

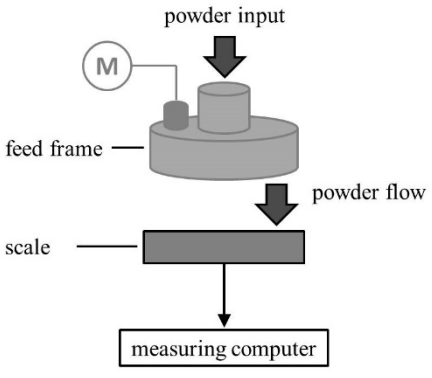

Figure 1. Schematic of the experimental set-up to determine the flow rate through a feed frame

Three powders were chosen as model substances due to their different flowability. Lactose monohydrate (GranuLac 200, Meggle Pharma, Wasserburg, Germany) is the most cohesive

powder. Microcrystalline cellulose (Emcocel 90M, JRS Pharma, Rosenberg, Germany) and dicalcium phosphate anhydrate (DI-CAFOS A150, Chemische Fabrik Budenheim, Budenheim, Germany) show a higher powder flow.

3. Results and Discussion

The results of the measurements with the ring shear cell (ff_c) are in the expected order: Di-Cafos A150 offers a high flowability due to a high and regular particle size (d_{50}=181 µm). GranuLac 200 is a cohesive powder (d_{50}=37 µm) and it consequently features low flowability. A similar order is found by determining powder flowability via the angle of repose α and the Hausner Ratio (HR). Contrary, the results of the mass flow through a funnel do not meet the expectations. The mass flow of Emcocel 90M is the smallest one, although the powder is less cohesive than GranuLac 200. This method should represent powder flow best, as it considers particle-related as well as dynamic process related factors [2]. By determining the powder flow rate through a feed frame of a rotary tablet press the same expected order can be measured as with the ring shear cell.

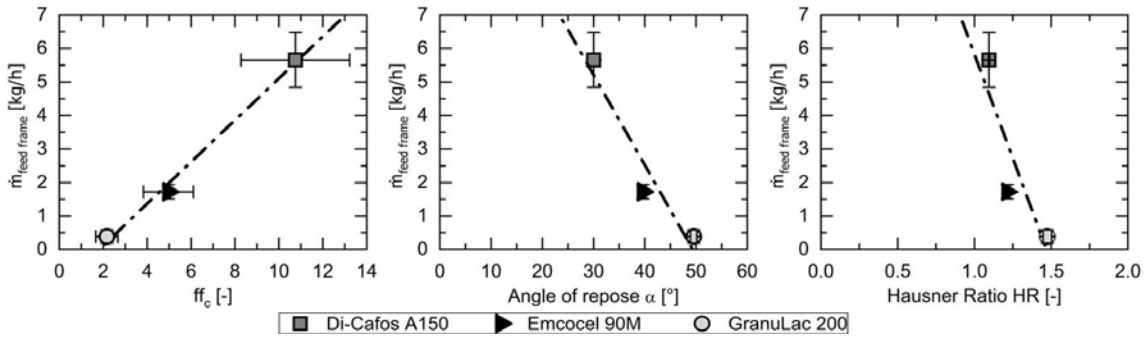

Figure 2. Correlation between powder flow rate through a feed frame (mean ± s, n = 10) and flowability index ff_c (mean ± s, n = 3), angle of repose α (mean ± s, n = 6) and Hausner Ratio (mean ± s, n = 6) of three model substances.

Correlation between mass flow rate through a rotary tablet press feed frame and values for flowability determined by standardized methods was proven (Figure 2). The characteristic coefficient of flowability ff_c is linearly dependent of the powder flow rate through the feed frame (coefficient of determination R^2 = 0.9938). Analyzing the angle of repose and the Hausner Ratio this correlation could not clearly be identified.

4. Conclusions

Powder flow rate through the feed frame of a rotary tablet press was investigated in order to determine a correlation with standardized methods. In comparison with the analyzed measurement methods the characteristic coefficient of flowability ff_c shows correlation with the mass flow from the feed frame best. Determining powder flowability by measuring the flow rate through an orifice even resulted in a different order.

Highlights

- PHEMA cryogels were prepared *via* cryopolymerization
- PHEMA cryogels were used as the cell entrapment carriers during *L. paracasei* fermentation
- Higher cell concentration using cryogels was observed than that without cryogels
- Dried cell concentration of 5.32 $g \cdot L^{-1}$ was achieved

1. Introduction

The bioproduction of high-value organic acids like phenyllactic acid (PLA) *via* microbial fermentation or biotransformation has received increasing attentions in biological and biotechnology fields in recent years. [1-4] During these processes, the culture of cells at high-cell-density to increase the total biomass concentration in the broth is of great important to the yield, the conversion rate and the productivity. In this work, the poly(2-hydroxyethyl methacrylate) (pHEMA) cryogels were prepared by cryo-polymerization under freezing conditions. The obtained cryogels were used the cell entrapment carriers during *L. paracasei* fermentation towards the production of PLA. The morphology and the cell concentration during the fermentation process were investigated experimentally.

2. Methods

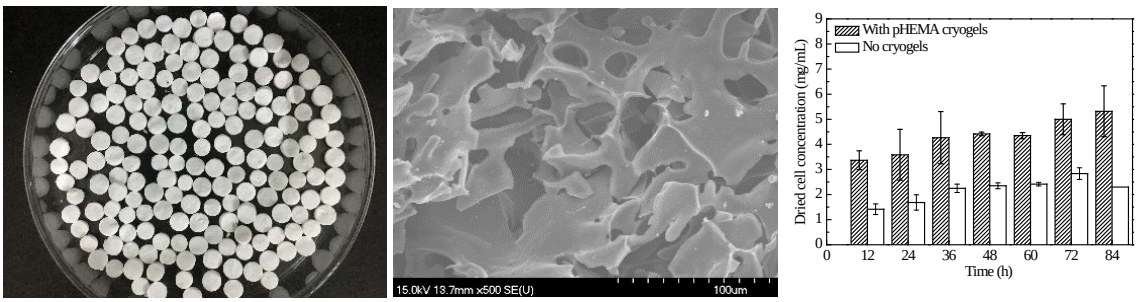
Monolithic pHEMA cryogels were prepared by cryo-polymerization. Typically, the reactive solution containing HEMA (11.6%, w/w) and poly(ethylene glycol) diacrylate (PEGDA, 3.5%, w/w) initiated by TEMED and APS (both with the mass ratio of 4% to the total mass of HEMA and PEGDA) was poured into glass columns with inner diameter of 4-6 mm and height of 100 mm. Free radical cryo-polymerization was conducted under freezing condition for 48 h to get the cryogel.

The cryogels were cut into pieces with height of about 3-5 mm and used as the cell carriers. *L. paracasei* 16C3 strain was cultured in MRS medium with and without cryogel pieces and the cell mass was measured at given time intervals. The pore morphology of the cryogel was investigated by scanning electron microscope (SEM, S-4700, Hitachi, Japan). The samples were cut from the

middle of the sample columns, directly dehydrated using an ethanol-water solution (10-30-50-70-80-90-99.5%), dried at critical point, coated with gold and then observed by SEM.

3. Results and discussion

The results showed that pHEMA cryogels have supermacropores with the sizes from several to 200 μm. These pores provided enough void space for the growth, entrapment and deposition of microbial cells during fermentation processes. The cryogel carriers permit more surfaces for the attachment and deposition of cells and also contributed to the reduction of the substrate inhibition during cell growth. The cell concentrations by using these cryogels as the carriers were higher than those without cryogels for the growth of *L. paracasei* 16C3 strain in MRS medium. The maximum cell concentration of about 5.32 $g \cdot L^{-1}$ in the fermentation broth was achieved, as shown in Figure 1(a), indicating that the cryogels could be used as potential and interesting cell carriers for high-cell-density fermentation and bioconversion.



(a) (b) (c)

Figure 1. (a) Morphology of pHEMA cryogel carriers, (b) microstructure within the cryogels an (c) cell concentrations with and without cryogels during the fermentation of *L. paracasei* 16C3 in MRS broth for the production of PLA.

4. Conclusions

PHEMA cryogels were interesting cell entrapment carriers and can be used for the high-cell-density culture of microbial strains like *L. paracasei* 16C3 for the production of bio-based organic acids. The concentration of cells using cryogels as the cell carriers can be increased to twice the biomass in traditional fermentation without cryogels.

Tailoring hydroxyapatite powder properties for 3D printing based on selective laser melting or sintering

Pedro Navarrete-Segado[1, 2*], David Grossin[2], Mallorie Tourbin[1], Christine Frances[1]

1 Laboratoire de Génie Chimique, Université de Toulouse, CNRS, Toulouse, France ;

2 CIRIMAT, Université de Toulouse, CNRS, Toulouse, France

Highlights

- The hydrodynamic parameters mainly impact agglomerates size distribution.
- Pure HAP can be produced ensuring relevant physicochemical conditions.
- An absorbing additive such as graphite may be used to increase HAP powder absorptance.

1. Introduction

The selective laser melting/sintering (SLS/M) as promising additive manufacturing (AM) technique allows the shaping of bioceramic parts as patient matched tissue engineering materials. These parts must have complex structures and ideal properties, like bioactivity and biocompatibility to ensure a good osseointegration/osseoincorporation of the implants, as well as good mechanical and chemical resistance. However, a deeper study of ceramic feedstock properties to achieve a better laser-material interaction during the shaping of the parts is essential to obtain an accurate control of the porosity, interconnected pores and to avoid the formation of cracks. For that, the production of nano-structured agglomerates is required in order to increase the surface and thus the reactivity required for effective sintering while keeping suitable flowability and dispersing properties. [1] Besides, ceramic powders absorptance at Nd-YAG laser wavelength (1.06µm) is not enough to produce a suitable heat/matter exchange between the particles to trigger the material densification. Improving the laser radiation absorption by means of use of absorbing additives is also of particular interest. [2, 3]

In this communication, we discuss the relationship between the hydroxyapatite (HAP) powder properties and the synthesis process parameters. Optimal purity, aggregate size distribution, and morphology of powder have been tailored in order to improve the laser-material interaction during 3D printing process of ceramic parts. Moreover, the influence of a commercial graphite (TIMREX KS44) as absorbing additive in the absorptance of HAP powder at Nd-YAG laser wavelength has been studied.

2. Methods

A scale-up of the HAP synthesis process was realized from a 1L reactor to a reactor of 4L. The precipitation of hydroxyapatite results from the reaction at a high temperature of phosphoric acid and calcium nitrate in an aqueous ammonia medium:

$$10Ca(NO_3)_2,4H_2O + 6(NH_4)_2HPO_4 + 8(NH_4)OH \rightarrow Ca_{10}(PO_4)_6(OH)_2 + 20NH_4NO_3 + 6H_2O$$

A double-jacketed cylindrical glass vessel, and three glass containers for the reactants (calcium nitrate, phosphoric acid and ammonia) compose the lab-scale apparatus. Initially a given volume of an aqueous solution of calcium nitrate is put into the reactor, then raised at the desired temperature for the synthesis. During a first period of the synthesis process, only ammonia is fed in order to increase the pH of the solution inside the reactor. Then during a second period, in which the synthesis itself is performed, the three solutions are continuously fed. At the end of the synthesis, the feeding of the reactants and of the ammonia solution is stopped but the system is maintained under stirring at high temperature during a maturation phase. Finally the reactor is drained, the particles are washed, during the suspension filtering itself done by suction through a Buchner funnel using a filter paper. The filtration cake is then freeze dried and calcined at 1000°C during 10 hours into an oven. This final step allows the drying of the crystallized HAP and the removal of any remaining impurity. For analysis purposes, samples are collected all along the process, as slurries to allow particle size distribution measurement, or as dried or calcined powders, to characterize the HAP purity.

Analysis of powder microstructural, chemical and physical properties was done by X-ray diffraction, FTIR, morphometer and SEM. The influence of the graphite (TIMREX KS44) as absorbing additive is studied by preparing different mixtures with the synthesized HAP and a mass of graphite in the range of 0% and 2.5% by mechanical mixing and measuring the absorptance at Nd-YAG laser wavelength.

3. Results and discussion

The effect of the stirring rate applied and the reactants flow rates was studied by analyzing the product recovered at the end of the synthesis process using different rates and different synthesis durations. The results showed that both parameters are closely related with the aggregate size distribution of the final product. A rather high stirring rate is needed to properly mix the reactants and get a product with a narrow size distribution around a few microns. The whole duration of the synthesis can be adjusted without affecting the product chemical purity ensuring a relevant pH regulation. A value of absorptance higher than 40% was observed from the mixture containing a proportion of 0.75% of graphite mass onwards showing promising results.

4. Conclusions

Stoichiometric HAP synthesis was studied varying physico-chemical and hydrodynamical conditions and analyzing their effect both on agglomerates size distribution and product chemical composition. The change in the absorption by graphite mixing was also analysed. A small proportion of graphite in the mixture is enough to obtain an absorption value close to the one observed in metal powders often used in SLS/M and it is expected to be higher enough for the use of the ceramic composite powder in AM technologies.

Synthesis and characterization of pitch from pyrolysed fuel oil (PFO)

Chul Wee Lee[1,2*], Seunghyun Ko[1,2], Jong-Eun Choi[1,2], Ji Sun Im[1,2], Young-Pyo Jeon[1,2]

[1] *Carbon Resources Institute, Carbon Industry Frontier Research Center, KRICT, Republic of Korea*

[2] *Adv. Materials and Chemical Engineering, University of Science and Technology, Republic of Korea*

**Corresponding author: chulwee@krict.re.kr*

Highlights

- Pitch was synthesized as a function of temperature in the range of 390-410°C.
- Pitch was identified by XRD, TGA, MALDI-TOF, EA, softening point analysis.
- Pitch showed enhanced stacking height (Lc), and C/H indicating graphitic structure.
- To control the softening point of pitch, a modified thermal treatment was studied.

1. Introduction

Petroleum residues can be used as a feedstock to prepare pitch which is one of a main precursors for the production of carbon materials [1]. The pitch characteristic is an important factor because the properties of carbon materials can be determined by the chemical and physical characteristics of pitch, which are classified as mesophase contents, solubility by organic solvents, softening point, chemical compositions, and molecular weight distribution (MWD) [2] etc. Previously, air-blowing is a simple and effective way to increase the softening point [3]. In this work, PFO based pitch was prepared by thermal reaction in the range of 390-410°C as a function of time, and the basic chemical/physical properties were characterized. Based on the results of MWD, a chemical reaction was suggested the changes of each molecular weight fraction during the thermal reaction. And also oxidative thermal treatment of pitch with O_2/N_2 mixture gas was investigated as an efficient way to increase softening point of pitch without loss of pitch yield. It is expected that using gas with a higher O_2 concentration than air would be a better effective way to increase softening point because a higher O_2 concentration could enable the condensation reaction to progress at lower gas flow rate, suppressing the volatilization of light components that can minimize the pitch yield.

2. Methods

PFO (Yeochun NCC Co., Korea) was used as a feedstock. 7,7,8,8-tetracyanoquinodimethane (TCNQ) was used as a matrix for MALDI-TOF analysis. The pitch synthesis reaction was conducted with a 1L scale batch type autoclave with the following procedure (1) 500g PFO was placed in the reactor, (2) 200cc/min of N_2 was injected for 30min, (3) the reactor was heated and the detailed reaction conditions and summarized in Table 1 In order to modify pitch properties, O_2 and/or N_2 containing gas was blown into the reactor with a flow rate of 0.5L/min at 360°C for 5hours. Treated pitch was identified by EA (Thermo Scientific FLASH EA-2000), XRD (Rigaku Ultima IV), softening point (DP-70, Mettler Toledo), MALDI-TOF (with Autoflex MALDITOF mass spectrometer).

3. Results and discussion

Table 1. Experimental conditions for synthesizing pitch from PFO

Sample	Reaction conditions					
	T (°C)	t (h)	P (P)	N_2 flow (cc/min)	Pitch yield (%)	Volatile mass (%)
P-390	390	1	1	100	28.9	67.5
P-400	400	1	1	100	26.5	68.3
P-410	410	1	1	100	25.4	69.2

The pitch synthesis reaction was considered with MWD variation relative to the area fractions as shown in Figure 1 [4]. Low boiling point components were emitted due to the volatilization during the thermal reaction or converted to the high molecular weight area fraction by means of condensation and polymerization reaction. The softening point increased linearly with vac. distillation time, as shown in Figure 2, the softening point was further increased with increasing flow rate reaching at 282°C. Heat treatment of PFO under inter condition at 360oC for 5h produced a pitch with a softening point of 130°C and a yield of 34.0%. In order to suppress the loss of pitch yield, O_2 concentration was increased rather than rather than increasing the flow rate of reaction mixture gas. When the O_2 concentration was increased to 35%, the softening point increased to 249°C [5].

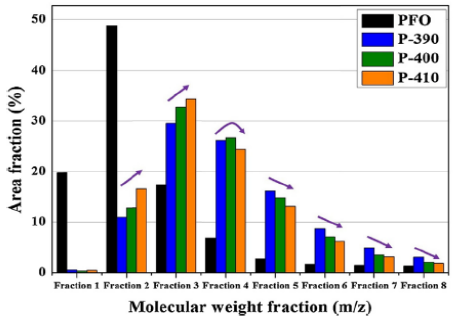

Figure 1. Diagram of the molecular weight fraction divided by the pseudo-component.

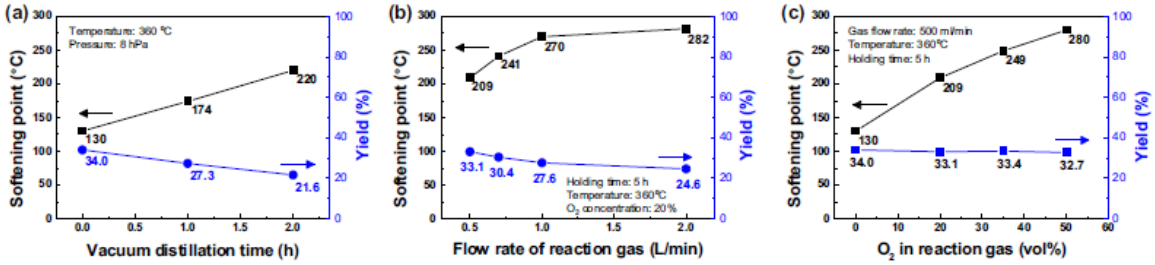

Figure 2. Softening point and yield variation of pitches prepared by thermal treatment as a function of (a) vacuum distillation time, (b) flow rate of reaction gas and (c) O_2 concentration of reaction gas.

4. Conclusions

(1) The empirical pitch synthesis reaction from PFO was carried out to reveal the physical and chemical properties of the feedstock and produced pitch. (2) The treatment was highly effective at increasing the softening point while maintaining high pitch yield by oxidative thermal condensation and suppressing volatilization of light components.

Experimental and analytical study of heat transfers in granular media

Viet Dung NGUYEN, Christophe MARIE

Laboratoire des Eco-PRocédés, Optimisation et Aide à la Décision, EPROAD EA 4669,

IUT de l'Aisne, 48 rue d'Ostende, Saint Quentin 02100, France

Highlights

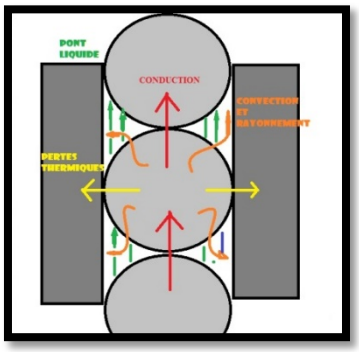
- Thermal transfers in granular media
- Experimental data
- Analytical study

1. Introduction

Granular media are generally biphasic or triphasic, with a solid phase and a gaseous or/and liquid phase, and are characterized by their porosity. Particle size, shape, distribution, and pore size are parameters that characterize the microstructure of a granular medium and have a consequent impact on fluid flow, fluidization behavior or mechanism of heat transfers... The present paper aims at presenting an experimental and analytical study of heat transfers in granular medium which have an important impact for many industrial processes as well as powder metallurgy, chemical reactors, food technology, thermal insulation or even simply storing particles in a silo after drying. However, few studies in the literature are interested in the understanding of heat transfers across contact area between particles or particle/wall (conductance). In this research, we firstly present an experimental campaign. Then, an analytical approach is proposed by using the iterative procedure of energy balance. Finally, the experimental data coupled with the analytical results is used to identify the thermal conductance.

2. Method

The experimental setup, as shown schematically in figure 1, consisted of a column of 11 steel spheres of same diameter of 20 mm arranged vertically in a insulated tube. The first sphere is heated at 50°C and the temperature evolution of other spheres are measured.



In the literature, the models for calculating the thermal conductivity of condensed or loose granular media have been developing for a few decades now. Most of the models proposed are generally simple models of the type series, parallel, or combination of the two, which do not take into account the constriction of thermal

flux lines. We have therefore developed a theoretical model for calculating the thermal conductivity of a stack of identical spherical particles by their diameter and composition. The principle of this model is the determination of the evolutions of the apparent thermal conductance according to the power and the heating time, and the stabilization of the transfer regime. This assessment, based on the obtaining of an analytical solution that binds thermal and mechanical behavior over time, allowed us to make comparisons between analytical and experimental measures.

3. Results

The following results present the comparison between experimental and analytical temperatures propagating through a pile of 5 heated spheres (among 11) under mechanical stress.

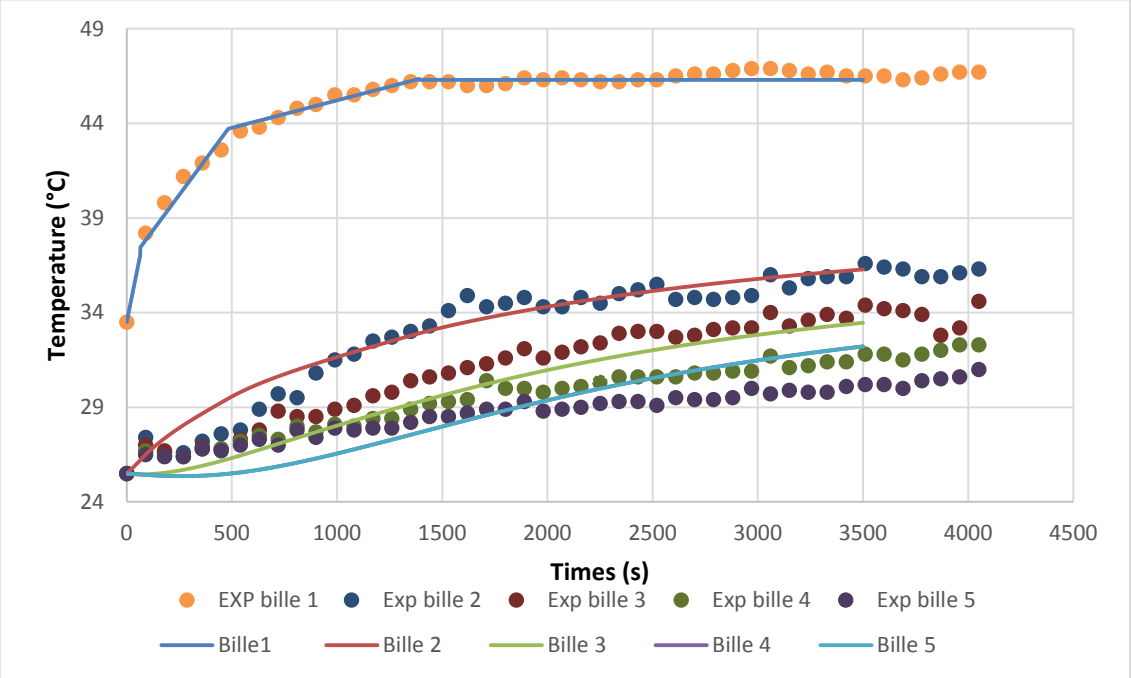


Figure 1. Experimental and numerical comparison of the temperature increase of a pile of spheres under mechanical stress

The graph shows that the numerical curves of spheres 4 and 5 (far from heat source) are confusing. The numerical curves of spheres 1, 2 and 3 are quite distinct, and are nearly superimposed with their experimental counterparts. While the experimental variations are clearly visible in the graph, the analytical variations are less and less precise and confirm the existence of a limit to the numerical model. However, these first results are promising, and will be completed by a Discrete Elements Method (DEM) comparison.

Highlights

- Microwave radiation shortens the reaction time for the etherification of glycerol to polyglycerols.
- New emulsifiers based in polyglycerol were synthesized.
  It is possible to produce emulsifiers with different functional properties by varying characteristics such as degree of polymerization and electric charge.

1. Introduction

The conversion to valued-added chemicals of the glycerol co-produced in the growing biodiesel industry is nowadays a focus of global research and a topic of great industrial importance. Among different approaches, the glycerol polymerization emerges as a promising alternative, leading to the formation of Polyglycerol (PG). Moreover, polyglycerol has been used as raw material for the production of polyglycerol esters, which are widely used as emulsifiers in different industries [1].

The properties of the emulsifiers and their particular applications depend on their structure. In the case of polyglycerol esters, it is possible to produce emulsifiers with different functional properties by varying characteristics such as the degree of esterification [2]. However, those properties are not only determined by the hydrophobic tail but also by the hydrophilic head features, for instance, the size or degree of polymerization and the electric charge.

In this work, we synthesized new emulsifiers based in PG and also analyzed the effects of degree of polymerization of polyglycerol and the cationic charge by Lysine amino acid addition on the emulsifying properties of polyglycerol esters The degree of polymerization leads to the synthesis of polymers with a variation of molecular weights and pendant hydroxyl groups. Meanwhile, the positive charge gives to the polymers the ability to absorb on negatively charged substrates to produce an antistatic and hydrophobic effect which is useful for a range of applications such as softeners and anti-static additives in textiles and, bitumen emulsifiers due to their compatibility with a range of aggregates [3].

2. Methods

Microwave radiation was used as the heat source in the synthesis of polyglycerol esters to reduce the reaction times compared to conventional thermal heating [4]. In order to form polyglycerol with different degrees of polymerization, the reaction was first carried out up to the gel point, i.e., an infinite polymer network first appears and the polymerization system loses its fluidity drastically.

After the termination of the gel point time, a polyglycerol sample was collected every 30 percent of the previously determined gel point. Polyglycerols with different degree of polymerization were characterized by Fourier transform infrared spectroscopy (FTIR) to confirm their chemical structure, the hydroxyl numbers were calculated according to ASTM D 4274-11 Test Method A, and molecular weight distributions were obtained using High-Performance Liquid Chromatography (HPLC) measurements.

Polyglycerol esters were synthesized using a proposed strategy of prepolymers complexes addition. Those complexes consist of glycerol esterified with (i) oleic acid and (ii) Lysine. This strategy was followed to guarantee the successful esterification of PG with each of these components. Infrared measurements confirmed the chemical structure of the synthesized complexes and their esterification reactions with PG. The hydrophilic-lipophilic balance (HLB) values of the emulsifiers from polyglycerol esters were calculated. Microscopy techniques studied the type of the resulting emulsion. The rheology, surface, and interfacial properties were also evaluated. The stability of emulsions, one of the more critical factor to be considered in the emulsion technology, was investigated and discussed at different concentrations of emulsifier and water-oil ratios (WOR) of emulsions. To measure emulsion stability, we used the half-life period.

3. Results and discussion

Polyglycerols with different degree of polymerization were synthesized. FTIR Results showed that functional groups presented in the reaction polymerization products are the same as polyglycerol functional groups identified in previous research studies [5]. Multimodal weight distributions were observed for all samples, and the number-average molecular weights and weight-average molecular weights showed an increase with the reaction time while the number of hydroxyl groups exhibited an expected decrease due to the progress of the polymerization. The esterification of polyglycerol with oleic acid and Lysine, through the proposed strategy of the addition of complexes, was corroborated by FTIR spectroscopy with the appearance of the bands associated with ester bonds. The hydrophilic properties of the emulsifiers increased with the molecular weight of polyglycerol. The degree of polymerization and the presence of the amino group in the modification of the PG determined the final characteristics of the type of emulsion, varying from the formation of W / O emulsions to O / W emulsions. The emulsions presented good stability that was examined using palm oil as the oil phase and distilled water as the aqueous phase.

4. Conclusions

The current study took advantage of the heating by microwave radiation in shortening the reaction time required for polymerization of glycerol. New emulsifiers were obtained from polyglycerol esters with fatty acid and amino acid. It was found that the structure of Polyglycerol ester emulsifiers could be tailored to stabilize different emulsion systems. The degree of polymerization and the amino group addition to polyglycerol esters influence the emulsifying Properties. Therefore, emulsifying properties of synthesized polyglycerol esters can be easily adjusted for target applications, this being of great interest for the industry of emulsion based products.

Segregation Modeling in the Course of rapid gravity Flow of particulate Solids on a vibrated rough Chute

Viktor Dolgunin[1]*, Andrei Kudi[1], Oleg Ivanov[1], Alexander Tarakanov[1], Vasilii Pronin[1]

1 106 Sovetskaya street, Tambov state technical university, Tambov, 392000, Russia

Highlights

- One experimental kinetic constant needs to model segregation on size-density.
- The less vibration frequency the greater interdiffusion-induced migration.
- Segregation on size dominates in the area of high solid fraction plateau.

1. Introduction

Earlier [1] the profiles of velocity, fraction of the void volume and test particle distribution in rapid gravity flows of granular materials on a vibrated rough chute were investigated experimentally. In the present paper the profiles of test particle distribution in the flow of binary granular mixtures consisting of particles differing in size and density are calculated analytically. The earlier obtained profiles [1] of velocity and fraction of the void volume are used for the mathematical modeling. As a result the vibration influence of high and low vibration frequencies on segregation dynamics and basic segregation mechanisms in rapid gravity flows of particulate solids are studied analytically.

2. Methods

The mathematical modeling was carried out on the basis of a general equation of segregation dynamics [2, 3]. In the case of the steady state of two-dimensional rapid shear flow this equation takes into account the fluxes of test particles caused by convection in the shear direction *x*, quasidiffusion mixing, interdiffusion-induced separation (migration) and segregation in transversal direction *y*. The general equation of segregation dynamics with the above mentioned fluxes describes the distribution of test particles $c(x,y,t)$ in the following way

$$\frac{\partial(c\rho_b)}{\partial t} = -\frac{\partial(uc\rho_b)}{\partial x} + \frac{\partial}{\partial y}\left[\rho_b\left(D_{dif}\frac{\partial c}{\partial y} - cD_m\frac{\partial \ln s}{\partial y} - K_S c\Delta M\right)\right], \quad (1)$$

where t - time, $u(y)$ – mean velocity towards shear direction x, s – mean distance between particles, ρ_b – bulk density, ΔM – driving force of segregation (total excess moment of forces of friction, gravity and impact moments, acting on a test particle), D_{dif}, D_m, K_S – coefficients of quasidiffusion mixing, migration and segregation respectively.

The kinetic characteristics D_{dif}, D_m, ΔM are calculated analytically as functions of shear rate, void volume fraction, concentration of particles $c(x,y,t)$ and their physical and mechanical properties [3]. Only the segregation coefficient K_S is determined experimentally as the velocity of a test particle towards *y*-direction per unit driving force of segregation ΔM [2, 3]. It was found out [2] the segregation coefficient has properties which characterize K_S as the kinetic constant for wide range of flow parameters and particle characteristics. Boundary conditions for eq. (1) are formulated as the flux absence of particles through the bed boundaries (free surface and bed bottom). During the mathematical modeling the general equation of segregation dynamics (1) with the boundary conditions had been integrated numerically.

3. Results and discussion

Figs. 1 and 2 show the experimental and calculated distributions of large and light particles as well as the profiles of fraction of the void volume. The adequacy of the experimental and analytical results creates conditions for analysis of physical separation mechanisms.

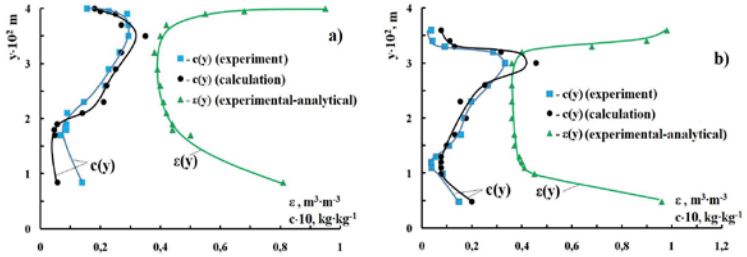

Fig. 1 Profiles of fraction of the void volume μ(y) and concentration of large particles c(y) in rapid gravity flow of binary mixture of glass beads (fractions +3.0-3.5 and +5-5.5 mm) on a vibrated rough chute (α=28.5°, a_v=2g) at vibration frequencies: a) – 15 Hz, b) – 50 Hz,

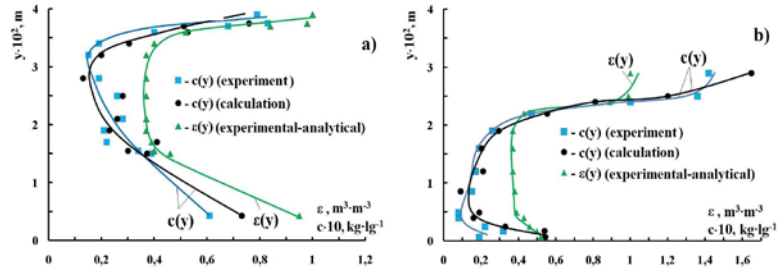

Fig. 2 Profiles of fraction of the void volume μ(y) and concentration of light particles c(y) in rapid gravity flow of particles differing in density (fraction +5-5.5 mm of glass beads and silica gel) on a vibrated rough chute (α=27°, a_v=2g) at vibration frequencies: a) – 15 Hz, b) – 50 Hz,

The combined analysis of distributions of the test particles and profiles of fraction of the void volume on the basis of the kinetics of separation fluxes in eq. (1) leads to the following conclusions. The segregation mechanism of separation dominates for particles differing in size and density when the relatively wide plateau of low values of void volume fraction is formed in the central part of the bed because of vibration of high frequency (Figs. 1-b and 2-b). Under such conditions $\partial ns/\partial y \approx 0$ and segregation of particles differing in size is most pronounced (Fig. 1-b). In the thin upper part of the bed of particles differing in density (Fig. 2-b) the effect of separation is enhanced by the coincidence of directions of segregation and migration.

On the contrary the migration mechanism of separation prevails when the relatively high gradients of the void volume fraction are formed in the most part of the bed volume under the action of low-frequency vibration (Figs. 1-a and 2-a). Under such conditions $\partial ns/\partial y >> 0$ and migration of particles differing in density is most pronounced (Fig. 2-a).

4. Conclusions

In order to study basic separation mechanisms of particles differing in size and density during rapid gravity flow on a vibrated rough chute mathematical modeling was used. It was found out that low-frequency vibration intensifies interdiffusion-induced separation (migration) and high-frequency vibration forms flow conditions conducive to segregation.

Highlights

- Compared three different antisolvents for glycine crystallisation
- Measured solubilities, metastable zone widths and induction times across metastable zones for all antisolvents
- Assessed effect of rapid antisolvent addition vs continuous mixing on induction times

1. Introduction

There has been a significant amount of research on metastable zone width (MSZW) and induction times for cooling crystallisation, while relatively little has been done for antisolvent crystallisation. Experimental data on effects that different antisolvents and antisolvent addition strategies have on nucleation behavior in antisolvent crystallisation is very limited and our understanding of these effects is sparse. In literature there has been no direct comparison of the effects of different antisolvents on induction times and only a single publication directly assesses the MSZW for different antisolvents [1]. Furthermore, only a single publication was found which investigates both induction times and MSZW for the same antisolvent crystallisation system [2]. With regards to mixing effects only a single publication was found which uses a continuous static mixer when measuring induction times for antisolvent crystallisation [3]. In this work we measured solubilities and MSZWs in the antisolvent crystallisation of glycine using methanol, ethanol and DMF as antisolvents. We then investigated induction times across the metastable zone for these antisolvents. In order to investigate the effects of mixing, induction times were measured either with rapid antisolvent addition or using a continuous static mixer.

2. Methods

Solubilities were measured by equilibration of solids with solvent mixtures under agitation and gravimetric determination of equilibrated liquid phase compositions. The MSZW were assessed under isothermal conditions by adding the antisolvent at constant flow-rate via a syringe pump to an agitated undersaturated aqueous glycine solution in an 8 ml vial. The point at which the solution became turbid was taken as the metastable limit. The MSZW was determined by measuring a series

of metastable limits starting from different initial compositions. The induction times were measured by preparing supersaturated solutions by mixing an antisolvent with an undersaturated aqueous glycine solution, either by rapid antisolvent addition or using a continuous static mixer. Induction times were recorded under agitated isothermal conditions in 8ml vials. The static mixer had a 1/8 inch internal diameter.

3. Results and discussion

Figure 1A shows the comparison of induction times within MSZs for the three different antisolvents using batch rapid antisolvent addition. For these antisolvents, there was a little difference between induction times at similar supersaturations. At lower supersaturations induction times were very long as expected. However, at higher supersaturations induction times were relatively short, similar among different antisolvents and only weakly dependent on supersaturation. This indicates that crystal growth and secondary nucleation may become rate limiting factors in observed induction times as supersaturation increases. Investigation of mixing effects showed that using continuous mixing with the ethanol antisolvent decreased the induction times by up to one order of magnitude compared to batch rapid antisolvent addition while using continuous mixing with the methanol antisolvent increased the induction times by up to two orders of magnitude (Figure 1B).

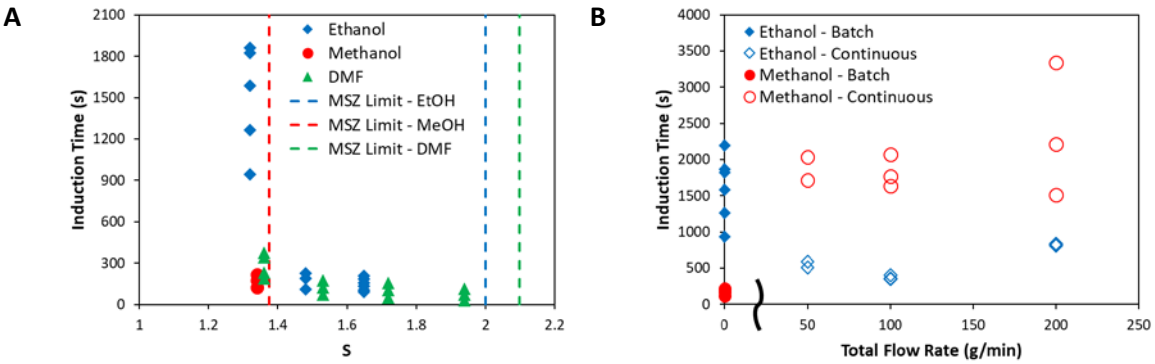

Figure 1. A) Induction time measurements for different antisolvents in batch rapid antisolvent addition. B) Comparison between batch rapid antisolvent addition and continuous static mixing (total flow rate = 0 is batch).

4. Conclusions

Well defined induction times were measured across MSZs which shows that primary nucleation is present at much lower supersaturations than those identified in conventional metastable zone width measurements. At higher supersaturations other factors become rate limiting, including crystal growth and secondary nucleation, which may need to be considered when interpreting induction time data in terms of primary nucleation kinetics as is commonly done in the literature. Induction times are strongly dependent on the mode of mixing (batch rapid antisolvent addition vs continuous mixing) which shows that appropriate mixing strategies are crucial for rational development of robust scalable antisolvent crystallisation processes.

Highlights

- Workflow approach to distinguish between different mechanisms of impurity incorporation
- Impurity rejection during crystallization studied in three pharmaceutical systems
- Incorporation into the crystal lattice is experimentally observed using X-ray diffraction

1. Introduction

Crystallization is a purification technique used across the pharmaceutical sciences and industries. Ideally, the solid product is composed of one single target compound with all other chemical entities remaining in the liquid phase for disposal. In reality, however, this can be difficult to achieve. Due to strict control of impurities in pharmaceutical products, even a small miscibility can be a cause for serious concern.

Unwanted compounds, such as structurally similar organic impurities, have many mechanisms to end up in the isolated solid product. Particularly difficult to overcome is solid-phase miscibility of target compound and impurity, which results in impurity incorporation into the crystal lattice and very little impurity rejection. Here we present a workflow development approach to rapidly identify the mechanism of impurity incorporation, and demonstrate one case of significant solid miscibility.

2. Methods

Small scale cooling crystallizations were designed and carried out using the Technobis Crystal16 and Crystalline systems. The resulting solid material was analyzed using multiple physical characterization methods. Crystal purity was measured using an Agilent 1100 HPLC, and using this data the distribution and selectivity coefficients were calculated. The melting temperature of solid materials were determined using differential scanning calorimetry on a Netzsch DSC214 Polyma, enabling binary phase diagrams and Tamman plots to be constructed. Plate powder X-ray diffraction patterns of recrystallized samples were collected using a Bruker AXS D8 Advance II diffractometer, and the unit cell dimensions determined using Pawley refinement methods.

3. Results and discussion

A series of cooling crystallizations of paracetamol in the presence acetanilide and metacetamol revealed the two structurally similar impurities have different rejection/incorporation behavior.

Especially for metacetamol the crystallization does not result in a sufficiently improved solid product purity. The experimental distribution coefficients for these crystallizations was found to vary with increasing the amounts of impurity ($K_{metacetamol}$ = 0.05 to 0.41, $K_{acetanilide}$ = 0.06 to 0.12), and the same trend was observed in the experimental selectivity coefficients.

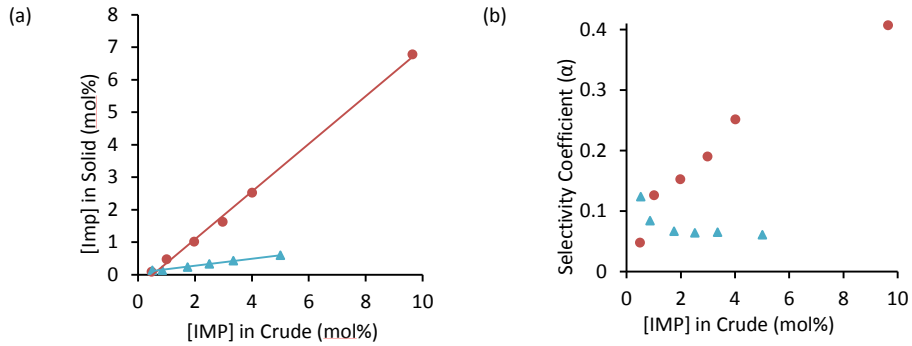

Figure 1. (a) Purification efficiency of crystallizations as measured by HPLC. Grey dashed line indicates no purification. Metacetamol (circles) linear regression y = 0.735x - 0.386, R^2 = 0.998. Acetanilide (triangles) linear regression y = 0.107x - 0.060, R^2 = 0.996. (b) The amount of impurity incorporation affects the selectivity coefficient of the crystallisations.

Investigating further, it was found that metacetamol incorporates into the paracetamol crystal lattice in significant amounts. X-ray powder diffraction revealed this incorporation modifies the crystal unit cell, with an elongation of one vertex and increase in cell volume thought to accommodate the intruding impurity molecule. The construction of Tamman plots for each binary system indicated a partial solid miscibility between paracetamol and metacetamol of 6.7 ± 2.1 %, further supporting the incorporation of the latter into the API crystal lattice.

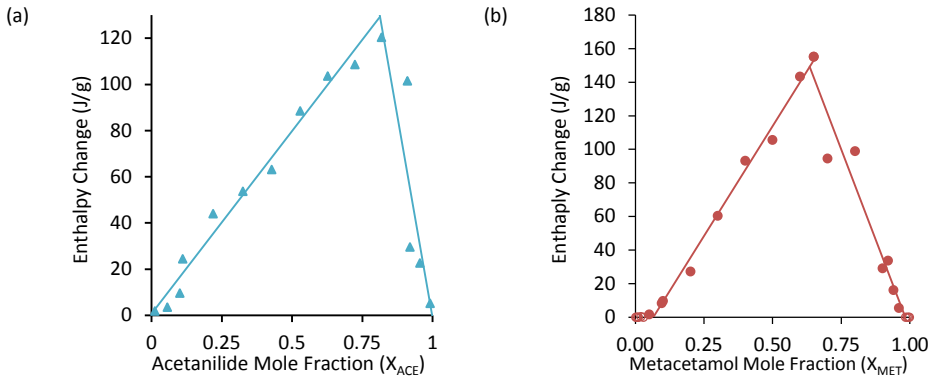

Figure 1. Tamman triangle plots. (a) Paracetamol-acetanilide. LHS regression y = 158.2x + 0.7, R^2 = 0.979, x-axis intercept = 0.002 ± 0.020. RHS regression y = -699.1x + 697.9, R^2 = 0.780, x-axis intercept = 0.981 ± 0.025. (b) Paracetamol-metacetamol. LHS regression y = 261.8x – 17.1, R^2 = 0.992, x-axis intercept = 0.067 ± 0.021. RHS regression y = -429.1x + 421.7, R^2 = 0.923, x-axis intercept = 0.972 ± 0.037.

This methodology has been formulated into a workflow and applied to two other systems; fenofibrate and mefenamic acid. These specific pharmaceutically relevant molecules have impurities which are difficult to remove using cooling crystallization techniques.

4. Conclusions

By utilizing physical characterization techniques, the mechanism of impurity incorporation during a cooling crystallization is determined. The specific incorporation of metacetamol into the paracetamol crystal lattice is due to partial solid miscibility, and so this impurity very difficult to remove by cooling crystallization.

Particle comminution in stirred media mill and high-shear impeller – modelling and experimental approach

Norbert Wiatr[1], Radosław Krzosa[1], Radosław Adamek[2], Wojciech Orciuch[1*], Łukasz Makowski[1]

1 Faculty of Chemical and Process Engineering, Warsaw University of Technology, Warsaw, Poland; 2 ICHEMAD-Profarb, Gliwice, Poland

**Corresponding author: Wojciech.Orciuch@pw.edu.pl*

Highlights

- Particle comminution in stirred media mill and high-sheer impellers
- Influence of geometry and process parameters on the ultra-fine grinding process

1. Introduction

Size reduction process is crucial in many branches of the industry. It is commonly used in pharmaceutical, paint, cement, pyrotechnical industries and many others. Important problem is choosing the right parameters which will allow to optimize the cost of such an operation [1, 2].

In this work authors consider de-agglomeration and breakage process in two characteristic systems. The first device is a tank mixer equipped with a high-shear impeller. This type of agitators is usually high-speed and occur in the form of discs with protrusions to break up solid particles. The second device is stirred media mill that is one of the apparatus designed for ultra-fine grinding. The basic parameters describing the mixing process are: the amount of energy that is supplied into the fluid in a time unit by the mixer, mixing time, shear stresses, solids concentration and energy dissipation rate. The intensity of mixing, the speed of circulation and the presence of dead zones are also important in description of the mixing process. In stirred media mill the suspension mass flow, milling media size and material and mill geometry needs to also be considered. The set of these parameters allows to analyze the mixing process in terms of product quality and process economy [3, 4, 5]. Computational fluid dynamics is a convenient and fast tool for determining the influence of process parameters and system geometry on the considered process. It could reduce the cost of process optimization by reducing the number of experiments.

2. Methods

The systems geometries were created using SolidWorks software. Next for computational simulations the Ansys Fluent 19 software was used. To obtain detailed information of the hydrodynamics generated by the rotating element the multiple reference frame (MRF) approach was used. Turbulent flow k-ε and VOF models were used. It was checked that the results of the computations were not sensitive to a further increase of the number of computational cells. The SIMPLE method was used for the pressure-velocity coupling and the second-order discretization schemes were used for all variables to minimize numerical diffusion effects. The computations were regarded as satisfactorily converged when the total normalized residuals were smaller than 10^{-6}.

In breakage experiments silica (SiO_2) or titanium oxide (TiO_2) particles suspended in water were used. The particle sizes distributions during process time were determined using Beckman&Coulter LS 13320 device.

3. Results and discussion

In this work we consider the influence of rotational speed, mass flow of suspension and mixing time on the dispersion and comminution processes. Additionally, in the case of a tank mixer, changes in the shape of the impeller were considered, while in the case of the mill the number and shape of the holes in the rotating discs were tested. In all cases global parameters of the system were determined as mixing power, mixing time, effective pumping number. Simulations for both studied systems were validated by comparison with experimental data obtaining a good agreement. Example of such simulation results is shown on fig. 1.

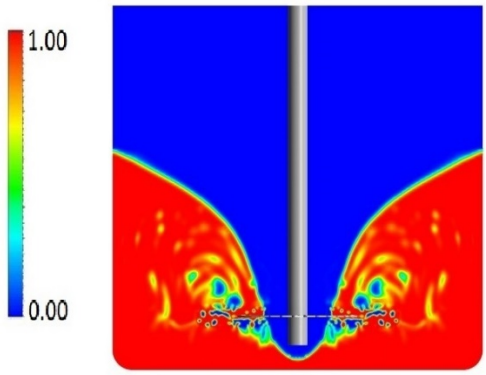

Figure 1. Volume fraction of suspension in tank mixer N=1000 rpm

4. Conclusions

Numerical simulations and experiments were carried out in order to gain influence of process parameters on comminution in two systems. Studying characteristic quantities as the power number or mixing time showed that the grinding process can be controlled by influence of the volume of the region of effective dissipation rate and particles residence time in this region. The obtained results help to predict better comminution conditions which may be useful especially when increasing the scale of process.

Granular vertical bladed mixer: flow patterns and homogenization

Martin Kozakovic[1*], David Kramolis[1], Tereza Travnickova[2], Petr Stanovsky[2], Martin Kohout[3], Jaromir Havlica[1,2]

1 University of Jan Evangelista Purkyne in Usti nad Labem, Ceske mladeze 8, 400 96 Usti nad Labem, Czech Republic, 2 Institute of Chemical Process Fundamentals Czech Academy of Sciences, Rozvojova 2/135, 165 02 Prague, Czech Republic; 3 University of Chemistry and Technology Prague, Technicka 5, 166 28 Prague, Czech Republic

**Corresponding author: martin.kozakovic@gmail.com*

Highlights

- Formation of primary and secondary flow patterns was analyzed
- Description of the primary and secondary flows influence on the homogenization process
- Determination of the best working conditions for homogenization process

1. Introduction

This contribution is focused on mixing dynamics and homogenization process during mixing of the dry granular material. Inasmuch as a granular flow is a very complex problem, it is still intensively researched. Our motivation is to interpret the complex behavior of the granular flow and to describe the connection between dynamics of primary and secondary granular flows and the homogenization process during the convection mixing mechanism. The results presented here are the continuation of our previous publishing activities[1-3], which were particularly focused on the description of the secondary flow formation during the mixing process.

2. Methods

This contribution deals with numerical simulations and experimental measurements of the granular mixing process in a vertical cylindrical mixer with two opposed flat blades with a 45° rake angle. The mixing process was performed for 42212 monodisperse colored spherical glass particles with 2 mm diameter and three limit initial packing configurations: tangential (side-by-side), axial (bottom-up) and radial (inside-outside). The blade rotational speed was changed from 0.1 rpm to 960 rpm. Each of simulated processes was performed for 80 stirrer revolutions. The simulation was conducted using open-source code LIGGGHTS with implemented Discrete Element Method (DEM). The experiments consisted of a borosilicate cylindrical glass vessel and bottom part was made from polyamide. The whole mixing process was recorded by color high-speed camera Redlake MotionPro X-3 with 50mm (Nikon f/1.2) lens to obtain sharp images even for higher rotational speed (with resolution 1280x1024 in speed range 30-1040 fps and exposure 722ns) [3].

3. Results and discussion

In order to better understand the behavior of the mixing process and what aspects affect the resulting process of homogenization, individual particles were tracked, force chains were visualized and also discrete quantities, such as velocity or concentrations, were transformed into Eulerian 1D,

2D and 3D fields. An important part was also the evaluation of mixing indexes, displacement characteristics and variation of the interface surface between particles of different colors during mixing process.

Especially in the first stage of the mixing process, the dominant mechanism is convection. The homogenization process takes place, when the phase interface between different types of particles significantly increases. In order to increase the interface, it is necessary for particles to move in the normal direction with respect to the interface and at the same time their mutual normal velocity has to be of different magnitude. Using different initial configurations and different blades rotational speeds, the relationship between the orientation of the phase interface and velocities of individual particles was determined. It was also described the influence of primary and secondary flows on the homogenization process. Fig. 1 presents an evolution of concentration fields for blades rotational speed 150 rpm and two different initial packing configurations (tangential and radial). For a tangential initial configuration (Fig 1a), it is possible to monitor the effect of primary flows (tangential velocity) on the homogenization process. On the other hand, Fig 1b illustrates the importance of secondary flows for mixing process especially for initial packing configuration with phase interface oriented in the tangential direction to the primary flow.

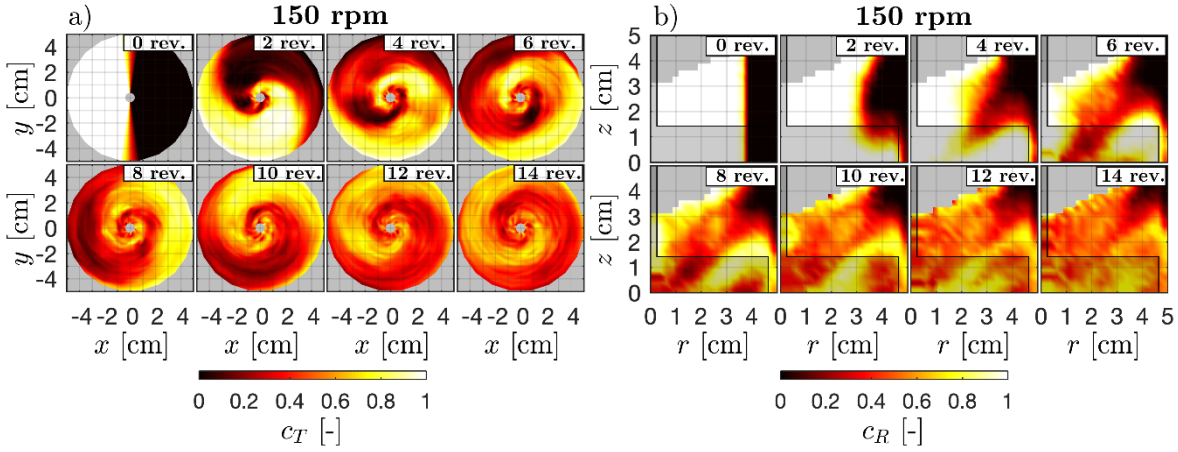

Figure 1. 2D concentration patterns for a) side-by-side and b) inside-outside initial packing. The stirrer is semi-transparent. The blades rotational speed is 150 rpm.

4. Conclusions

The mixing process of granular material in a vertical mixer with two opposed flat blades for different blades rotational speeds and initial configurations was studied by numerical simulations and experimentally. Results from simulations and experiments describe the mixing process in the same way with significant agreement in observations. This study shows the influence of both primary and secondary flows on the homogenization process. Based on these results, ideal working conditions were determined for investigated mixing process.

Single crystals of metal-organic coordination complexes by using CO_2 as antisolvent

Margarethe Roskosz*[1], Sabine Kareth[1], Bert Mallick[2], Marcus Petermann[1]

1 Chair of Particle Technology, Ruhr University Bochum, Universitaetsstrasse 150, 44801 Bochum, Germany;

2 Inorganic Chemistry II, Ruhr University Bochum, Universitaetsstrasse 150, 44801 Bochum, Germany

**Corresponding author: roskosz@fvt.rub.de*

Highlights

- Gas antisolvent crystallization of metal-organic coordination complexes.
- Tunable crystal sizes and suitable crystals for single crystal X-ray diffractometry.
- Reduction of crystallization time compared to conventional methods.

1. Introduction

In pharmaceutical and fine chemicals industries, crystallization methods are well-established for the production of solid products. The driving force in crystal formation is supersaturation. Conventional techniques such as cooling or evaporative methods are not always suitable for producing fine and pure particles. Crystallization with compressed gases or supercritical fluids seems to be a promising alternative technique. One version of this technique is the gas antisolvent process (GAS). In this method, a gas is added to a solution, loaded with the desirable substance. The solvent power of the conventional solvent decreases, while a rapid volume expansion occurs. Supersaturation triggers off the precipitation of particles. [1-2]

Research on this method was focussing on precipitation of small and uniform crystals, modifying particle properties. We would like to introduce the GAS crystallization as a possible method for producing crystals large and clear enough for single crystal X-ray diffractometry. This analytical technique provides detailed information about the internal lattice of crystalline substances and is most commonly used for identification of crystal structures. The chosen class of metal-organic coordination complexes is a quite new one, in which direct structural solutions on the molecular level are important to reveal the chemical structure obtained. [3]

2. Methods

The gas antisolvent crystallization was tested on various metal-organic coordination complexes similar to the copper complex. These results are presented as example.

Complex synthesis. 0.1 g of copper(II) acetate and the organic linker, diethyl cyanomalonate, were dissolved in a 1:2 metal:ligand molar ratio in 70 ml chloroform and stirred for 24 h at room temperature. The metal-organic coordination complex was obtained as a precipitate in powder form, that was filtered and vacuum dried for 12 h.

Gas antisolvent crystallization. For the crystallization CO_2 was used as an antisolvent. The experiments were carried out in a high-pressure view cell loaded with a solution of the metal-organic coordination complex in a chosen solvent. A crystallization time of 2 h, a pressure of 100 bar and a temperature of 40 °C were set. After the specified time, the autoclave was purged for 30 min with CO_2. The precipitate was obtained as crystals. [4]

3. Results and discussion

The GAS crystallization was performed with three different starting concentrations, but same temperature and pressure profile. The products of the antisolvent crystallization were obtained as green crystals. With decreasing the initial concentration, a decreasing average size and an increase in uniformity of the crystals can be observed. Most of the crystals were obtained with a minimum size of 50-200 µm, sufficient for single crystal X-ray diffractometry (figure 1).

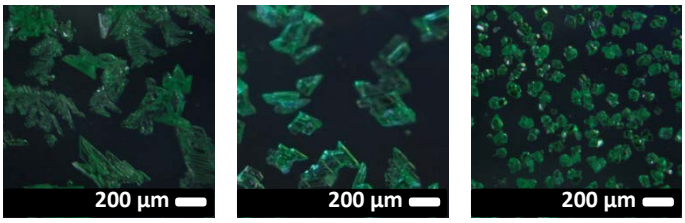

Figure 1. Microscopic images of crystals from GAS crystallization from different starting concentrations; A: 15 mg/ml; B: 7.5 mg/ml; C: 5 mg/ml.

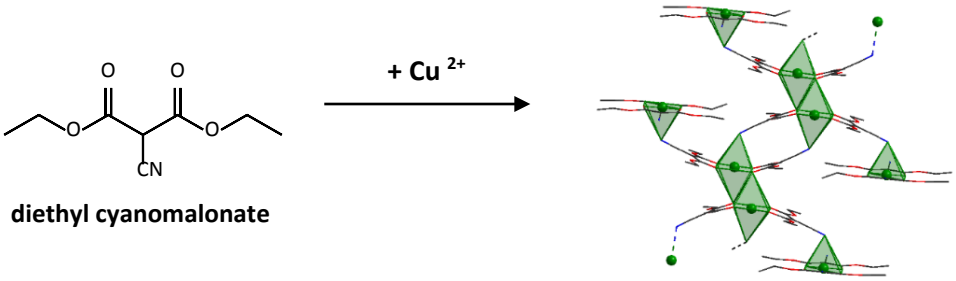
The data sets from the X-ray analysis showed that the structure of the copper complex, obtained from the antisolvent crystallization, is a one-dimensional coordination polymer (figure 2). For comparison, the same copper complex was also crystallized by evaporating the solvent at room temperature. Crystals were obtained after days to weeks, depending on the concentration and the chosen solvent. Those data sets from the X-ray analysis showed the same one-dimensional coordination polymer, like from the GAS crystallization.



diethyl cyanomalonate

Figure 2. Formation route of the copper complex build of diethyl cyanomalonate and copper(II) acetate. Molecular crystal structure obtained from single crystal X-ray data sets. (copper: green; oxygen: red; nitrogen: blue; carbon: black)

4. Conclusions

The use of CO_2 as an antisolvent opens up new possibilities for the crystallization of metal-organic coordination complexes next to other solids. It was possible to get X-ray suitable single crystals from different starting concentrations. Compared to the conventional method, these crystals were obtained just in a few hours, instead of days or weeks. In this case no structural differences have been determined. Compared to the evaporation crystallization, this method would be a possible alternative to conventional crystallization methods.

Highlights

- PHB, a biodegradable polymer was precipitated by supercritical fluid technology.
- Solvent selection is essential for the precipitation and future antioxidant inclusion
- Antioxidants were extracted and concentrated from green tea

1. Introduction

Supercritical antisolvent process (SAS) is widely being used to micronize pharmaceutical and nutraceutical compounds. The advantage of SAS over other conventional processes is that thermal degradation is avoided in the active compounds as the operating temperature is near to room temperature. Therefore, the micronization of thermally labile compounds such as antioxidants or colorants has been widely studied by SAS with carbon dioxide as antisolvent [1]. Also, by the coprecipitation of biodegradable polymers and active compounds it is possible to produce formulations with controlled release of the active compound prolonging its effect over time. The selection of the solvent is essential in this process, it must meet the solubility requirements for both the active compound, the polymer or carrier, and be miscible or form a single phase with the antisolvent fluid. On this study, two different solvents were used for an ultrasound assisted extraction of catechins and antioxidants from green tea, and to study the precipitation of a biodegradable polymer, namely Polyhydroxybutyrate (PHB) by means of the supercritical antisolvent process.

2. Methods

In the antioxidant extraction, 5.0 gr of green tea was extracted with 300 mL of the selected solvent assisted by ultrasound in an ultrasonic bath (Testlab TB04) for 30 minutes at 160 W. The total polyphenol content was quantified by the Folin-Ciocalteu. A scheme of the antisolvent precipitation process can be observed in Figure 1. In a typical experiment the whole process is filled with carbon dioxide and stabilized at the desired pressure and temperature and CO2 flowrate, then 250 mL of solution containing the polymer or active compounds is pumped into the precipitation unit, afterwards the solution inlet is stopped, and a certain amount of CO2 is introduced to remove any remaining solvent from the formed particles. The formed particles are retained by a metallic frit placed inside the precipitation unit.

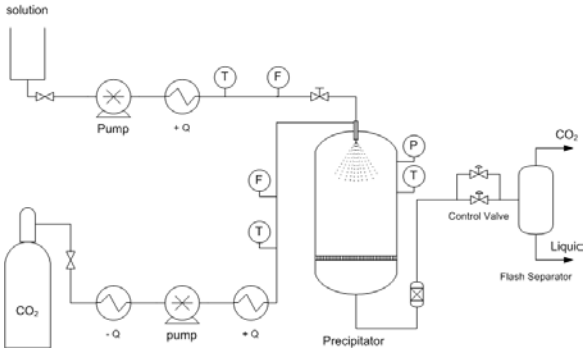

Figure 1. Antisolvent precipitation process scheme.

3. Results and discussion

The total amount of extracted polyphenols expressed as mg of polyphenol per gram of green tea was 3.02 for DCM and 126.06 for 1,3-dioxolane. The solubility of catechins in DCM is very low compared to other typical solvents like ethanol or water, however PHB has no appreciable solubility in those typical solvents. The precipitation of PHB from DCM solutions rendered particles with a mean size of 1.42 µm with a needle shape by using a pressure of 120 bar, temperature of 40°C, CO2 flow of 4Kg/h, solution flow of 1-2 mL/min and PHB concentration of 0.5 g/L. For the precipitation from 1,3-dioxolane similar operation conditions were used and concentrations of PHB ranging from 0.26 g/L to 0.75 g/L, obtaining particles with a mean size of 1.95 µm.

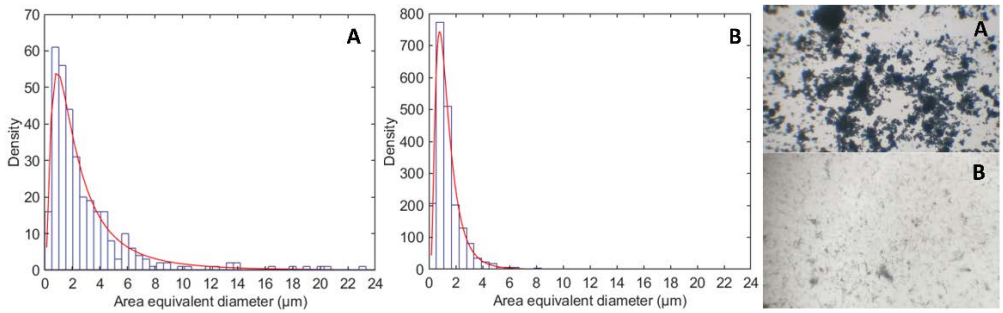

Figure 2. A) commercial PHB size distribution and morphology (left), B) particles of PHB obtained by supercritical antisolvent process from DCM solutions.

PHB microparticles obtained from SAS with DCM had a mean particle size of 1.42 µm with a variance of 0.94 µm, with represent a 53.2 % reduction on the mean size and 90.6 % reduction on the variance, compared from the commercial powder which has a mean size 3.04 µm of with a variance of 9.97 µm.

4. Conclusions

Both DCM and 1,3-dioxolane are suitable solvent for the precipitation of PHB with the CO2 antisolvent process. DCM is not as good as 1,3-dioxolane for the extraction of catechins and the later may be preferred for the coprecipitation and formation of antioxidant sustained delivery compound based on PHB.

Highlights

- Batch crystallization of fesoterodine fumarate active pharmaceutical ingredient
- Mathematical model of the process was developed, optimized and validated
- Larger, but more agglomerated particles are formed by increasing antisolvent amount
- Solubility decreases and crystallization kinetic rates increase with antisolvent amount

1. Introduction

Crystallization of active pharmaceutical ingredients (API) is one of the most important separation and purification operations in pharmaceutical industry. However, it is also one of the most complex ones, due to various thermodynamic, transport, and kinetic phenomena taking place in a heterogeneous system [1-2]. Fesoterodine fumarate is an API used to treat overactive bladder. High temperature-dependent solubility, high secondary nucleation rate, and slow crystal growth rate have been acknowledged for fesoterodine fumarate crystallization from 2-butanone in our previous work [3]. The present work examines the impact of antisolvent cyclohexane on the various properties of cooling batch crystallization of fesoterodine fumarate in 2-butanone.

2. Methods

The experimental part of the work was performed in a 2 L batch reactor. It consisted of in-line attenuated-total reflectance Fourier-transform infrared spectroscopy (ATR-FTIR) calibration of fesoterodine fumarate solutions in two different solvent compositions (2-butanone with 5 wt. % cyclohexane and 2-butanone with 10 wt. % cyclohexane). Equilibrium solubility between -10 and 40 °C in both compositions was determined by ATR-FTIR. A specified number of cooling crystallization and dissolution experiments in both solvent mixtures under various operating conditions were performed for estimation of kinetic parameters of crystallization and dissolution, as well as model validation. Experiments were monitored by ATR-FTIR and final products were analyzed by microscopic, thermal, and X-ray techniques.

In-house mechanistic mathematical model of the crystallization process based on population balance equation methodology was developed. Equilibrium solubility, mass and energy transfer resistances, and kinetic equations for nucleation, crystal growth, crystal dissolution, and crystal agglomeration were incorporated into the model. Values of unknown kinetic parameters were estimated via nonlinear regression of simulated and experimental quantitative results.

3. Results and discussion

Increase in the amount of antisolvent in the mixture from 0 to 10 wt. % resulted in decrease in fesoterodine fumarate solubility in the studied temperature range (Figure 1). This stems from the fact that fesoterodine fumarate is a polar solute, while cyclohexane is a very nonpolar solvent. Due to similar physical properties of 2-butanone and cyclohexane, no major difference in convective solid-liquid mass transfer coefficient, average turbulent energy dissipation rate, and overall heat transfer coefficient were calculated for different solvent mixtures. Kinetic rates of secondary nucleation, crystal growth, crystal dissolution, and crystal agglomeration all increased. Mass transport limitations on crystal growth and crystal dissolution kinetics were shown to be negligible under the used operating conditions. This indicates that the amount of antisolvent influences these two processes due to different rates of various mechanisms on crystal surface, such as integration of molecules into the crystal lattice. Overall, the increased rate of crystal agglomeration has a prevailing effect on final particle size distribution and particle morphology, which may be important for further pharmaceutical operations.

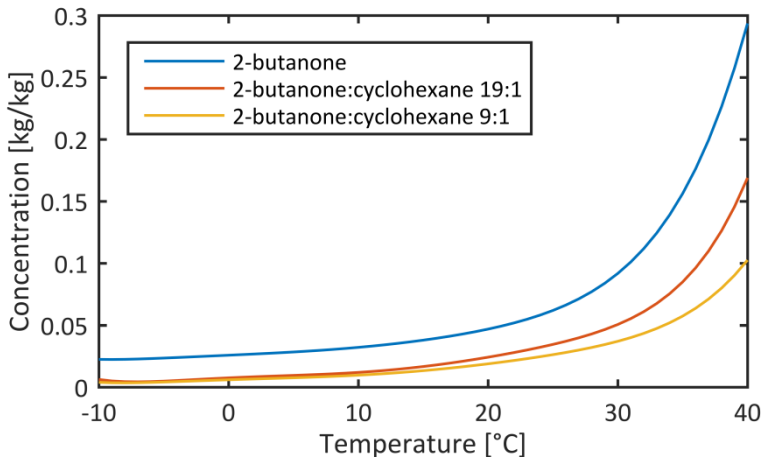

Figure 1. Solubility curves of fesoterodine fumarate in 2-butanone, 2-butanone with 5 wt. % cyclohexane, and 2-butanone with 10 wt. % cyclohexane, represented by sixth degree polynomials.

4. Conclusions

The impact of antisolvent cyclohexane on fesoterodine fumarate batch crystallization in 2-butanone was evaluated by combined experimental-modelling approach. Major influence on thermodynamic and kinetic properties of the system was observed and taken into account for model simulations. The present work thus shows a comprehensive mechanistic approach to take into account various possible ways how solvent composition may impact a crystallization process. It also presents further possibilities for model-based process optimization and intensification by tuning the amount of antisolvent and values of other operating variables.

3D-structuring of highly filled nanoparticle-reinforced epoxy composites by vibration-controlled nozzle

Lisa Windisch[1], Benedikt Finke[1], Carsten Schilde[1]

[1] *Institute for Particle Technology, TU Braunschweig, Volkmaroder Str. 5, 38104 Braunschweig, Germany*

Highlights

- Composite materials with particulate contents up to 90 wt% can be achieved.
- Material combinations and powder layering can generate functionally graded components
- Composite samples can further be adapted locally by microdosing of fine powders with high resolutions and accuracies.

1. Introduction

Composite materials are the fundament for a wide variety of applications in areas such as aerospace, shipbuilding, or electromobility. Compared to pure materials, they make it possible to increase the efficiency of structures significantly. Additionally, by using nanomaterials, especially nanoparticles, product properties can be further improved, or even new properties can be achieved. Through 3D-structuring of components, properties can be adapted even more individually and locally, resulting in a wide variety of design possibilities. Especially when dealing with fine powders, precise and high-resolution dosing of materials remains a major challenge in research and development. Microdosing is relevant, for example, in the pharmaceutical industry for exact dosing of smallest amounts of active substances or in additive manufacturing processes for varying the properties of the powder bed.

2. Methods

Nanoparticles (CNTs, Carbon Black and AluC) as well as the intermixture of epoxy resin HexFlow RTM6 (Hexcel Corporation) and the corresponding diamine based hardener were dissolved in MEK using an ultrasonic dispersing device at 40 °C for 30 – 120 min with particulate contents of 1-5 wt% in the suspension. The stability of these suspensions against reagglomeration was characterized via transmission measurements using the Turbiscan Lab (Quantachrome, 25 °C) and particle size analysis via laser diffraction method (Nanophox, Sympatec). Subsequently, the solvent phase was evaporated for 90 min in a lab kiln at 50 °C. The remaining suspensions with solids content between 10 wt% and 90 wt% were grinded in a steel mortar. The composite powder was further processed by hot press molding at a temperature of 150 °C and a specific molding pressure of approx. 6 kN/cm^2 for 180 min. The unmolded composite cubes were polished for further characterization, e.g. measurement of the electrical (four-point measurement) and mechanical (nanoindentation with Berkovich tip; Triboindenter, Hysitron) properties or visual analysis by scanning electron microscopy (Helios G4 CX, FEI). The 3D-structuring was carried out using a self-constructed setup for piezo-controlled microdosing of fine powders. The experimental

setup and the dosing behaviour were evaluated using model particles (boehmite, γ-AlOOH), whereby the influence of various particle properties such as surface roughness and bulk properties (e.g. flow properties) was investigated.

3. Results and discussion

The resultant mechanical, thermal and electrical properties show a distinct enhancement with increasing particulate content. By mixing and layering of powder based composite materials, tailor made functionally gradients like shown in Fig. 1 (left) have been generated. With CNT fillings maximal electric conductivities of 838 S/m at a content of 60 wt% have been achieved. Deviations can be seen in the peripheral areas of the specimens, caused by air inclusions in the composite structure due to the production process. Stabilization of the particulate material in the solvent matrix by additives showed a huge impact on the homogeneity of the samples. Specimen properties have further been adapted by local deposition of fine powder quantities. By varying dosing parameters like sonication energy, pulsation time and inner nozzle diameter a strong correlation between particle interactions and dosing behaviour was found. Powder quantities of down to 50 µg ($V_{Powder\ heap}$ = 0.5 x 0.5 x 0.2 mm = 0.05 mm³) were deposited with high accuracy (Fig.1, right).

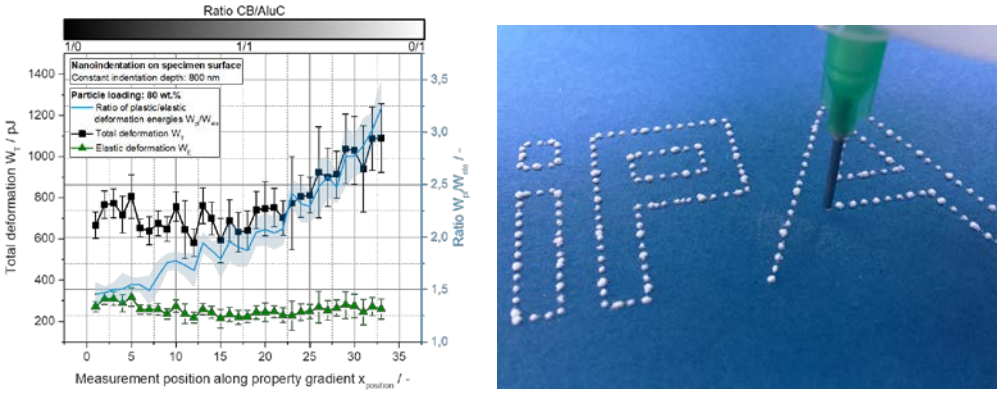

Figure 1. Property profile of a graded specimen with a CB and AluC content of 80 wt% (left) and micrometer ranged powder heaps deposited by vibration-controlled nozzle (right).

4. Conclusions

In this process high particulate loadings between 10 wt% to 90 wt% are realized. High loadings of filler materials have a great potential for an extraordinary modification and enhancement of epoxy resins and other polymers regarding thermal, electrical and mechanical properties and even though the processing is difficult, they are relevant for new design and construction concepts [1]. The resulting properties are investigated for various particle types, stabilization and loadings. By powder layering, functionally graded components have been generated. The gradient shows up as a clear profile in the measured values. An experimental setup for 3D-structuring of materials was successfully established and correlations between the dosing behaviour and the particle properties have been revealed, making it possible to produce tailor made components with individual properties.

Rheological Spectra of New Cellulosic Ionogels with Cholinium Lysinate

M. Mar Villar-Chavero, Juan C. Domínguez, M. Virginia Alonso, Mercedes Oliet, Francisco Rodriguez

Chemical Engineering and Materials Department. Complutense University of Madrid. Av. Complutense S/N. 28040, Madrid, Spain.

**Corresponding author: mdm.villar@ucm.es*

Highlights

- Formulated cellulosic ionogels formulated were physical weak well-structured gels.
- Elastic behavior was dominant rheological behavior of the ionogels.
- The ionogel with 2% of cellulose exhibited the highest rheological properties.

1. Introduction

Cholinium amino acid ionic liquids (ChAAILs) are a type of ionic liquid (IL) classified as a third generation IL or bionic liquid (BIL) [1]. ChAAILs are composed of a cholinium cation and an amino acid anion (e.g. glycine, serine, lysine, etc.). The interest in these ILs is due to they are substantially harmlessness, biodegradable, and non-toxic [2]. In recent years, the applications of ChAAILs have gone beyond the field of biomass pretreatment. Thus, ChAAILs has been proposed to use in CO_2 capture, as lubricants, or in drug delivery formulations [2]. In this work, the use of ChAAILs for the development of gels, called ionogels, is proposed for their use in medical/pharmaceutical industry. Ionogels are composed of an IL and a continuous phase (CF). The interactions between IL and the CF can be physical or chemical, i.e. reversible and irreversible, respectively [3]. Cellulose can be used as CF for the development of ionogels due to its renewability, biodegradability, non-toxic and biocompatibility [4]. This work studies the influence of the amount of cellulose on the rheological spectra of reversible ionogels formulated with the ChAAIL cholinium lysinate (ChLys).

2. Methods

The ionogels were formulated by dissolution of microcrystalline cellulose in ChLys, both previously dried for 12 h in a vacuum oven at 40 °C. The dissolution process was conducted under magnetic stirring at 100 °C under N_2 atmosphere. The percentages of cellulose added for each ionogel were 0.5, 1, 1.5 and 2 wt. %. The dissolution time was determined by acquiring different aliquots every 30 min and visualizing them under a Carl Zeiss Axio Scope A1 microscope equipped with a Zeiss AxioCam ICc1. When the cellulose was dissolved completely, solutions are poured into a steel mold covered with PET film at room temperature up to gelation.

The rheological characterization was carried out in an Ares rheometer (TA Instruments). Dynamic frequency sweep tests from 0.01 to 50 Hz were conducted at 25 °C, with a strain of 0.01% (within the lineal viscoelastic region).

3. Results and discussion

The rheological spectra of the formulated cellulosic ionogels belonged to *plateau* region. The storage modulus (G') was higher than the loss modulus (G''), therefore the dominant behaviour was elastic in the studied range for all ionogels (Figure 1). The ratio G'/G'', or tan δ, for 1 Hz was ranged between 4.7 and 7.8, indicating that ionogels were physical weak well-structured gels.

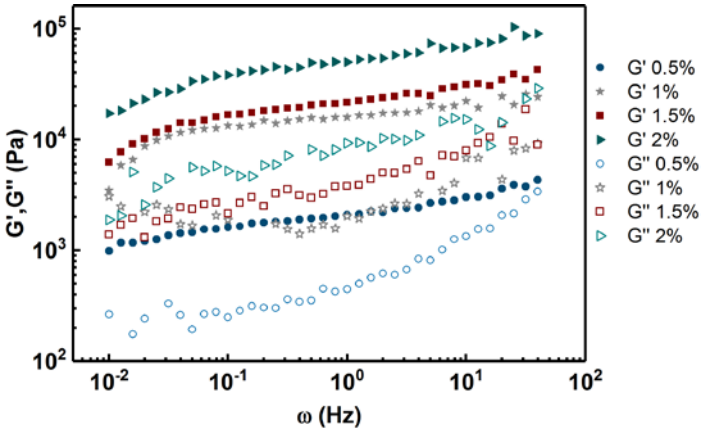

Figure 1. Rheological spectra of the cellulosic ionogels formulated.

The rheological behaviour of the ionogels was changed by the cellulose concentration (Figure 1). The elastic moduli increased as the load cellulose was increased; for 1 Hz, G' for 2% was nearly twenty-fold higher than that 0.5% of cellulose. However, this increase was less pronounced in the case of the loss moduli. Similar results and behaviours have been found for other polysaccharide-based ionogels, such as agarose or guar gum [5-6]. The ionogel strengths (G_0), defined as the measure of the elastic energy stored in the unit volume of network, were 2133, 16179, 22051, and 51586 Pa for 0.5, 1, 1.5 and 2%, respectively. For these reasons, the cellulose had an influence on the rheological properties of the ionogels.

4. Conclusions

The cellulosic ionogels were formulated successfully and can be classified as physical weak well-structured gels according to the obtained rheological spectra. The dissolved cellulose had a significant influence on the rheological properties, being the ionogel with 2% of cellulose the ionogel with the most solid-like behaviour.

Scalable production of silicate glass flakes via compression in the liquid phase

Julian Esper[1], Alexander Strobel[1,2], Stefan Romeis[1], Wolfgang Peukert[1,2]*

[1]Institute of Particle Technology, Friedrich-Alexander Universität Erlangen-Nürnberg; [2] Interdisciplinary Center for Functional Particle Systems (FPS), Friedrich-Alexander Universität Erlangen-Nürnberg

*Corresponding author: wolfgang.peukert@fau.de

Highlights

- Production of silica-based glass flakes in the liquid phase
- Characterization of process parameter influence on Feret diameter and flake thickness
- Influence of glass composition on brittle-ductile transition particle size

1. Introduction

Comminution is a frequently applied, scalable and versatile unit operation of chemical process engineering and particle technology [1-3]. Comminution processes are applied for a wide range of materials including minerals, ceramics, foods, drugs and waste. The acting stressing mechanisms are usually divided into one-sided impact or two-sided compression. In stirred media mills, particle stressing and size reduction takes place between colliding grinding beads, i.e. by compression. In general, comminution processes can be described by the 'process function' and the 'material function' [4-6]. The 'process function' links process parameters such as grinding bead size or stirrer tip speed to the actual stressing conditions in the mill. The 'material function' describes the reaction of a material to the stressing conditions. Clearly, both functions are widely distributed, are so far often unknown but can be determined by recent progress based on stressing of mechanically well-characterized model particles [4-6]. Typically irregular shaped particles with a rather wide size distribution are obtained from comminution. Whereas crystalline materials have been extensively studied there is only a very limited amount of information on wet comminution of amorphous materials with complex chemical composition. In this study, we characterize the stressing behavior and deformation of silica-based glasses with different chemical compositions in a stirred media mill and analyze characteristic dimensional parameters via SEM image analysis.

2. Methods

Commercially available soda lime glass (Carl Roth, Germany) and borosilicate glass (Schott, Germany) were used for all experiments. The as-received bulk materials were pre-crushed with pestle and mortar and classified to a size ≤ 250 µm prior to wet grinding. All wet grinding experiments were conducted in a stirred media mill PE075 (Netzsch, Germany). The grinding parameters were varied in terms of stirring speed and process time as well as grinding bead size to determine the possible influence of the process parameters on the final product particle size. All shape-anisotropic particles were characterized in means of the Feret diameter and average flake thickness via SEM image analysis. Furthermore, true powder density and mass-specific surface area were determined via helium pycnometry and nitrogen adsorption measurements, respectively. These results were used to

determine the Sauter diameter and the theoretical Feret diameter for comparison with experimental values from single particle micromanipulation experiments.

3. Results and discussion

All experiments show that the process can be divided into two distinct steps. The first step comprises the size reduction where irregularly shaped feed particles are crushed in between agitated milling beads until a certain particle size, also known as the brittle-to-ductile transition particle size, is reached. In the second step, the compression and deformation of the glass particles takes place without further fracture. The main size reduction can be observed during the first processing hour whereas plastic deformation is the predominant mechanism afterwards. This can be seen in Fig. 1 where the average flake thickness is shown for different stirring speeds and processing times. The average transferred energy E_{50} per collision determined according to Strobel et al. was 0.48 µJ (v_{tip} 4.87 m s^{-1}) which indicates that the energy transferred in one collision is sufficient to plastically deform a glass fragment into a plate-like particle [5]. The stirrer tip speed seems to exhibit only a minor influence on the average lateral dimensions of the flakes. However, it shows a significant influence on the average flake thickness. The average flake thickness decreases with longer processing times and converges at around 185 nm.

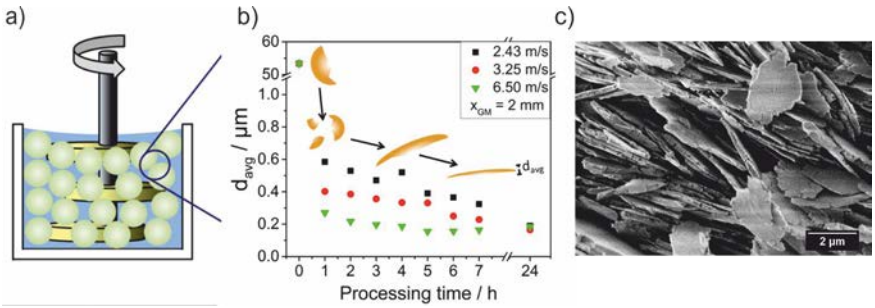

Figure 1. (a) Schematic of a stirred media mill and (b) flake thickness evolution of soda lime glass flakes for different process times and stirring speeds and (c) SEM side view of obtained glass flakes.

4. Conclusions

A facile and fully scalable method to produce amorphous silica-based glass flakes w presented. The influence and effects of stirring speed, process time and bead size is systematically examined and depicted. Our experiments show, that size reduction occurs only during the first hour of grinding while a plastic deformation of the glass fragments is the predominant mechanism in the following hours of process time. These remarkable results are unique because wet grinding is used here as a novel method for well-controlled particle shape formation. The Feret diameter and thickness distributions for all glasses as determined via SEM image analysis and the corresponding size distributions are found to be quite narrow.

Selecting concentrated seawater in salt manufacturing process for $CaMg(CO_3)_2$ production by CO_2 fine bubble injection

Masakazu Matsumoto[1*], Yoshinari Wada[1], Yuko Tsuchiya[1],
Koji Masaoka[1,2], Toshihiko Hiaki[1]

1 College of Industrial Technology, Nihon University, 1-2-1 Izumi-cho Narashino, Japan

2 Research Institute of Salt and Sea Water Science, The salt Industry Center, 4-13-20 Sakawa, Odawara, Japan

**Corresponding author: matsumoto.masakazu@nihon-u.ac.jp*

Highlights

- Fine bubble injection into the removed K brine is well suited for dolomite production.
- Production of dolomite accelerates with an increase in Ca and Mg concentrations.
- High CO_2 flow rate accelerates the crystallization of dolomite with higher Mg/Ca ratio.

1. Introduction

In the Japanese salt manufacturing process as one of the utilization system of seawater resources, the electrodialysis (ED) brine is obtained after concentrating seawater through an electric dialysis membrane. Thereafter, the concentrated brine is prepared by secondary concentration of ED brine using the evaporation operation up to the crystallization point of NaCl. Finally, NaCl is manufactured by evaporative crystallization from the concentrated brine, and then the removed K brine that separated KCl by cooling crystallization is obtained. In order to streamline the salt manufacturing process, a novel recovery and upgrading method for calcium (Ca) and magnesium (Mg) from the discharge concentrated seawater of salt manufactory is indispensable. In this study, we used the minute gas-liquid interfaces around CO_2 fine bubbles as new reaction fields where the crystal nucleation proceeds dominantly and selected the suitable concentrated seawater for synthesizing the dolomite ($CaMg(CO_3)_2$) with a high Mg/Ca ratio. Three concentrated seawater as ED brine, concentrated brine, and removed K brine coming from salt manufacture discharge each have a different concentration product of Ca^{2+} and Mg^{2+} ($[Ca^{2+}][Mg^{2+}]$). In this paper, we report the effects of $[Ca^{2+}][Mg^{2+}]$ as one of operational index and F_{CO2} on the reactive crystallization of $CaMg(CO_3)_2$.

2. Experimental

2.1 Concentrated seawater The ED brine, concentrated brine, and removed K brine coming from salt manufacture discharge in Japan was used. The major ion components of each concentrated seawater are shown in **Table 1**. The concentration ratio of Mg^{2+} for Ca^{2+} in the ED brine, concentrated brine, and removed K brine was approximately equal to 3.

Table 1 Concentrations of each concentrated seawater

Concentration [mol/*l*]	ED brine	Brine	Removed K brine
$[Ca^{2+}]$	0.031	0.062	0.67
$[Mg^{2+}]$	0.083	0.18	2.1
$[Na^{+}]$	2.6	4.0	0.84
$[Cl^{-}]$	2.9	4.6	7.0

2.2 Experimental apparatus The semi-batch type crystallization apparatus consists a gas flow controller, a pH/EC meter, a self-supporting bubble generator, a crystallization vessel, and a thermostatic bath. CO_2 fine bubbles with an average bubble diameter (d_{bbl}) of 40 µm were generated using a self-supporting bubble generator by the shear of the impeller and a negative

pressure owing to high-rotation [1], with the rotation rate maintained at 1500 min^{-1} and the CO_2 flow rate (F_{CO2}) controlled in the range of 5.96 – 23.8 mmol/(*l*·min).

2.3 Experimental procedure CO_2 fine bubbles with d_{bbl} of 40 µm were continuously supplied to 300 m*l* of ED brine, concentrated brine, or removed K brine in a crystallization vessel and the reactive crystallization of $CaMg(CO_3)_2$ was performed. The reaction temperature was maintained constant at 298 K using a thermostatic bath, and the reaction time (t_r) was controlled within 60 min. The solution pH during reactive crystallization was monitored and constantly adjusted to 6.8 by adding 4.0 mol/*l*-NaOH aqueous solution. The selectivity of solid products was identified by the peak area ratio from XRD and the Mg/Ca ratio of $CaMg(CO_3)_2$ was estimated from the amount of peak shift between calcite $CaCO_3$ (2θ = 29.4°) and $CaMg(CO_3)_2$ (2θ = 30.7°) [1,2].

3. Results and discussion

The relationships between $[Ca^{2+}][Mg^{2+}]$ and the production rates of aragonite $CaCO_3$ ($r_{aragonite}$) and $CaMg(CO_3)_2$ ($r_{dolomite}$) or the rate of increase in the Mg/Ca ratio of $CaMg(CO_3)_2$ ($r_{Mg/Ca}$) as a function of F_{CO2} are shown in **Figure 1**. At a ln $[Ca^{2+}][Mg^{2+}]$ of -6, aragonite $CaCO_3$ and $CaMg(CO_3)_2$ were obtained irrespective F_{CO2}. $r_{dolomite}$ and $r_{Mg/Ca}$ increased with an increase of $[Ca^{2+}][Mg^{2+}]$ in the concentrated seawater, and the dependence of $[Ca^{2+}][Mg^{2+}]$ on $r_{dolomite}$ and $r_{Mg/Ca}$ was increased with an increase in F_{CO2}. Consequently, when the removed K brine with a high $[Ca^{2+}][Mg^{2+}]$ was used, the increase in F_{CO2} is effective for the high-yield crystallization of $CaMg(CO_3)_2$ with higher Mg/Ca ratio.

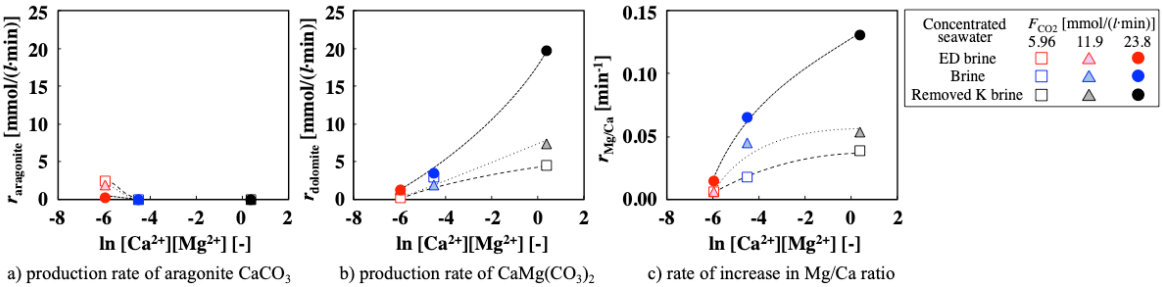

Figure 1. Relationships between $[Ca^{2+}][Mg^{2+}]$ and $r_{aragonite}$, $r_{dolomite}$, or $r_{Mg/Ca}$ at various F_{CO2} values.

4. Conclusions

In order to select the concentrated seawater in salt manufacturing process in Japan for the production of $CaMg(CO_3)_2$ with a high Mg/Ca ratio, CO_2 fine bubbles were supplied into the three concentrated seawater discharged from salt manufacturing process and $CaMg(CO_3)_2$ was crystallized. In the case where the removed K brine with a high $[Ca^{2+}][Mg^{2+}]$ was selected at greater F_{CO2}, $CaMg(CO_3)_2$ with higher Mg/Ca ratio can be produced by the reactive crystallization with briefer period.

**Corresponding author: riccardo.casadei11@unibo.it*

Highlights

- Flawless dispersion of GO in Pebax®2533 with concentration of 0,02 to 1 wt%
- Study of permeation trend caused by GO addition in Pebax®2533
- Comparison of permeation performances improvements of Pebax®2533 by addition of GO, PGO and PEAGO in low concentration (0,02 wt%)

1. Introduction

In this work, Pebax®2533 (figure 1a) and Its GO-based nanocomposites have been studied to check the CO_2 and N_2 permeation performances of these materials for carbon capture applications [1][2]. As nano-fillers, Graphene Oxide (GO), Graphene Oxide functionalized with Polyetheramine (PEAGO) [3] and Porous Graphene Oxide (PGO) [6] have been employed (Figure 1b, c, d respectively).

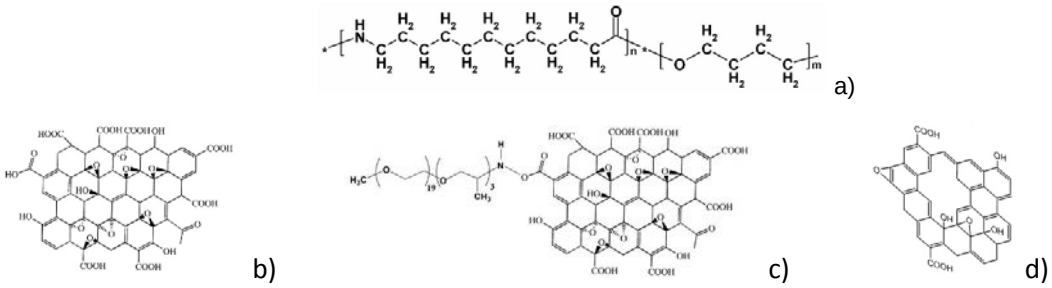

Figure 1: Structure of the materials used: a) Pebax®2533, b) GO, c) PEAGO and d) PGO

2. Methods

For the dispersion of GO in Pebax®2533, a double-solvent solution has been achieved: water dispersion of GO was dropped in a Pebax®2533 - ethanol solution in order to reach concentration GO/Polymer of 0,02 to 1 wt%, leading to smooth and totally homogeneous membranes. Same mixing procedure have been used for PEAGO and PGO, but in these cases only 0,02 wt% loaded composites were homogeneous and reasonable to test.

All membranes have been obtained by pouring some polymer solution, or polymer + filler dispersion, in a PTFE petri, to then let the solvent slowly evaporate at room temperature

CO_2 and N_2 permeation test on the different materials have been carried out by using a single-gas static permeometer. All permeation tests have been conducted at 35 °C. with an upstream pressure

of 1 bar. The permeability was measured by monitoring the pressure increase in the calibrated permeate site, which was in vacuum condition at the beginning of each test.

3. Results and discussion

Permeation results are reported in Figure 3 and table 1; the data in the figure in particular reports the effect of loading of separation performance on Pebax + GO matrix and showed that adding GO over 0,02 wt% decrease the CO_2 permeability while has no effect on CO_2/N_2 selectivity. At 0.02% loading on the other hand a slight increase in permeability was observed which became higher when other types of GO were considered. Porous GO in particular resulted the best material tested with a permeability increase in the order of 10% with respect to pure Pebax2533. As the increase in permeability did not caused any loss in selectivity, the addition og GO based nanofiller generally improved the separation performance of the original polymer.

4.

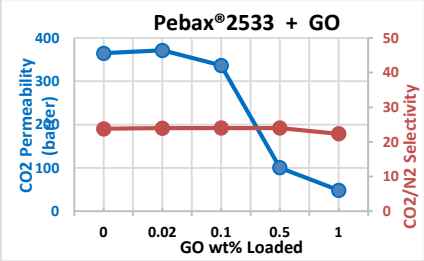

Figure 3 Pebax-GO permeability as a function of loading

Table 1 CO2 ppermeability and CO2/N2 selectivity of the different materials testedin the present work

Sample Name	wt% loaded	P CO2 (barrer)	Ideal α CO2/N2
Pebax2533 Pristine	0,00	364,62	23,80
Pebax2533 + GO	0,02	371,39	24,00
Pebax2533 + PEAGO	0,02	380,44	24,19
Pebax2533 + PGO	0,02	397,35	23,75

Conclusions

In this work, It has been shown that mixing ethanol solution of Pebax®2533 with water dispersion of graphene oxide leads to a very homogeneous system and membranes.

It has been also determined that low concentration (0,02 wt%) of nano-fillers used in Pebax®2533 increase CO2 permeability (1%, 5% and 10% increase respectively achieved with GO, PEAGO and PGO) without any loss of selectivity thus slightly improving the separation performance of the composite membranes with respect to the initial polymer.

Highlights

- Sawtooth and 45°PBT impellers were studied to characterise their blending performance over the turbulent and transitional regimes at two scales of operation.
- Numerical modelling results under selected conditions could be validated with data.
- Experiments performed using liquids that simulate the physical properties of coating formulations have led to the development of a process for the manufacture of high performance automotive coatings.

1. Introduction

A formulation can require the introduction of several additives in different forms into a liquid and hence single and multiphase mixing processes (dispersion of agglomerates of solids or immiscible liquid droplets) are performed during manufacture. It is desirable to use the same equipment throughout the process or even for different products. In this study, the blending performance of a sawtooth impeller, which is typically used for dispersion processes, was investigated in comparison to that of the mixed flow pitched blade turbine (PBT). Blending performance of different types of sawtooth impellers has not been studied as widely as the PBT [1]. The study has been performed in support of process development for a new formulation coating for automotive applications. Simulant liquids were chosen to replicate the viscosity of the additives used in the new formulation coating allowing a range of Reynolds numbers to be covered at different scales of operation.

2. Experimental

Experiments were conducted using two tanks of a diameter of T= 0.13 and 0.30 m, equipped with 4 equally spaced wall baffles. The liquid height was equal to the tank diameter (H = T). Either a sawtooth impeller, R500, (SPXFlow) or a 6-blade 45° pitched blade turbine (PBT) was used. These were of a diameter of around half the tank diameter. Water and glycerol solutions of a viscosity range of 0.001 to 1.2 Pa s were used as simulant liquids to replicate the properties of the formulation and added liquids, some of which are of hazardous nature. Physical property differences taken into consideration[2] when preparing tracers. Power input was calculated from the measured torque value using torquemeters. Flow pattern observations and mixing time measurements were performed from the colourisation/decolourisation method by adding $Na_2S_2O_3$ into the aqueous mixtures in the presence of starch-iodine solution.

Under selected conditions numerical simulations were performed with STAR CCM+ 13.02 using the, moving reference frame approach.

3. Results and discussions

Power numbers obtained from numerical simulations were in agreement with those determined experimentally for both impellers with a higher value of the characteristic power number for the PBT compared to the sawtooth impeller as expected (Figure 1). These could be used to calculate the power input over a range of conditions.

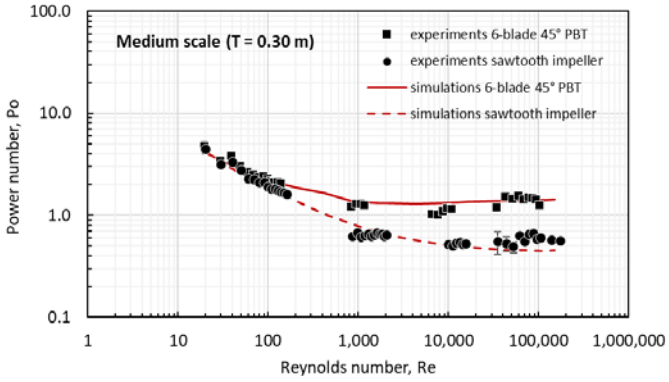

Figure 1: Characteristic power curves, T= 0.30 m

Results from blending experiments have shown that the dimensionless mixing time (Nθ) is inversely proportional to the Reynolds number with higher Nθ values for the sawtooth impeller (Figure 2). When mixing time results are compared on the basis of volumetric power input, the performance of both impellers appeared to be a comparable.

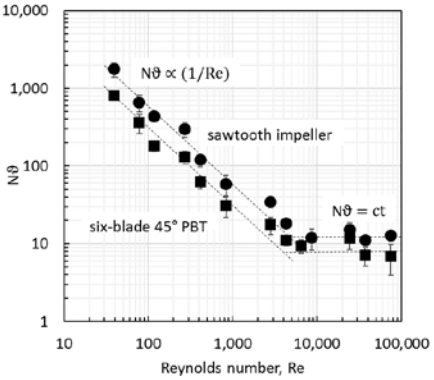

Figure 2: Dimensionless mixing time over a range of Re, T= 0.30 m

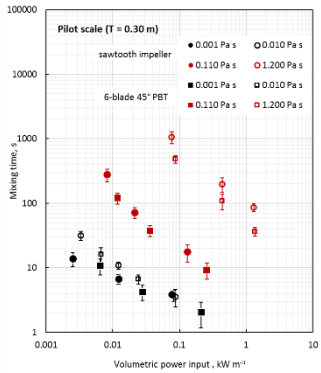

Figure 3: Mixing times at ct P/V (red are data in transitional regime)

Trends were similar in the smaller T= 0.13 m tank.

4. Conclusions

Power and flow characteristics of sawtooth impellers were studied over a range of Reynolds numbers using simulant liquids that replicate the viscosity during the manufacture of a new formulation automotive coating at two scales of operation. Numerical simulations performed under selected conditions showed good agreement in predicting the power input and hence can be used for different designs. Mixing times compared on the basis of constant volumetric power input were found to be comparable for the two impellers. Further work is underway in a larger scale tank.

Highlights

- Set-up of the SAS process with ELRs was done reaching high process yields.
- Physico-chemical characterization shows particle size of 40 nm in aqueous solution.
- Drug delivery profiles were found to fit to the equation of Peppas-Sahlin.
- Breast cancer cells were more affected and showed diminished cell viability.

1. Introduction

The controlled release of drugs from biodegradable polymer nanoparticles is having a great medical impact in a wide range of therapeutic areas. Elastin Like Recombinamers (ELRs) [1] whose sequence is inspired in natural elastin and consist in repeats of the sequence (VPGXG)n, where X can be any amino acid except proline, are unique in this field thanks to their recombinant nature. ELR sequence can be altered by adding specific functionalities such as cell adhesion domains and their natural capacity of self-assembly and their stimuli responsiveness allow intelligent processes [2]. The encapsulation of Docetaxel (DTX) has been the subject of study by many researchers, implementing long and complex methods, which also involve the use of toxic organic solvents and post-processes. Therefore, a very powerful idea would be to coat the DTX avoiding toxic organic solvents and in one-step process. In this work, Supercritical AntiSolvent (SAS) [3] technique has been proposed to co-precipitate both compounds, due to, it serves as a completely clean separation agent since it uses mild temperatures in the process that do not harm the product, it is a non-flammable, non-corrosive, non-toxic, non-carcinogenic element, has a large selective capacity and does not generate waste [4].

2. Methods

Nanoparticles of DTX coated with ELRs, (EI)2 and (EI)2RGD, were obtained by Supercritical Antisolvent technology (SAS) studying process parameters to achieve the best operational conditions. The proportions of both compounds were determined by NMR. The morphology of the dry particles from SAS process was study by Scanning Electron Microscopy (SEM). Furthermore, Surface charge of the particles (ζ-Potential) and particle size in aqueous solution were measured by Dynamic light scattering (DLS) using a Zetasizer Nano ZS at 37°C and neutral pH. Particle morphology and amphiphilic behavior of the particles in aqueous media, was observed by TEM at neutral pH

and at room temperature. Drug delivery experiment was performed in triplicate using dialysis method at 37ºC under sink conditions and determined by UV-vis spectrometer and fitted with mathematical models. After characterization of nanoparticles, the effect of ELR-based nanoparticles was measured *in vitro* in endothelial (HUVEC) and breast cancer (MDA-MB-231) cells.

3. Results and discussion

The setting-up of the SAS pilot plant were performed with (EI)2 biopolymer and DMSO as a solvent, using a new coaxial nozzle designed in this work to get the best operational conditions. Results achieved with this conditions shows a drastic reduction in the solvent residues and a high process yield. The particles analyzed by SEM did not present a remarkable aggregation and has a smooth surface with many small particles stuck to them that provides a wide particle size distribution. Microparticles of (EI)2+DTX and (EI)2RGD+DTX obtained after the process can be disaggregate in aqueous solution forming a nanoparticulate delivery system keeping the drug inside with PDI below 0.2 and with ζ-Potential of around -30 mV, which clearly indicates that is monodisperse and stable in time. This results were confirmed by TEM where same size and behavior were found. Drug release study of the (EI)2+DTX particles shows a clear delay in the delivery of the DTX and the Peppas-Sahlin equation used to fit the profiles shows that the process is governed by the Fickian diffusion mechanism. In the cellular assays carried out, it has been proven that thanks to the incorporation of the RGD sequence in the ELR, the treated breast cancer cells were more affected and showed a lower cellular viability than cells treated with free DTX. This effect was not seen in HUVEC cells, which could be explained by the fact that cancerous cells have enhanced ability to internalize due to their enhanced metabolic rate and higher expression of integrins.

4. Conclusions

In this work, we have been able to set up the operational conditions in the Supercritical Antisolvent pilot plant with CO_2 to make both microparticles of Elastin Like Recombinamers and co-precipitated Docetaxel-ELRs in one step process. Microparticles after the SAS process are able to disaggregate in aqueous media forming stable nanoparticles with low PDI which shows a controlled DTX release profile following Fick diffusion mechanisms. In addition, we may emphasize that it has been possible to increase the solubility of this highly hydrophobic anti-tumoral drug in aqueous solution by 5 orders of magnitude. Moreover, in the cellular assays carried out, it has been proven that thanks to the incorporation of the RGD sequence in the ELR, the treated breast cancer cells were more affected and cell proliferation was completely abolished, therefore, the strategy developed in this work opens the way to new systems of controlled release, more precise than non-selective chemotherapeutic drugs and with a very promising potential.

Multidimensional classification of quantum dots: Investigation of flock properties during selective agglomeration for process design

Christina Menter[1], Doris Segets[2]

[1] Institute of Particle Technology (LFG), Friedrich-Alexander-University Erlangen Nürnberg (FAU), Germany;

[2] Process Technology for Electrochemical Functional Materials and Center for Nanointegration Duisburg-Essen (CENIDE), University Duisburg-Essen (UDE), Germany

1. Introduction

Quantum confined semiconductor nanoparticles (quantum dots, QDs) are highly interesting materials due to their unique electronic and optical properties and are used for various applications, such as dye sensitized solar cells and light-emitting devices. Within the relevant size range of a few nanometers, QDs exhibit pronounced and unique structure-property relationships. Hence, a narrow particle size distribution (PSD) becomes one of the most important factors to tailor product performance. **Size selective agglomeration** has already been proven to be an efficient post processing strategy for ZnS QDs [1,2]. It is based on the titration of a poor liquid into an already existing stable dispersion, which leads to a reduction of the particles' steric stabilization. Therefore, larger ZnS particles with larger van der Waals attraction flocculate first while smaller structures stay dispersed as primary particles. Finally, the flocculates have to be separated from the continuous phase. While on lab scale, the formed flocks of several 100 nm can be easily separated by centrifugation from the fine fraction that stays as primary particles in the supernatant, for larger scale preparation using continuous processes, new concepts are urgently needed. Herein, the objective was to develop a filtration process to achieve continuous flock removal by two alternating filtration units without affecting the separation efficiency governed by the microprocesses. Noteworthy, this is the first time that a scalable classification strategy for such small entities below 10 nm is reported. Key to reach this ambitious goal is to know how the properties of the flocks can be controlled and how stable the generated flocks are against shear forces.

2. Methods

For the synthesis of 3-mercapto-1,2-propanediol capped ZnS QDs a method of Nanda et al. was applied[3]. Via analytical centrifugation (AC) the sedimentation profiles of the flocculated dispersions were recorded to determine the sedimentation equivalent diameter distribution of the flocks. AC measurements were performed with a LUMiSizer LS 651 (LUM GmbH, Berlin, Germany). Absorbance spectra of ZnS QDs were recorded using a SPECORD Plus UV/Vis spectrophotometer (Analytik Jena AG, Germany) with quartz glass cuvettes of 0.2 mm optical path length. Absorbance measurements were analyzed with respect to their volume PSDs by means of a previously published and carefully validated deconvolution algorithm [4].

3. Results and discussion

In Figure 1 the classification procedure is summarized. After the flocculation of larger particles by the addition of a poor liquid to a stable ZnS dispersion, the complete separation of the flocks from the dispersed particles is fundamental. Entering of flocks to the fines would lead to a significant degradation of the classification result. Since separation by centrifugation is restricted to lab scale, our objective was to develop a filtration process for the separation of larger quantities. Continuous operation can then be achieved by using alternating filtration units.

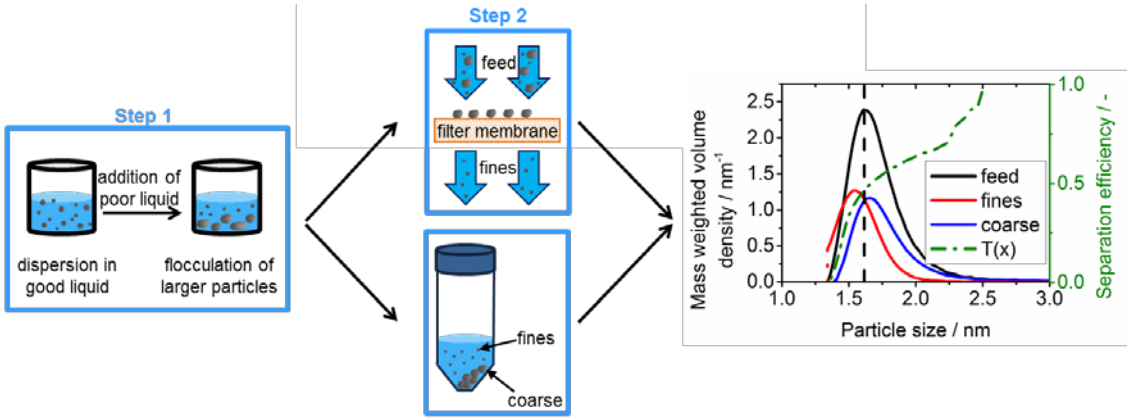

Figure 1: Summary of the two-step classification procedure (left and middle) and classification result with separation efficiency (right).

For filtration process design it is indispensable to know how stable the generated flocks are and how the flocks properties can be controlled. In a systematic parameter study we found out that the flocks are comparatively stable against shear forces generated at varying energy inputs, weakly affected by solvent polarity and that the flock diameter rises with increasing solid concentration. With this knowledge we designed a filtration process to separate flocks from the primary particles. After the flocculation of larger particles by addition of a poor liquid to a stable dispersion, the flocks were separated by filtration instead of centrifugation. Afterwards, the dried filter cake was proven to be redispersible in water. Thus, we were able to proof that it is possible to **replace the separation of flocks from the fines by centrifugation through filtration** during a nanoparticle classification experiment **without affecting the separation efficiency**.

4. Conclusions

Our work demonstrates for the first time the scalable classification of QDs < 10 nm by size selective precipitation. We successfully replaced the classical centrifugation step for flock separation by filtration without affecting the separation efficiency that is determined by the microprocesses. Noteworthy, this process is not restricted to classification by size, but can be extended towards multidimensional separation, e.g. size and composition or surface properties.

Manganese dioxide (MnO_2) based Janus nanoparticles for emulsion stabilization with potential application for enhanced oil recovery

Paula Rivera[1], Luz Ballesteros[1], D. Fabio Mercado[1], Dary Malagon[1]

[1] Centro de Investigaciones en Catálisis CICAT, Parque Tecnológico Guatiguará km 2 Vía el Refugio, Universidad Industrial de Santander, Piedecuesta (Santander), 681011, Colombia

Highlights

- MnO_2 nanoparticles were synthetized with different phases and geometries.
- Different MnO_2 Janus nanoparticles were synthetized and characterized.
- The effect of amount surfactant in MnO_2 Janus nanoparticles were studied.

1. Introduction

In the Oil - thermal recovery processes, various techniques are employed to heat the residual oil in the formation, resulting in reduction of the viscosity of crude oil which improves its mobility, facilitating its fluidity toward production wells [1, 2]. These kinds of techniques are mainly divided into two types: steam injection and in-situ combustion (ISC) [3]. One of the most advantageous yet complex thermal methods is in-situ combustion (ISC) process [1].

The transport of ultradispersed catalysts in the reservoir is essential to bring this material into contact with the crude [4]; the catalysts used can be based on transition metal nanoparticles (NP), which have a high catalytic activity [5]. However, the transport of particles in very narrow reservoirs can be a challenge, an important factor to consider is the permeability of the reservoir. Manganese dioxide (MnO_2) is cheap and non-toxic [6], their diverse phases are successfully used in potential applications such as batteries, catalysis, water treatment, and chemical industry [7,8]. Additionally, when a material is present in a nanometric scale, it has larger surface areas compared to its macroscopic analogues [9].

Resasco [10] studied the application of hybrid nanoparticles in water/oil interfaces for improved recovery reactions and found that Janus particles are very effective to act as emulsion stabilizers and catalyst supports. It can be inferred that this type of nanomaterials could propagate in the flow of water through the porous media and reach the oleic phase [10]. The challenge of the oil industry is then to inject these catalysts into the reservoir through the porous medium without significantly affecting the permeability of the rock. For this purpose, it is essential that the catalytic systems form stable emulsions to transport them through the injector well [11]. Therefore, the main objective of this work is to formulate emulsions stabilized by Janus nanoparticles of manganese dioxide for their application in enhanced oil recovery.

2. Methods

α-MnO_2, β-MnO_2 and δ-MnO_2 nanoparticles (NP) were prepared by a redox hydrothermal method with some modifications [12]. An aqueous solution composed of $MnSO_4 \cdot H_2O$ and $(NH_4)_2S_2O_8$ with

different ratios of reagents was charged into a Teflon-lined autoclave. The autoclave was kept in an oven at different temperatures for certain period and then cooled at room temperature. The obtained black slurry was filtered and dried with water and ethanol. The NP were mainly characterized by FT-IR and DLS.

The as-obtained nanoparticles were selective surface functionalized through a Pickering emulsion [13] method in order to obtain Janus nanoparticles (JNP) and then a model emulsion was formed with an equal amount of oil and water.

With rheological tests as an index of fluency were chosen the best JNP for formulate emulsions and the percentage of functionalizing agent was varied to find a stable emulsion.

3. Results and discussion

An easy method was performed to synthesize MnO_2 nanoparticles from reagents with different charge ions, the characterization showed a narrow size distribution and the desired oxide on a nanometric scale. The synthesis also showed that the variation of reagent concentration and drying temperature affect the size and phase of nanoparticles, due to the change in the concentration of NH_4^+ and SO_4^- ions.

The synthesis of Janus manganese dioxide nanoparticles has not been widely studied, due to this finding the optimal fabrication conditions represented a challenge for the authors. The percentage of functionalizing agent was varied to analyze its effect on the JNP properties

4. Conclusions

In this work, the effect of the functionalizing agent in the stabilization of emulsions through Janus nanoparticles prepared by a Pickering emulsion method was studied. With this study, it is possible to understand the behavior of stable emulsions to be applied in different applications such as food, pharmaceutical, biochemistry, and the oil industry.

3 Laboratory for High Performance Ceramics, Empa, Swiss Federal Laboratories for Materials Science and Technology, Überlandstrasse 129, 8600 Dübendorf, Switzerland

Highlights

- MS2 virus removal by adsorption is proportional to MWCNT mass.
- SRNOM adsorption onto MWCNT follows Freundlich isotherms.
- MS2 removal depends on SRNOM concentration.

1. Introduction

Safe drinking water access in low and middle-income countries is limited, especially in urban slums and rural area [1]. To increase safe water access and reduce waterborne diseases, water kiosks at community-scale were developed. For these decentralized water facilities, the water treatment technologies are selected according to their low costs, low maintenance, sustainability and ease of use [2]. In well operated and equipped water kiosks, bacterial removal is performed, while virus removal is seldom feasible [3]. It is therefore of major interest to develop solutions to increase virus removal and consequently decrease the waterborne diseases associated with these pathogens. The purpose of this study was to evaluate the interest of using MWCNT to produce filters that could be applied as a post-treatment in water kiosks, acting as a safe barrier against virus. In recent decades, the development of Carbon NanoTubes filters showed a high potential for water treatment and most specifically for virus removal in the case of electrochemical CNT filters [4]. However, NOM is expected to be a major limitation for virus removal, since it is also known to adsorb onto MWCNT. To better target the application of MWCNT for virus treatment, it is therefore important to better understand the competition mechanisms between virus and NOM.

2. Methods

MS2 (DSMZ 13767) were used as human virus pathogen surrogates due to their similitude with enteric viruses of human health concern. MS2 infectivity was evaluated using the MS2 plaque assays.

The MWCNT used in this study were purchased from CheapTubes. Their specific surface is equal to 116.63 m2/g, their diameter varies between 10-25nm, while their length is equal to 100µm.

SRNOM (IHSS) was used as a NOM surrogate to be able to compare our results with the existing literature. NOM characterization was performed using Liquid Chromatography with Organic Carbon Detector (LC-OCD) and TOCmeter.

Batch experiments were performed in glass vials of 25mL, using the bottle technique (one bottle corresponds to one point). After adding a fixed mass of MWCNT into MS2 stock solution, with or without SRNOM, the vials were mixed for 3h at 40rpm. After adsorption, samples were filtered with 0.45µm PES filters prior analysis.

3. Results and discussion

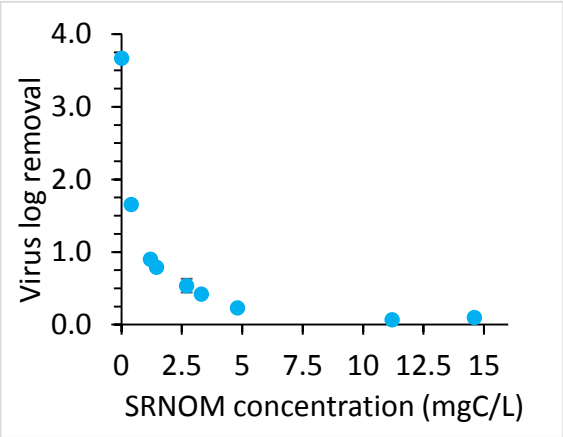

Figure 1: Virus removal by MWCNT as a function of Suwannee River Natural Organic Matter (SRNOM)

Batch experiments showed that MS2 removal is due to adsorption and is proportional to the mass of MWCNT. For pH between 5 and 8, the removal is equal to 0.3log/mgMWCNT. Batch experiments with SRNOM at different pH showed that SRNOM adsorbs onto MWCNT too, with a higher affinity at pH5. Competition between SRNOM and MS2 was tested with co-adsorption experiments and with preloading experiments. Figure 1 shows the results of the co-adsorption experiments, where the competitive effect of SRNOM even at low concentration. Virus removal drops by 38% at a concentration equal to 0.4mgC/L. This concentration corresponds to concentrations found in clean ground waters. Virus removal in low and middle-income countries using pristine MWCNT filters is highly compromised since a wide diversity of waters could be used for drinking water treatment.

4. Conclusions

The use of pristine MWCNT filters for virus removal is highly compromised by the presence of NOM that irreversibly adsorbs onto MWCNT. Saturation is quick since at a concentration of 5mgC/L of SRNOM, virus removal drops from 3.7log to 0.02log. MWCNT functionalization could be on option to limit NOM adsorption.

1. Introduction

Local temperature control in water environment is essential for both, soft matter- and life-science applications. The thermal sensing techniques developed are not directly applicable for thermal studies in water environment, particularly if simultaneously high thermal sensitivity, ratiometric and all-optical response are desired. A realistic temperature sensing alternative could be the process of triplet-triplet annihilation photon energy upconversion [1] in water environment (TTA – UC): It is inherently micro-scale sensing techniques – the sensing function is carried out by ensembles of organic macromolecules embedded in micelles of non-ionic surfactants. The TTA – sensing function is performed in all-optical regime by using a single excitation wavelength, although two characteristic optical signals (ratiometric response) are registered [2].

2. Results and discussion

Since the TTA – UC is a process controlled by the rotational diffusion of the interacting photo excited species it will depend extensively on the local mobility of the participating molecules, embedded in the hydrophobic core of the optically inactive micelles (Figure 1). Therefore, the dependence of the core viscosity on the sample temperature will lead to temperature dependence of both, the emitter delayed fluorescence and the residual sensitizer phosphorescence. Those two optical signals acting as ratiometric material response on the local temperature change ensure inherent & instantaneous compensation of the possible local changes of the sample parameters, and create non-ambiguous temperature calibration curve (Figure 2).

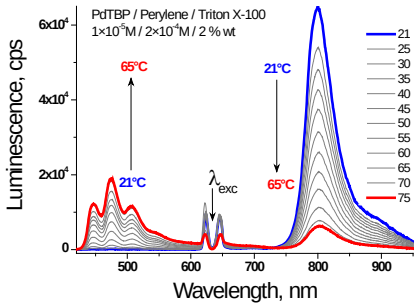

Figure 1: Dependence of the luminescence spectra of the micellar TTA-UC system in water environment on the sample temperature.

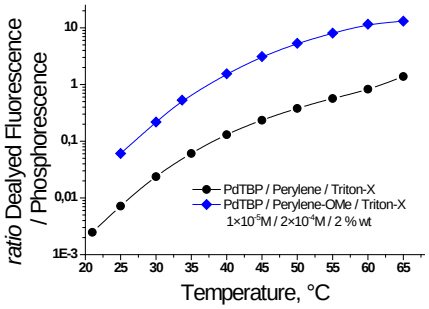

Figure 2: Calibration curve - dependence of the ratio of UC-delayed fluorescence versus residual phosphorescence on the sample temperature.

The influence of emitter hydrophobicity on the energetic and dynamical properties of process of TTA-UC in micelles of non-ionic surfactants, as well as identification of the non-ambiguous temperature calibration curves and measurement of local temperature in all-optical regime with sensitivity better than 0.05 K and temporal resolution of 200 µs will be demonstrated and discussed.

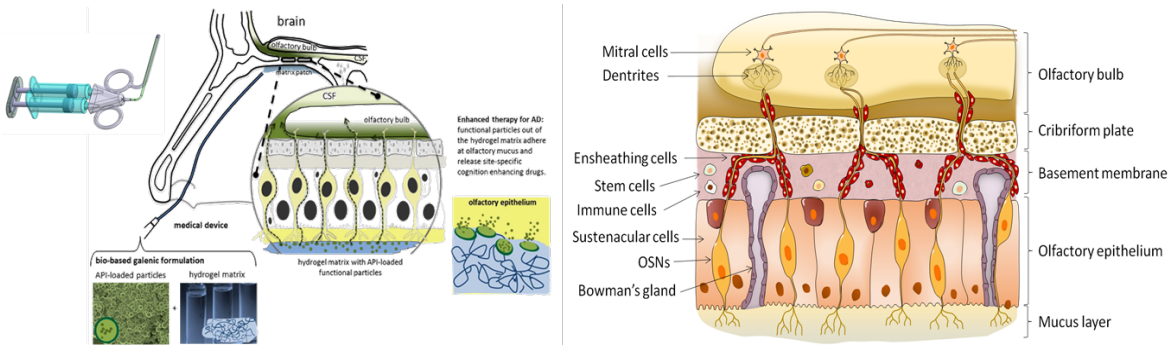
Highlights

- Sustained and controlled drug delivery.
- In situ hydrogel formation and swelling dynamics.
- Drug release from a population of drug-loaded particles.
- Drug diffusion through particle, hydrogel and biological barriers.

1. Introduction

Central nervous system (CNS) disorders (e.g., multiple sclerosis, Alzheimer's, Parkinson's or Huntington's disease, etc.) represent a growing public health issue, primarily due to the increased life expectancy and the aging population.



The role of the nasal cavity as an entry point for the brain-targeted delivery of various medications has been long identified as a potential alternative administration route to the intravenous delivery mode. Although highly advantageous due to its non-invasive nature, rapid onset of action and highly localized delivery resulting in low systemic exposure, the delivery of medications to the brain via the nasal cavity exhibits particular challenges, associated with the controlled and sustained release of biopharmaceutics across biological barriers or/and low drug stability attributed to the activity of enzymes residing in the nasal cavity.

In the present work, the development of an innovative nanotechnology-based formulation and application technology are described for the chronic treatment of CNS disorders. The novel drug formulation consists of biodegradable polymer nanoparticles (NPs) loaded with cognition enhancing drugs (e.g., long-acting insulin analogues). The drug loaded particles are embedded into

a biodegradable hydrogel matrix that is deposited, via a nasal endoscopic applicator as a thin liquid-gelling film, onto the olfactory region.

2. Computational Methods

A multi-scale modelling approach, comprising models at different time and length scales, is applied to quantify the fundamental physical, transport and biological processes in relation to the nose-to-brain delivery of biopharmaceutics from the embedded nanoparticles in a hydrogel film deposited onto the olfactory epithelium. In particular, a CFD-based model is developed to describe the flow and deposition of a reactive polymer solution, through an endoscopic applicator, onto the olfactory mucus/epithelium, in terms of a polymer solution flow, its viscoelastic properties, gelation kinetics, extruded volume and applicator diameter, in relation to the formation of a hydrogel film onto the olfactory cleft. Moreover, a hydrogel/mucus model is developed to predict the polymer solution spreading, hydrogel formation and degree of swelling. To predict the cross-linking kinetics of functionalized hyaluronic (HA-ox, HA-Tyr) and hydrogel swelling, a kinetic model is developed, in terms of the leading moments of the molecular weight distribution. The crosslinking kinetic model takes into account the effects of initial molecular weight of the polymer, pH and ionic strength of the medium. In order to examine the long term stability and detachment of the deposited hydrogel patch onto the olfactory region, the hydrogel swelling deformation is analyzed in terms of the environmental conditions in the olfactory region. A dynamic drug release model is developed to describe the drug release rate from the drug-loaded nano-carriers embedded in the hydrogel matrix in terms of molecular and morphological properties of polymeric carriers and hydrogel matrix. Finally, a drug release model is derived to calculate the drug release rate for a population of size-distributed particles and analyze the effects of particle size distribution, particle loading, particle swelling and polymer degradation on the drug release profile. Note that the derived model can simulate the observed phenomena including the observed burst in the drug release rate or/and delayed release from the drug-loaded particles. Moreover, the effects of system variables (i.e., gelation onset time, patch volume, particle size and particle drug loading, polymer and hydrogel degradation kinetics, etc.) on the drug release rate are assessed and compared with available experimental measurements.

3. Results and discussion

The various sub-models are numerically solved to calculate the drug mass transfer rate from the embedded nanoparticles in the hydrogel matrix through the mucus layer and epithelium to the olfactory bulb. It is shown that model predictions are in close agreement with experimental measurements obtained from nose to brain drug transfer experiments in rats reported in the literature.

4. Conclusions

A multi-scale mathematical modeling framework has been developed to aid the design, simulation and optimization of nose to brain controlled drug delivery for treatment of CNS disorders and maximize the drug efficacy and bioavailability.

Highlights

- Nanofibrillated cellulose was used to prepare facilitated transport membrane for CO2 capture
- PVAm – Naocelllulose membrane showed interesting separation performance close to the 2008 upper bound for CO2/N2 separation.
- Arginine-Nanocellulose membranes were able to overcome 2008 upper bound for CO2/N2 separation.

1. Introduction

Carbon capture and storage (CCS) technologies represent an interesting medium-term solution to tackle climate change and CO2 emissions, removing the greenhouse gas before its release in the atmosphere. In order to make it a viable solution, high performance separation techniques must be applied, and gas separation membranes are a strongly investigated solution.

Within this work a new family of facilitated transport membranes (FTM) has been investigated that uses nanofibrillated cellulose (NFC) has matrix for the CO2 carriers. Thanks to its high hydrophilicity, the high mechanical resistance and the already interesting separation performances showed [1] this materials seems indeed a very interesting candidate to obtain high performing and stable Hybrid Facilitated transport membranes (HFTM).

A series of membranes loaded with different amounts amine based carriers such as L-Arginine and polyvinylamine (PVAm) were prepared and tested under humid conditions for CO2 and N2 permeability in order to assess their potential for post combustion carbon capture applications.

2. Methods

Two different types of nanocellulose were produced at inofib starting from the raw materials, namely the Carboxymethlated nanocellulose (NFC-CMC) where some of the idroxyl group on the fiber surface were substitute with carboxilyc acids and aminosilane modified Nanocellulose (NFC-AEAPTMS. L-Arginine was purchased from sigma adrich, while PVAm was obtained through a three step purification form the commercial product Lupamin® 9095 kindly provided by BASF Italia.

The membranes were produced by solvent casting from an aqueous solution obtained by adding the amine compound solution in a water dispersion of nanocellulose. Permeation test were carried out in humid condition in order to exploit the facilitated transport mechanisms which needs water

to be fully active. To that aim a purposely built apparatus was used [1] able to use well known barometric technique for gas permeability evaluation ls in presence of water vapor.

3. Results and discussion

The data obtained from the different experiments are shown in figure 1 a and b for the NFC-Arginine and for amonosilane treated NFC. It can be seen that the addition of the amino acid resulted in a significant increment of both permeability (from 29 to 220 Barrer) and ideal selectivity (from 56 to 185). Introduction of PVAm determined the formation of strong interactions with the NFC matrix, which reduced permeability respect to a pure mobile carrier, but improved stability at high relative humidity. Lastly, a chemically modified NFC, with amine-bearing moieties grafted onto the surface (NFC-AEAPTMS) was tested with a content of 20 wt% PVAm, also showing promising performances.

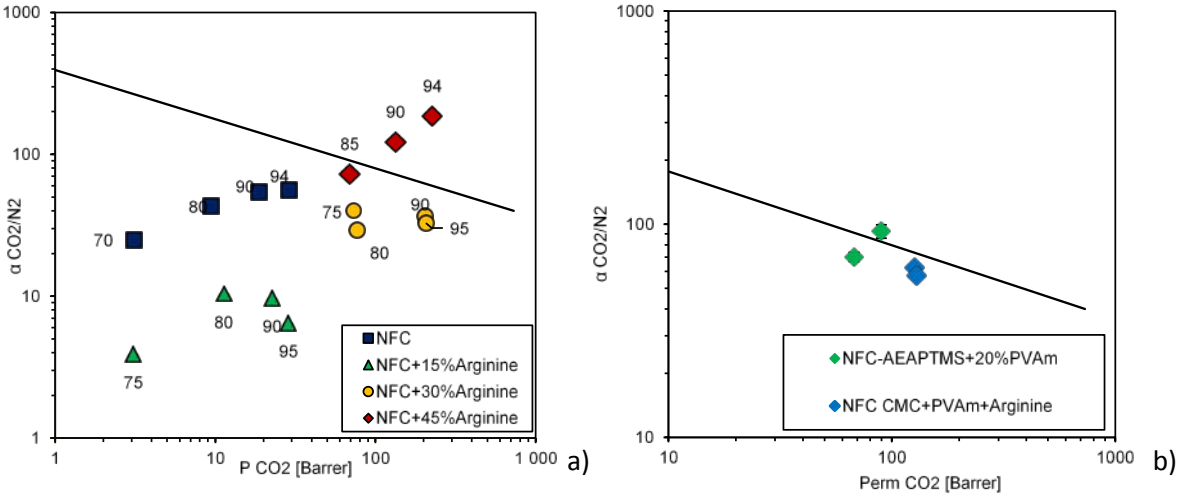

Figure 1 a) CMC-NFC permselectivity at different loadings of L-Arginine and relative humidity and b) of aminated NFC plus polyvinylamine at 100 RH% with respect to Robeson's Upper Bound [2]

4. Conclusions

In the present works a new type of nanocellulose based facilitated transport membranes were investigated for their use in post combustion carbon capture application. The general results showed that nanocellulose thanks to its hydrophilicity is a good candidate to be sed in facilitated transport membranes and is coupled with mobile carrier such as L-arginine it allows to obtine mebrane with separation performance well above the 2008 Robeson's Upper Bound.

Sonochemical Synthesis of Dolomite ($CaMg(CO_3)_2$) for Utilize Seawater Resources and Application for Phosphor Material

Shinnosuke Kamei[1], Masakazu Matsumoto[2], Shigeki Furukawa[1]

1 Department of Sustainable Engineering, College of Industrial Technology, Nihon University, Chiba, Japan 275-8575; 2 Department of Liberal Arts and Basic Sciences, College of Industrial Technology, Nihon University, Chiba, Japan 275-8575

**kamei.shinnosuke@nihon-u.ac.jp*

Highlights

- A new synthetic approach of dolomite ($CaMg(CO_3)_2$) with ultra-sound irradiation by a liquid phase reaction was found.
- The average particle diameter was 470 nm.
- From energy dispersive X-ray spectrometry, dolomite of the high purity (Ca/Mg atomic ratio of 1.08) was successfully synthesized with the ultrasonic irradiation.
- Red-emitting Eu^{3+} doped dolomite phosphor and green-emitting Ce^{3+}-Tb^{3+} codoped dolomite phosphor were successfully synthesized by immersion treatment.

1. Introduction

Recently, ultrasonic irradiation assisted synthesis of inorganic materials has been actively conducted. On the other hand, synthesis of alkaline earth metal carbonate from the components dissolved in seawater is expected We focused on dolomite ($CaMg(CO_3)_2$). Dolomite is a double salt in which calcium carbonate ($CaCO_3$) and magnesium carbonate ($MgCO_3$) are regularly combined at a molar ratio of 1:1. By using ultrasonic irradiation, it is advantageous that the particle diameter obtained becomes nano-sized. Therefore, the synthesis of nanomaterial from seawater becomes possible. We introduce a new synthetic approach to obtain dolomite and report the synthesis of dolomite phosphor as an application material.

2. Methods

The preparation of $CaMg(CO_3)_2$ nano-powder was used $CaCl_2$, $MgCl_2$, $NaHCO_3$ and Na_2CO_3 powders as starting materials. Mixing of suspension was carried out by the mechanical stirring and the ultrasonic irradiation. With stirring and the ultrasonic irradiation (20kHz, 40W, 3-6mm horn diameter) reaction was maintained at 65°C for 1 hour. After reaction, the resulting suspension was filtered, washed with pure water, and dried at 40°C. Similarly, the same treatment was carried out using de-K ion bittern. The synthesis of dolomite phosphors used immersion method. The product was immersed in europium chloride solutions of 0.05～0.20 $mol \cdot dm^{-3}$ at room temperature, for 1 hours, with suspension concentration 1 mass%. Eu^{3+} doped dolomite phosphors were thus obtained. Using the same method, Ce^{3+}-Tb^{3+} codoped dolomite phosphors were obtained. Each sample was characterized by X-ray diffraction, scanning electron microscopy and Energy dispersive X-ray spectrometry. The fluorescence properties of the sample were measured using a spectrophotometer.

3. Results and discussion

Figure 1 shows the XRD patterns of the sample prepared with sonochemistry reaction. The diffraction patterns of the prepared samples showed good agreement with the powder patterns of dolomite and the single phase of dolomite was confirmed. In the case of using de-K ion bittern, the synthesis of dolomite was possible by controlling Ca concentration in de-K ion bittern. Figure 2 shows SEM image the sample prepared with sonochemistry reaction. The average particle diameter was 470 nm. Nano-sized particles are prepared easily made by sonochemistry reaction method. Moreover, from energy dispersive X-ray spectrometry, The Ca/Mg atomic ratio was 1.08. It was shown that dolomite of high purity can be easily synthesized. On fluorescence property of Eu^{3+} doped dolomite phosphor, the emission band was observed at 614 nm which is attributed to the $^5D_0$-$^7F_1$ transition of Eu^{3+} under excitation at 254 nm. In the case of Ce^{3+}-Tb^{3+} codoped dolomite phosphor, the emission band was observed at 544 nm which is attributed to the $^5D_4$-$^7F_5$ transition of Tb^{3+} under excitation at 254 nm. It was possible to make the prepared dolomite samples into phosphor materials.

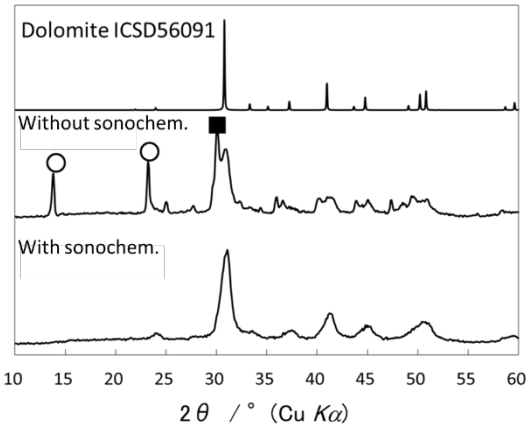

Figure 1. XRD patterns of the sample prepared with sonochemistry reaction.
○: Magnesium carbonate trihydrate
: Base-magnesium carbonate

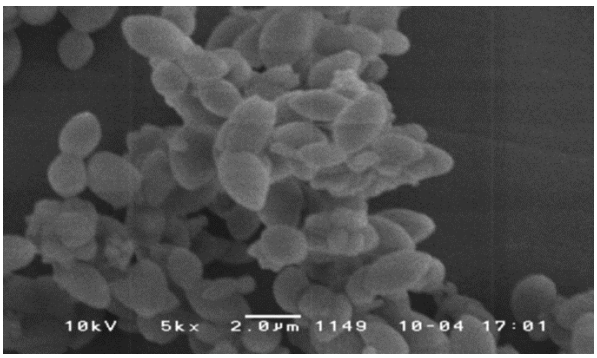

Figure 2. SEM image of the sample prepared with sonochemistry reaction.

4. Conclusions

We found a new synthesis of dolomite with ultrasonic irradiation under simple aqueous solution. Dolomite could be synthesized even using de-K ion bittern that is one of concentrated seawater. By immersion treatment, it was possible to synthesize dolomite phosphors showing the red or the green emission.

Highlights

- Nanoparticles size is affected by the concentration of the different compounds of the system.
- Quercetin is encapsulated by poly-lactic-co-glycolic acid.
- Experimental investigations are in a good agreement with simulated ones.

1. Introduction

Quercetin (2-(3, 4-dihydrohyphenyl)-3, 5, 7-trihydroxy-4H-1-benzopyran-4-one) is a flavonoid widely distributed in plant kingdom. Quercetin has been reported to be an antioxidant and which is known for its anti-carcinogenic effect, antibacterial, anti- antihypertensive and anti-inflammatory properties [1]. Nevertheless, the solubility of quercetin in water and many organic solvents is very weak (<0.01 (g/L)) [2, 3]. Many strategies were developed to improve its solubility and stability by physicochemical approaches [4]. In this work, MesoDyn simulations were used to study the quercetin organization as a nanoparticles in poly-lactic-co-glycolic acid/water system. Results obtained from simulations were compared to experimental data. The effect of the concentrations of quercetin, PLGA, PVA (polyvinyl alcohol) and the lactic acid: glycolic acid ratio on the aggregation phenomena was studied.

2. Methods

2.1. Study of quercetin organization as a nanoparticles in poly-lactic-co-glycolic acid/water system by MesoDyn: in the MesoDyn method, the molecules are defined on a coarse-grained level as "Gaussian chains of beads". Each bead is of a certain component type representing covalently bonded groups of atoms (Figure 1). The solubility parameter-dependent method was used to calculate the Flory Huggins (χ_{ij}) parameter depending on the Hildebrand solubility of the different compounds. The interaction parameters that were used in the MesoDyn simulations were calculated using χ_{ij}. The aggregation and phase separation behavior of different beads was followed by the order parameter, P. P is a time dependent parameter obtained as an output of the MesoDyn simulation.

2.2. Nanoparticles preparation and characterization: PLGA nanoparticles loaded with quercetin were prepared by the solvent displacement method. The mean particle diameter and polydispersity index (PI) of the nanoparticles were determined by dynamic light scattering. The morphology of the PLGA-Q nanoparticles was examined by transmission electron microscopy.

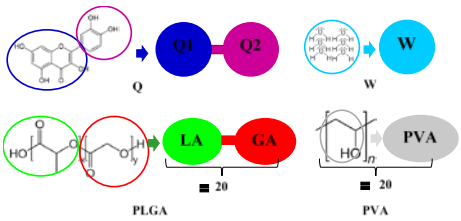

Figure 1. Coarse-grained model: molecules and monomer conversion into beads for Quercetin (Q), Poly (Lactic-co-Glycolic acid) (PLGA), Polyvinyl alcohol (PVA) and Water (W).

3. Results and discussion

Mesoscale simulations indicated that the studied systems allowed to produce nanoparticles well distributed in the continuous medium (water). The rapidity of the formation of nanoparticles is affected by the composition of the system. The fast kinetic of nanoparticle formation is reached with 10 g/L of poly-lactic-co-glycolic acid, 0.5 g/L of quercetin and 0.5% of polyvinyl alcohol. The increasing poly-lactic-co-glycolic acid and quercetin concentrations and LA content in poly-lactic-co-glycolic acid favor the formation of nanoparticles with large size. The formed nanoparticles were composed by quercetin (Q1 and Q2 parts) in the center of the system, poly-lactic-co-glycolic acid (lactic acid and glycolic acid) as a second layer and polyvinyl alcohol as third layer. The water is the continuous phase. The shape and the organization order of nanoparticles were checked experimentally. The obtained results showed that experimental investigations are in a good agreement with simulated ones (Figure 2).

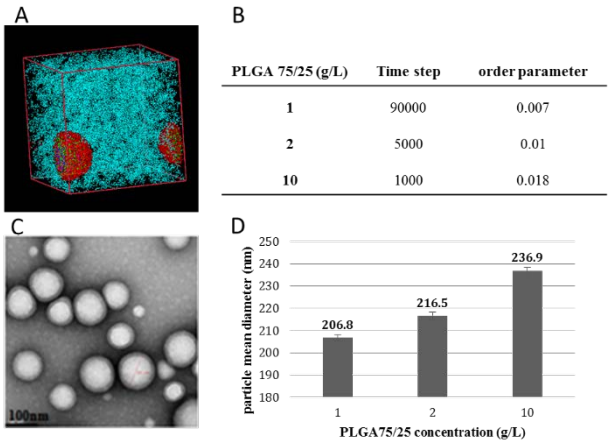

Figure 2. Main results obtained from mesoscale simulations (A, B) and experimental data (C, D).

4. Conclusions

Computational mesoscopic modeling approach can be used as a successful tool to understand and predict the behavior of quercetin/poly-lactic-co-glycolic acid/water systems under different operating conditions.

Nanoemulsions Produced at Large Scale by Premix Membrane Emulsification – Influence of Process Parameters and Formulation.

Océane Alliod[1],Catherine Charcosset[1]

1 Univ Lyon, Université Claude Bernard Lyon 1, CNRS, LAGEP UMR 5007, 43 boulevard du 11 novembre 1918, F-69100, VILLEURBANNE, France

**Corresponding author: catherine.charcosset@univ-lyon1.fr*

Highlights

- Nanoemulsions were produced by premix membrane emulsification
- A high pressure syringe pump controlled the pressure and flowrate
- W/O nanoemulsions with droplet size down to 260 nm were obtained

1. Introduction

Nanoemulsions find a wide range of applications in cosmetics, pharmaceuticals or food industry and are defined by their droplet size which is smaller than 1000 nm, 500 nm or 100 nm, depending on the definition used [1]. Generally, nanoemulsions are oil-in water emulsions (O/W) as the oil phase is dispersed into the water continuous phase, but can also be water-in-oil emulsions (W/O) when the water phase is dispersed into the oil continuous phase. W/O and O/W nanoemulsions can be produced by sonication and high pressure homogenization.

Membranes can be used for emulsification either in direct membrane emulsification (DME) or premix membrane emulsification (PME) [2]. DME consists in injecting under mild pressure the dispersed phase through a microporous membrane to the continuous one, whereas PME relies on injecting a coarse emulsion through the membrane. PME produces emulsions of smaller size range and with greater flowrate but DME does not require a premix step.

However, the production of nanoemulsions by membrane emulsification is challenging. Bunjes et al. prepared nanoemulsions by PME with droplet size lower or around 200 nm with narrow size distribution with SPG membranes for volumes up to 10 mL [3]. In previous works, we produced O/W and W/O nanoemulsions by PME and SPG membranes at high flowrate and relatively large volumes up to 500 mL [4, 5]. The aim of this communication is to report the preparation at large scale of O/W and W/O nanoemulsions using PME.

2. Methods

The experimental set-up used for the preparation of nanoemulsions by PME is shown in Figure 1. The set-up was composed of a high pressure cylinder pump BTSP 500-5 (Floxlab, Nanterre, France). Hydrophilic and hydrophobic tubular SPG membranes were provided by SPG Technology Co. Ltd (Miyazaki, Japan). Hydrophilic SPG membranes were used for O/W nanoemulsion production and hydrophobic for W/O nanoemulsions. The continuous and dispersed phases were first prepared and then mixed under magnetic stirring for 10 min to produce the premix.

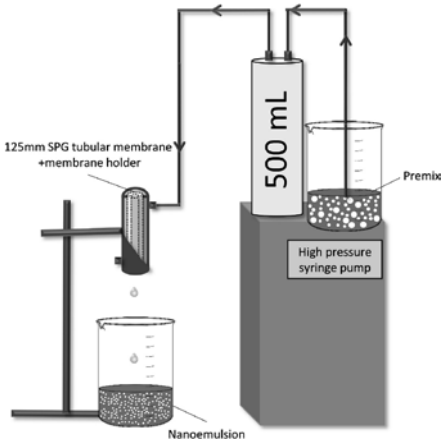

Figure 1. Experimental set-up of the high syringe pump with membrane holder and SPG membrane.

3. Results and discussion

The effect of several parameters was investigated: process parameters (scalability, cycle number, membrane pore size, flowrate) and formulation (oil and surfactant concentrations). Nanoemulsions were prepared at large scale up to 500 mL at production rate up to 200 mL/min, pressure below 60 bars and one cycle. The droplet size was linearly related to the membrane pore size and highly monodispersed nanoemulsions of around 260 nm in diameter and stable for 9 months at room temperature were achieved with the smallest pore size membrane (0.2 µm).

In addition, the effect of viscosities on pressure and droplet size was investigated: the water phase viscosity by increasing glycerol concentration, the oil phase viscosity with mineral oils of different viscosities and the overall emulsion viscosity by increasing the dispersed phase content of the emulsion. The pressure required to break up the droplets inside the membrane pores did not depend on viscosities, while the pressures generated by the flows through the pipe and the membrane were proportional to the viscosity of the overall emulsion. W/O nanoemulsions were more difficult to produce, they were obtained with mean droplets size around 600 nm and flowrate of 50 mL/min.

4. Conclusions

PME with SPG membranes produced O/W monodispersed nanoemulsions down to 260 nm with controlled size and very long stability over time. W/O nanoemulsions were produced with mean droplets size around 600 nm. W/O nanoemulsions were more difficult to produce and to characterize, but the different viscosities had the same influence on the membrane pressure as for O/W nanoemulsions.

Effect of the solvation force and the van der Waals forces on the Pull-off between Two Slightly Rough Surfaces from a Molecular View.

Gerson E. Valenzuela[1*]

1 Chemical Engineering Department, Universidad de La Frontera, Av. Francisco Salazar, Temuco 01145, Chile; Centro de Excelencia de Modelación y Computación Científica CEMCC, Universidad de La Frontera, Temuco 01145, Casilla 54-D, Chile.

**Corresponding author: gerson.valenzuela@ufrontera.cl*

Highlights

- Water bridge effect on the pull-off.
- Solvation versus van der Waals forces.
- Molecular dynamics simulation of nanometric systems.

1. Introduction

The correct understanding of the interaction forces between particles and surfaces is determinant in technological development [1] and processes with nanoparticles. [2] Such interaction in the air is composed of the van der Waals and electrostatic forces, and the capillary and solvation forces because of water bridges. [3] The effect of humidity on the interaction force is expressed in the pull-off measurement obtained in force spectroscopy during retraction of the tip in atomic force microscopy. [4] Computer simulations have been shown the solvation force produces pull-off between smooth hydrophilic surfaces. [5]. In this work it is shown that, during a pull-off, the van der Waals forces between two slightly roughness surfaces can be hidden by the solvation force, depending on the size of the bridge. The systems and the results are of nanometric resolution.

2. Methods

Figure 1-A1 shows a general diagram of the system. Each substrate (S1 and S2) have a circular roughness of radius 3 nm and depth 0.25 nm (Fig. 1-A2). When S2 is moving down the water droplet (500 molecules) becomes in a water bridge. S1 and S2 are hydrophilic. Interaction parameters of the system can be reviewed in refs. [5] and [6], the droplet forms a contact angle of 57°. The simulations are performed with a program that has been used in previous works. [5, 6, 7] The water temperature is controlled at 298 K. The force laws are obtained according to the method developed in refs. [6] and [7]. The pull-off simulations are performed according to ref. [5]. Cross interaction S1-S2 is defined by the Lennard-Jones potential with parameters $\sigma_{S1-S2} = 0.3$ nm and $\epsilon_{S1-S2} = 5\mathrm{k_B}$, providing a Hamaker constant of $0.98x10^{-20}$ J (similar for glass [8]).

3. Results and discussion

The force laws in Fig. 1-B shows that the water bridge controls the adhesion between the smooth surfaces. The interaction of the two-layer bridge (B2) and the monolayer (B1) appears with repulsive walls at a higher distance of separation than the interaction of S1 and S2. When the substrates are roughness (Fig. 1-C) the force law of the water bridge displaces to the left (in *D* axis) due to the depth of the roughness, and the interaction of B2 develops in a similar range than the

interaction S1-S2. In an approach and retraction of S2, the pull-off simulation (Fig. 1-D) shows a small peak (P1) when interaction S1-S2 are on. From P1, S2 is pull-off out of the interaction domain S1-S2, but the attraction increases with the retraction because the pull-off is controlled by the bridge. The effect of the bridge is clear considering a smaller one (256 water molecules) which is fully trapped into the roughness (inset Fig. 1-E). Figure 1-E show the pull-off, the water bridge does not affect the maximum attraction between S1 and S2 showing in Fig. 1-C (red line).

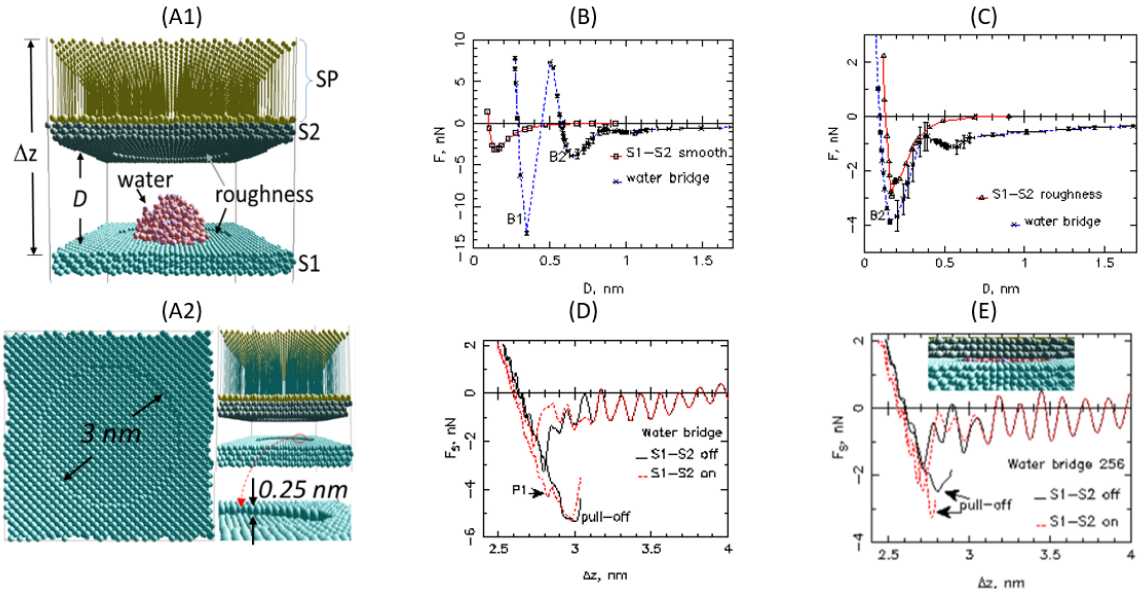

Figure 1. (A1) System. The force exerted by the bridge and the interaction S1-S2 is measured by the deflection of the SP. The "tip" (S2) is moved by displacing the top sites of the "cantilever" (SP) with constant speed, analogous to an AFM experiment; (A2) Detail of the roughness. (B) Force law for the interaction S1-S2 smooth alone (without a water bridge) and the force law for the bridge alone (interaction S1-S2 off) (C) Force laws between S1 and S2 roughness and for the bridge between them. (D) Pull-off for 500 water molecules (E) Pull-off for 256 water molecules.

4. Conclusions

The pull-off force between two smooth hydrophilic surfaces may be entirely dominated by a water bridge due to repulsive walls in the force law. For slightly roughness surfaces, the bridge affects the pull-off depending on its size. For a small bridge (250 water molecules) the van der Waals force between the surfaces is not affected by the solvation force, but for a bigger bridge (500 water molecules), the pull-off correspond to the solvation force.

Analytical ultracentrifugation – A versatile tool for the multidimensional characterization of nanoparticles

Johannes Walter, Simon Wawra, Wolfgang Peukert

Institute of Particle Technology (LFG), FAU Erlangen-Nürnberg, Germany
Interdisciplinary Center for Functional Particle Systems (FPS), FAU Erlangen-Nürnberg, Germany

Knowledge about the size, shape and optical properties of nanoparticles (NPs) is of high importance for many processes because product properties are directly influenced by these parameters. So far, combined analysis of size and shape or the determination of size and shape dependent optical properties has been a major challenge for nanoparticulate systems. Scattering or microscopic techniques are often limited by statistics, resolution and applicability to broad particle size distributions (PSDs). Ensemble based measurement devices such as the benchtop UV/Vis spectrophotometer fail to provide spectral information about individual species and require narrow size fractions instead.

These ubiquitous challenges provide the motivation and basis for the studies presented in this contribution. We have shown that analytical ultracentrifugation equipped with an UV-Vis multiwavelength detector (MWL-AUC) is a powerful tool for the simultaneous analysis of hydrodynamic and optical properties without the necessity of doing any purification step beforehand.[1] AUC combines the fractionation of particles in a gravitational field with up to 280,000 g with UV-VIS spectroscopy. The distribution of particles in an optically accessible cell is measured in-situ using a CCD spectrometer, which captures full spectra ranging from 250 to 1000 nm at each radial position with very high temporal resolution during centrifugation.[2]

Sedimentation coefficients can be calculated for all species out of which PSDs can be derived. Our recent developments on the instrumentation, acquisition as well as the evaluation of MWL-AUC data allow us to significantly extend the possibilities of MWL-AUC.[1, 3-4] Information on the size of all species in a mixture can be directly linked to their optical properties. Either extinction spectra can be determined or optical information can be used to deconvolute PSDs consisting of chemically heterogeneous NPs. For CdTe semiconductor quantum dots it is shown that the size dependent band-gap is derived in a single experiment.[5] For plasmonic nanorods, a full 2D size and shape distribution is accessible using MWL-AUC.[6] This is possible as hydrodynamic properties can be directly linked to the extinction spectra without any up-stream processing.

In case of non-plasmonic anisotropic particles, AUC can be coupled with analytics in the gas phase for mobility analysis using a scanning mobility particle sizer.[7] This allows deriving the mean length and diameter of nanorods (e.g. ZnO). For mono-layered graphene oxide nanosheets, it will be shown that AUC is capable of resolving shape distributions with high accuracy, statistical confidence and experimental throughput, which makes it superior to the usually applied and very time consuming image analysis.[8] For polydisperse PSDs, excellent statistics are obtained due to the evaluation at multiple wavelengths.[4]

In summary, our contribution will demonstrate that MWL-AUC is a powerful technique, which provides multidimensional access to an extensive range of particulate systems not accessible so far by any other technique. The direct correlation of size, shape and optical properties of NPs in the range between 1 nm and 1 µm is highly relevant for a variety of new applications because targeted product design becomes possible.

The Role of Surface-Ligand Interactions in Stability of All Inorganic Cesium Lead Halide Perovskite Nanocrystals.

Kiyoung Kim[1], Shin Ae Song[1], Sung Nam Lim[1], and Ju Young Woo*[,1]

1 Micro/Nano Scale Manufacturing R&D Group, Research Institute of Industrial Technology Convergence, Korea Institute of Industrial Technology (KITECH), Republic of Korea

Highlights

- $CsPbX_3$ NCs prepared in typical synthetic procedure is unstable under air.
- The stability of $CsPbX_3$ NCs can be considerably enhanced by modifying the synthesis.
- Origin of enhanced stability of $CsPbX_3$ NCs can be interpreted in the context of modified surface.

1. Introduction

Recent drastic increase of interest in colloidal all inorganic cesium lead halide perovskite ($CsPbX_3$, X is Cl, Br, and/or I) nanocrystals have derived from their extremely bright photoluminescence (PL), narrow full width at half maximum (FWHM) of PL spectrum, band gaps which are tunable over entire visible spectrum, defect tolerance, and highly dynamic interaction between ligands and atoms on NC surfaces (surface-ligand interactions).[1,2] However, the NCs are significantly unstable under air, hence further investigation is strongly hampered.[2] Here we present new synthesis of $CsPbX_3$ NCs with modified surfaces, thus considerably enhanced air stability. Also, the origin of instability (and stability) of $CsPbX_3$ NCs is revealed in the context of surface-ligand interactions.[3]

2. Methods

The synthesis are described in previously reported studies.[1,2] For the synthesis of typical $CsPbBr_3$ NCs, hot Cs-oleate solution is injected into degassed mixture solution of $PbBr_2$, oleic acid (OA), and oleylamine (OLA) in 1-octadecene (ODE) at 170 °C. The NCs are immediately formed upon the injection and the flask containing reaction mixture is rapidly cooled in an ice bath. For the synthesis of surface modified and air-stable $CsPbBr_3$ NCs, the mixture solution is formed by adding additional metal bromides (e.g., $ZnBr_2$) to $PbBr_2$, OA, and OLA in ODE. And other procedures are carried out identically with typical $CsPbBr_3$ NCs. After the synthesis, the NCs are purified by multiple centrifugations with or without polar antisolvent (e.g., methyl acetate). Finally the $CsPbBr_3$ NCs are dispersed in organic solvents such as hexane and toluene, or stored in the form of films for further characterizations.

3. Results and discussion

The typical $CsPbBr_3$ NCs prepared without additional metal halides fused along (110) direction when the NCs were exposed to air in the form of films. Also, the PL QY of typical $CsPbBr_3$ NCs decreased drastically under air condition possibly due to relaxed confinement of exciton upon

fusion of the NCs.[4] In contrast, $CsPbBr_3$ NCs synthesized with additional of additional metal bromide are highly stable without nearly no sign of fusion in air. In addition, the PL QY of the NCs relatively well retained compared to typical NCs (Figure 1).[2]

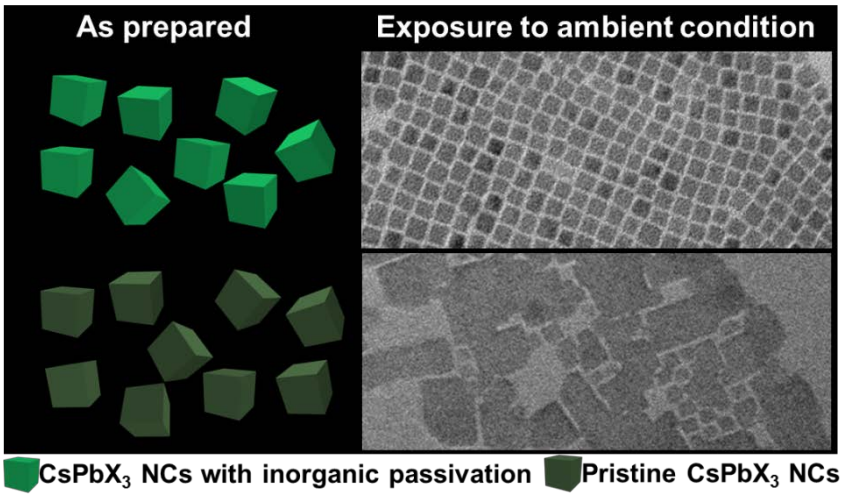

Figure 1. Schematic illustration and TEM images of typical (bottom) and modified (upper) $CsPbBr_3$ NCs.

4. Conclusions

In conclusion, we successfully present $CsPbX_3$ NCs with dramatically enhanced stability under air by adding additional metal halides in the synthesis.[2] Further study will be presented to reveal the origin of instability (stability) of $CsPbX_3$ NCs in the context of modified surface-ligand interactions with the addition of additional metal halides during the synthesis.

Stability of nanobubble dispersions in liquids of various composition and physicochemical properties

Karol Ulatowski, Paweł Sobieszuk*, Tomasz Ciach

Warsaw University of Technology, Faculty of Chemical and Process Engineering, Warynskiego 1, Warsaw, Poland

**Corresponding author: Pawel.Sobieszuk@pw.edu.pl*

Highlights

- Gas nanobubbles are stable even in deionized water.
- The stability of nanobubbles varies in liquids of different polarity.
- Nanobubbles are stable for low absolute values of zeta potential (under 30 mV).
- Diameter of bubbles is different for each gas phase used.

1. Introduction

Bulk nanobubbles are spherical gas domains in liquid which are characterized by diameter under 1 µm. In consequence, the rising velocity of nanobubbles is extremely low (according to Stokes law) and their internal pressure is high as for Laplace equation [1]. What is more, nanobubbles are reported to be stable for a long time (weeks to months) in aqueous dispersions [2-4]. However, the investigation of generation in non-polar liquids and systematic research of stability of bubbles in aqueous solutions with salt or surfactant additions is still to be done. This study aims to show the results of research of stability of bubbles generated in mentioned liquid phases.

2. Methods

Nanobubbles were generated in the system presented schematically in Figure 1. Gas from the cylinder squeezes through the pores of the ceramic membrane and forms hemispherical domains which are cut off by the flowing liquid. Several gases were used, including nitrogen, oxygen and air among others. The two-phase flow was returned to the storage tank. Liquid stored in tank was sucked by the rotary pump which induced the flow of the liquid inside the cylindrical membrane. Liquids ranged from pure (deionized) water, through water with salt and surfactant additions up to nonpolar organic liquids.

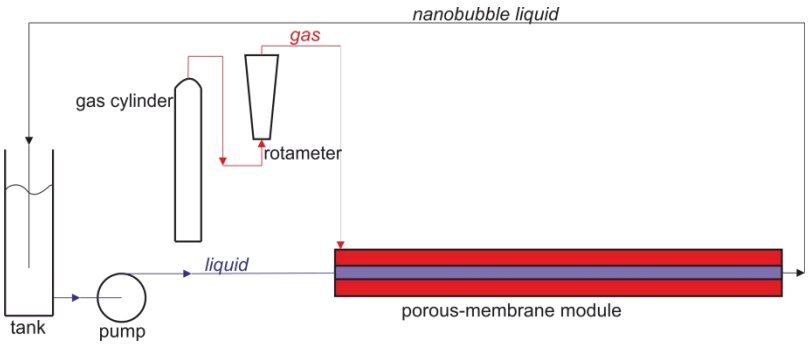

Figure 1. Scheme of the experimental setup

The distribution density of bubbles and zeta potential was measured using Malvern Zetasizer Nano ZS using DLS technique. For each measurement the Sauter diameter (d_{32}) was calculated.

3. Results and discussion

In Figure 2 one can see the exemplary results of Sauter diameter obtained for nitrogen and oxygen nanobubbles with deionized water as a liquid phase. It is clear that the diameter of bubbles over time is nearly constant. Another interesting fact is that oxygen nanobubbles are about two times smaller than the nitrogen nanobubbles. The reasons for such extraordinary stability of nanobubbles are not clear. Ulatowski et al. [2] proposed the possible explanation of this phenomenon, linking it with the reduction of surface tension due to accumulation of charge on nanobubble surface (analogously to reduction of surface tension on charged drop proposed by Lord Rayleigh theory). Another theory proposed by Ohgaki et al. [4] states that water molecules form hard shells around bubbles, due to their hydrophobicity. That leads to a reduction in diffusivity of gas through the gas-water interface and increase of surface tension. The stability of nanoobjects is linked to zeta potential value. For solid nanoparticles, the absolute value of zeta potential which indicates high stability of dispersion is assumed as 30 mV. In this work, the stable nanobubbles were obtained for low value of zeta potential of about –15 mV.

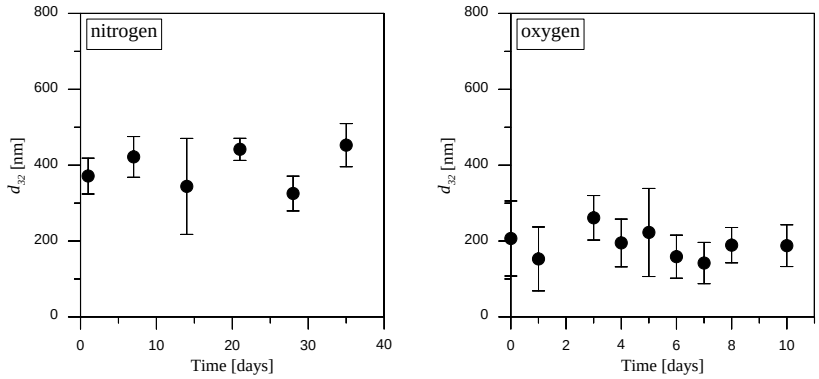

Figure 2. Sauter diameter of bubbles as a function of time for nitrogen and oxygen nanobubbles in pure water

4. Conclusions

Investigation of reasons of nanobubble stability is not a closed case. There is much to discuss and investigate in future. This works aims to investigate the stability of nanobubbles in various liquids of different polarity, ions presence and other physicochemical properties.

Abstract

Fluorescent nanomaterials have received intense scientific attention and offer promising applications from molecular sensors through cancer diagnosis agents to optoelectronic devices. Aggregation-induced emission (AIE), which effect is exactly opposite to the notorious ACQ (aggregation-caused quenching), are among the most attractive of fluorescent nanomaterials, offering possibility with any concentration for bioassays in the use of dye solutions. However, most AIE materials, such as hexaphenylsilole (HPS), are soluble in toxic organic solvents (e.g. tetrahydrofuran), and insoluble in green solvents (such as water), which limited the further application of biological applications. The high pressure reactors widely used in supercritical/subcritical fluid technique, can generate subcritical water (SBCW) referring to liquid water with pressure in the temperature range of 373.15 K to 647.15 K, which can be used as the solvent to eliminate the use of organic solvents and provide a green route to synthesize fluorescent nanomaterials. In this work, we reported a green process for the synthesis of AIE fluorescent nanoparticles via solvent anti-solvent precipitation, in which the SBCW and cold water were used as the solvent and anti-solvent respectively. The obtained AIE fluorescent organic nanodots showed an average size less than 10 nm with uniform distribution, and exhibited good optical performance and well-dispersion in aqueous solution. The use of SBCW as the solvent overcomes the limitations of using toxic organic solvents during solvent anti-solvent precipitation, offering a green method of manufacturing AIE fluorescent nanoparticles, as well as other poor water soluble fluorescent nanomaterials, and it is also more convenient for real-time monitoring of the temperature and pressure in the reaction system and more reliable for scalable mass-production.

Controllable Preparation of Multi-scale Silica Using High-gravity Technology Combined with Spray Drying Process for Dental Restoration Application

Dan-Lei Yang[1,2], Hao Niu[1,2], Dan Wang[1,2], Jie-Xin Wang*[1,2]

1 State Key Laboratory of Organic–Inorganic Composites; 2 Research Center of the Ministry of Education for High Gravity Engineering and Technology, Beijing University of Chemical Technology, Beijing 100029, PR China

**Corresponding author: wangjx@mail.buct.edu.cn*

Abstract

Resin-based composites have been frequently used in dental restoration because of their outstanding esthetics, mechanical performances, biocompatibility, and clinical operability. The particle size, dispersity and structure of inorganic filler are decisive for the properties of resin composite. In this study, monodisperse silica nanoparticles (MSNPs) with a controllable diameter were efficiently prepared with high-gravity technology in an internal circulation rotating packed bed (ICRPB), and then the spray-drying technology was used to efficiently construct micron-scale nanoparticle clusters (MSNCs). The results indicated that the particle size, morphology and dispersion of silica nanoparticles were influenced by the rotating speed of ICRPB and the concentration of reactants. Compared with traditional stirred tank reactor, the hydrolyzation process in ICRPB had one-third descent in reaction time and the size of MSNPs dramatically decreased. The prepared nanodispersions could be stably conserved for over 12 months without any changes in particle size, transparency and monodispersity. After being modified by the silane coupling agent, the MSNPs were mixed with the resin matrix to preparing the resin composites. The effects of filler content, particle size and structure on mechanical performances were further examined. It could be found that the mechanical properties of composites were significantly improved with the increased filler content from 40 to 70 wt.%, and enhanced first and then dropped with increasing particle size when the MSNPs were used as the fillers. Due to the excellent dispersity, the maximum content of MSNPs was 30% higher than that of commercial silica nanoparticles with the same size, thereby resulting in better properties of the composites. Furthermore, compared with silica microparticles with the similar average size and the MSNPs, the MSNCs showed an obvious improvement in flexural strength and compressive strength due to its steady porous structure inside, which was capable to produce a stronger interlocking between organic resin and inorganic fillers. This method could be applied to the preparation of hydroxyapatite, zinc oxide and zirconia nanoparticle clusters, and will provide a new idea for the controlled preparation of high-performance multifunctional fillers for dental restorative resin composites.

Multi-stimuli-responsive liquid marbles for miniature reactors

Zhijian Zhao[1,2], Yuan Pu[1,2], Dan Wang[1,2,*]

1 Beijing Advanced Innovation Center for Soft Matter Science and Engineering, State Key Laboratory of Organic Inorganic Composites, Beijing University of Chemical Technology, Beijing 100029, China;

2 Research Center of the Ministry of Education for High Gravity Engineering and Technology, Beijing University of Chemical Technology, Beijing 100029, China

** Dan Wang (wangdan@mail.buct.edu.cn)*

Liquid marbles (LMs) were first reported by Aussilous and Quéré in 2001 to realize the microfluidic motion without wetting solid surface[1] and this has attracted increasing research interest. LMs prevent the contact of encased liquid inside with supporting plan so that the problem of surface contamination is avoided and surface friction is significantly reduced. As a new approach to manipulating liquid, LMs can be driven by external forces, such as gravity, electricity, light, based on the liquid or component attributes; However, most LMs reported, as far as we are aware, respond to a single external stimulus only with limited prospects. The formation of LMs triggered by various stimuli is important for its potential application, which, however, are still problematic.LMs used as droplet reactors have also been adopted recently due to the advantages of compartmentalization, miniaturization, mono-dispersity, and high throughput, which can reduce the use of chemical reagents and solvents with confined micro-environments and controllable reaction conditions. However, existing research almost is based mainly on the static properties of LMs without turbulent mixing, or basically perform LM-based microreactions with the encapsulation of all reagents in an individual reaction system; this limits the performance of LMs as microreactors, since mass transfer and molecular mixing are crucial for chemical engineering processing. The interactions between LMs vary depending on the properties of the coating particles and liquid encapsulated within them, particularly. LMs coalescence is one of the most essential manipulation schemes to functionalize microfluidics with an application like micro-mixing and microreaction. When two LMs are placed in contact, they will not coalesce naturally even pressed against each other. However, the surface deformation during collision will convert the kinetic energy to an accumulated impetus for triggering and even intensifying reaction processes. A number of techniques have been reported to collide LMs such as magnetic force and DC voltage. However, the coalescence that intensifies a microreaction in LMs is rarely reported. In this talk, we report a set of LMs which were multi-stimuli-responsive to light, electricity, ultraphonic and magnetism. Therefore, LMs-based microreactors can be manipulated in different ways accordingly. The effects of drop size and collision on both reaction rate and nanomaterials size were investigated by both theoretical calculation and experimental studies. This work opens the way to for expand the functions of LMs, and offers analysis tools to study the mechanisms of micromixing in a large variety of applications.

Designing hybrid nanocomposites of molybdenum disulphide/carbon nanomaterials

Zuzanna Bojarska[1], Marta Mazurkiewicz-Pawlicka[1], Monika Arasimowicz[2], Łukasz Makowski[1]

1 Faculty of Chemical and Process Engineering, Warsaw University of Technology, Waryńskiego 1, 00-645 Warsaw, Poland; 2 Centre of New Technologies, University of Warsaw, Banacha 2c, 02-097 Warsaw, Poland

**Corresponding author: 6701@pw.edu.pl*

Highlights

- Method of the producing MoS_2 nanoparticles on carbon nanomaterials has been developed.
- Effect of carbon materials on properties of the obtained composite was investigated.

1. Introduction

In recent years, remarkable interest has been focused on the 2D nanomaterials and their applications, due to their unique properties. Designing and manufacturing new nanostructures with improved properties using modern techniques is a tempting prospect for nanotechnology. One of the most famous 2D nanomaterials is graphene. It is an amazing material, which has a large theoretical specific surface area (2630 m^2g^{-1}), high intrinsic mobility (200 000 $cm^2v^{-1}s^{-1}$), high Young's modulus (~1.0 TPa) and thermal conductivity (~5000 $Wm^{-1}K^{-1}$). It also has very high optical transmittance (~ 97.7%) and good electrical conductivity. Graphene and its derivatives such as graphene oxide (GO) or reduced graphene oxide (rGO) are new nanomaterials that have recently found numerous applications, such as graphene-based electronic devices, catalysts, transparent conductive electrodes and others [1]. Similarly, molybdenum disulphide (MoS_2) is a widely used 2D nanomaterial. Molybdenum disulphide has a crystal structure consisting of layers of S–Mo–S where a layer of molybdenum atom is sandwiched by two layers of sulphur atoms. Individual layers of S–Mo–S are coupled together by weak van der Waals forces, which could move relatively easily against each other. Furthermore, MoS_2 is a widely studied semiconductor, with a large band gap of around 1.8 eV. Thanks to the above-mentioned properties MoS_2 found numerous applications such as a dry lubricant, in hydrogen evolution reaction catalysis, hydrogen storage and others [2]. In addition, MoS_2 can be an excellent candidate for being combined with carbon nanomaterials to obtain new hybrid nanocomposites with outstanding properties including higher photocatalytic activity, increase of the adsorption of pollutants, and improved rheological properties [3].

2. Methods

The aim of the conducted research was the preparation of hybrid nanocomposites formed from molybdenum disulphide and carbon nanomaterials such as graphene oxide (GO), reduced graphene oxide (rGO), graphene oxide modified with ammonia (GO-NH_3), and reduced graphene oxide modified with ammonia (rGO-NH_3). Graphene oxide was synthesized from graphite powder,

following modified Hummer's method [4]. Reduced graphene oxide was prepared by the chemical reduction method using a 50% hydrazine solution. Furthermore, GO and rGO materials were modified with ammonia solution, which led to the addition of nitrogen-containing groups in the structure. Molybdenum disulphide nanoparticles were synthesized in the turbulent micromixer with coaxial geometry, using ammonium molybdate tetrahydrate, citric acid and ammonium sulfide as the substrates for the reaction. Physicochemical analysis of obtained carbon nanomaterials and molybdenum disulphide was carried out, using various analytical techniques: Fourier-transform infrared spectroscopy, thermogravimetric analysis, X-ray Diffraction, elemental analysis, particle sizing analysis, and electron microscopy. Molybdenum disulphide/carbon materials hybrid nanocomposites were obtained by: a) mixing both materials in an ultrasonic bath, followed by an ultrasonic homogenizer, b) a precipitation process in the turbulent micromixer. The full analysis of the samples was carried out. In addition, the optical properties of the obtained nanocomposites were evaluated by UV-vis spectroscopy, following the degradation of methylene blue (MB) under solar-like irradiation and under UV irradiation.

3. Results and discussion

Reduction of GO leads to partial removal of oxygen groups from GO (the content of oxygen in GO was 43.71 wt.%, and in rGO was 17.51 wt.%). Modification of GO with ammonia resulted in an enrichment of the GO structure with nitrogen (from 0.58 wt.% to 3.67 wt.%). Modification of rGO with ammonia solution resulted in an enrichment of the rGO structure with nitrogen (from 0.00 wt.% to 0.53 wt.%). The dispersion using an ultrasonic bath, followed by an ultrasonic homogenizer is a good method to obtain hybrid MoS_2/carbon nanomaterials, which was confirmed by XRF and TGA method. The precipitation method that allows controlled heterogeneous nucleation of primary nanoparticles of MoS_2 on graphene particles still needs improvement, due to the excess of sulphur present in the final product. The conducted research has shown the hybrid nanocomposites have better photocatalytic activity toward the photodegradation of methylene blue compared to pure MoS_2.

4. Conclusions

The aim of the presented research was the preparation process of hybrid MoS_2/carbon nanomaterials. Carbon nanomaterials including graphene oxide, reduced graphene oxide, graphene oxide modified with ammonia, and reduced graphene oxide modified with ammonia have been tested for this purpose. The obtained hybrid nanomaterials possess both favorable features and disadvantages and still needs further research. Although, the degradation of MB tests allowed to state that the presence of the carbon nanomaterials in the hybrid materials improve photocatalytic activity.

This work was supported by the National Science Centre [No.2017/27/B/ST8/01382].

Highlights

- Y-shaped millireactor application to the continuous synthesis of hydroxyapatite
- Lecithin used as a surfactant to control the morphology of particles
- Synthesis provides carbonated hydroxyapatite with a spherical shape
- The aging temperature affects the particles size

1. Introduction

Hydroxyapatite (HAp) is the main inorganic part of human hard tissue (bones and teeth) [1]. Therefore synthetic HAp is a common material in regenerative medicine, particularly in bone tissue regeneration [2]. Those applications create a demand for new methods of HAp synthesis. Among all the methods for producing hydroxyapatite powders, synthesis in a continuous reactor seems to be a promising way to obtain better control over the reaction conditions. Production of hydroxyapatite nanoparticles using ultrasonic tubular microreactor, meso-oscillatory flow reactor, tube-in-tube microchannel reactor, among the others, has been reported in the literature [3]. We present results of HAp nanoparticles synthesis using a Y-type millireactor. For this purpose, we use 3D printing technology to produce a continuous reactor with 1 mm inner hydraulic diameter and 10 mm in length of the outlet channel. We investigated the influence of the lecithin concentration used in the synthesis and the aging conditions on the properties of the powders.

2. Methods

We synthesized hydroxyapatite in the presence of lecithin (HAp-LE) by chemical precipitation method using a solution of $Ca(NO_3)_2 \cdot 4H_2O$ and solution of $(NH_4)_2HPO_4$ in ultra-pure water as starting media [4]. Ca/P molar ratio was maintained at 1.67 as in a stoichiometric HAp. The synthesis was conducted in Y-shaped continuous reactor (1 mm inner hydraulic diameter and 10 mm in length of the outlet channel) under atmospheric pressure with each starting media flow rate of 500 ml/h. The resulting suspension of hydroxyapatite was aged in an aging reactor for 24 h at room temperature (RT) or at 60 °C, or directly centrifuged without aging (wa). After the aging process, the suspensions were centrifuged, washed with fresh water and then dried in an oven at 50°C for 24 h. Four different concentrations of lecithin were tested: 1, 3, 5 and 15 g/L in the reaction mixture. Resulting powders were characterized by X-ray diffraction (XRD), Fourier transformed infrared spectroscopy (FTIR), scanning electron microscopy (SEM), nanoparticle tracking analysis (NTA), dynamic light scattering (DLS) and zeta potential measurement.

Moreover, we implemented the method of Chemical Oxygen Demand (COD) analysis to the quantitative determination of lecithin concentration in powders.

3. Results and discussion

Results of investigation of phase purity (XRD) and chemical composition (FTIR) show that we obtained carbonated hydroxyapatite regardless of the aging conditions and the amount of lecithin used. COD measurements confirm predicted increase in the concentration of lecithin in the final product with an increasing concentration of lecithin used in synthesis. SEM images show structure consisting of spherical particles with size 10-25 nm. The sizing techniques used (NTA and DLS) demonstrate broad particle size distribution indicating particles agglomeration with sizes to about 500 nm in NTA and about 1 000 nm in DLS. The values of the zeta potential around –5 mV explain instability and tendency of particles to agglomerate. Of the parameters tested here, the aging temperature has the greatest influence on the final properties of the HAp-LE. An increase in aging temperature causes higher crystallinity, larger crystal size, and larger particle sizes. What is more, we obtain a minimum particle size depending on the lecithin concentration - for samples aged at room temperature with a lecithin concentration of 5 g/L (around 10 nm), and for samples aged at 60 °C and without aging with a concentration of 3 g/L (around 15 nm).

4. Conclusions

The continuous process of hydroxyapatite precipitation in a 3D-printed millireactor was achieved and the final products were characterized. We present a simple and low-cost method to produce spherical nanoparticles modified with lecithin. Among tested parameters, the aging temperature has the most significant influence on powders properties (size, crystallinity). The concentration of lecithin also has an influence on the size of the resulting HAp-LE particles. Therefore, we conclude that lecithin is an addition that permits control over the size of the obtained particles. Summarizing, when planning the production of hydroxyapatite using the proposed approach, it is essential to control the lecithin concentration and the temperature in the post-processing reactor.

Abstract

The controllable synthesis of monodisperse nanocrystals has attracted broad attentions because of their scientific and technological applications. In this study, a novel route was presented to controllably prepare transparent dispersions of monodispersed ZrO_2 nanocrystals with inexpensive inorganic zirconium salt under an acid aqueous surrounding by using high-gravity reactive precipitation in a rotating packed bed reactor combined with solvothermal treatment. By altering reaction conditions, the controllability for the crystalline forms from monoclinic to tetragonal phases, the average particle size from 3 to 20 nm, the shapes of sphere, rice, spindle, rod, and cube can be achieved. The as-prepared monodispersed ZrO_2 nanocrystals can be readily dispersed in many solvents including water, alcohols, esters, cycloalkanes, oils, etc, thereby forming highly-concentrated (>60 wt%), highly-stable (>18 months) and highly-transparent nanodispersions. Furthermore, highly transparent polyvinyl alcohol (PVA)/ZrO_2 and polystyrene (PS)/ZrO_2 nanocomposite films with high refractive index were conveniently prepared with a simple solution mixing route. The refractive index can be tuned from 1.53 to 1.75 (@ 589 nm) by changing the mass fraction (0-80 wt.%) of ZrO_2 in transparent nanocomposite films. It could be envisioned that such highly dispersed ZrO_2 nanocrystals would be potential in many areas including LED encapsulation, dental ceramics, solar cells, catalysts and so forth.

Highlights

- The study focuses on the Interfacial shear strength (IFSS) in polymer composites reinforced with natural fiber yarns
- This study proposes a quantitively method for the evaluation of the IFSS
- The results indicated that there is a relationship between the IFSS and the type of chemical treatment performed on the natural fibers
- The NaOH treatment and coating with reduced oxygen graphene (rGO) increase the IFSS to a thermoset matrix in 80 % approximately

1. Introduction

Recently, natural fibers (NF) used as reinforcement for polymeric and cementitious composites have gained interest among researchers in materials engineering, mainly due to their specific tensile properties, such as their elasticity modulus, low costs, sustainability, high socio-economic impact on farming communities and reduction of the environmental impact mostly generated by the use of inorganic fibers such as glass, asbestos or carbon [1], [2]. Fique *"furcraea macrophylla"* fibers are obtained from the leaves of an agave plant with the same name, they are similar to Brazilian sisal and Mexican henequen fibers. In Colombia, they are cultivated mainly in the Andean areas such as Santander, Antioquia and Nariño. [3]

One of the most important properties used to analyse the mechanical performance of polymer composites is the adherence between the phases (matrix and reinforcement), that property is also known as interfacial shear strength (IFSS). The performance of a polymer composite reinforced with NFs like fique, can be compromised in the medium to long term because of the hydrophilic behaviour of fibers; to evaluate the IFSS, both qualitative and quantitative methods are used, which lately seek to establish the efficiency of different treatments on NFs such the previously mentioned among others, one of the most accepted methods is the uniaxial pull-out test, which has been researched mainly on inorganic singular fibers because the for the ease and precision in carrying out the calculations. The main advantage of this method is that it is a quantitative method of direct measurement, which allows to evaluate in a more accurate way the mechanical composite performance. However, due to the irregularity in the geometry of NFs, both longitudinally and transversally directions, such as fique fibers, this type of experiment can yield results with high degrees of dispersion.

2. Methods

In this work, uniaxial pull-out tests using fique fibers yarns (multifilament fibers) [4] instead of singular fibers, is proposed. The influence of three different treatments: NaOH cationization, nanoTiO_2 and rGO fibers coating on the IFSS in a thermoset composite was evaluated. 5 specimens of each type of modification were tested. The initial length was 100 mm (±0.5 mm). The tensile tests were performed using 2 mm/min displacement speed and at room temperature (≈25º C). For the critical immersion length determination, fique yarns with 20, 15, 10, 5, 2 and 1 mm of immersion were tested. The IFSS were calculated for the different types of modified yarns and the influence of the treatments on the IFSS was analysed.

3. Results and discussion

The main purpose of the multifilament probes instead of singular fibers or filaments was to reduce the dispersion on the obtained data and adjust the results to the commercial products that are marketed in Colombia for the company "Coohilados del fonce". The tensile tests showed a maximum resistance between 374,5 and 433,8 MPa for the fique yarns, similar to other natural fibers as sisal or henequen [5,6]. Table 1 shows the results of maximum resistance, elasticity modulus and deformation percentage at break for fique fibers yarns.

Table 1. Tensile test results for fique yarns

Treatment	σ_{max}	E	ε_{break}
	MPa	GPa	%
Untreated	433,8 ± 81,2	13,0 ± 4,5	0,0272 ± 0,005
NaOH	400,8 ± 122,2	12,4 ± 2,3	0,0301 ± 0,007
NaOH + TiO2	374,5 ± 62,1	11,4 ± 2,8	0,0321 ± 0,003

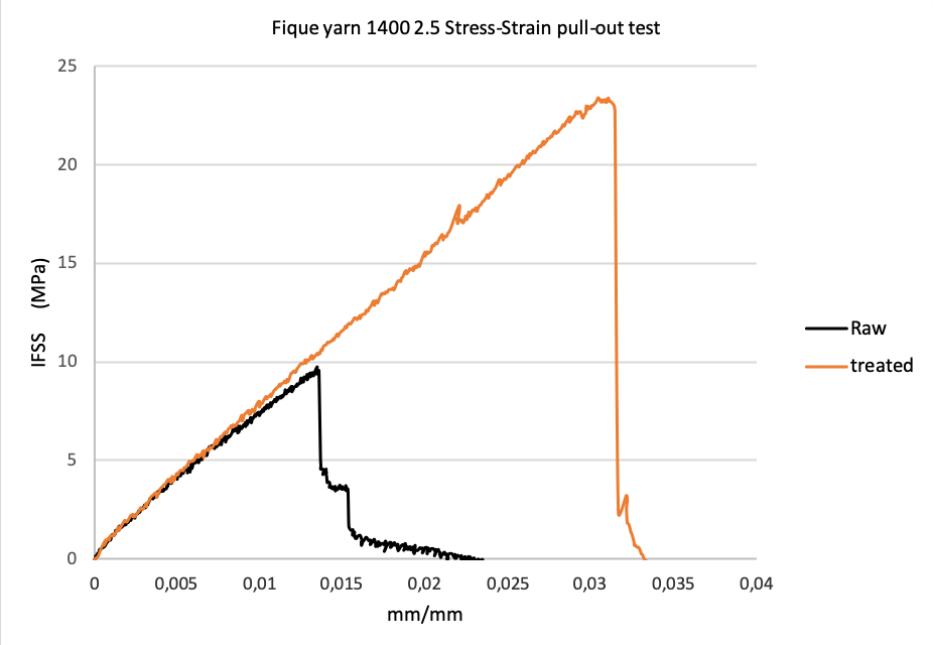

Figure 1. Interfacial shear strength vs strain tensile curve on raw and rGO coated fique natural yarns

The results from the uniaxial tensile test of IFSS are shown in Fig.1. The figure shows a typical IFSS stress strain curve, in this case obtained for the fique yarns tests, the curve indicates that the maximum IFSS stress for fique yarns increase from 9,75 MPa on raw fibers to 23,2 MPa on chemical treated fibers [7].

4. Conclusions

The results indicated that there is a relation between the IFSS and the type of treatment performed on the fique fibers, that is how fique fibers IFSS values increases with the treatments performed from 9,78 MPa for raw fique fibers to more that 20 MPa for the NaOH+rGO coated fibers average for the single fibers, assuming a circular cross section of 82 μm; for fique yarns the same values increase from 25, 5 MPa to 27,4 MPa, by calculating the cross section al area of 0,2278 mm^2 for raw yarns.

This study proposes the application of a direct measurement method of IFSS to achieve a more accurate evaluation of the interfacial adhesion properties for fique fibers and their derivate products.

Investigating Ion-Exchange Adsorption of Proteins through Experiments and Molecular Dynamics Simulations

Marine Tournois[1,*], Jérémy Esque[1], Isabelle André[1], Stéphane Mathé[1], Maria A. Fernandez[1]

1 LISBP, Université de Toulouse, CNRS, INRA, INSA, Toulouse, France

Highlights

- The adsorption of α-chymotrypsin on SP Sepharose FF is investigated.
- The steric mass action model is used to describe single adsorption isotherms.
- MD simulations using all-atom models are performed.
- Results from MD simulations are in good agreement with macroscopic experiments.

1. Introduction

Chromatographic processes, especially Ion Exchange Chromatography (IEC), are extensively used in protein purification. However, their industrial scale-up remains under-optimized and is still based on empirical methods. Today, their cost represents up to 80-90% of the global cost for protein production. The protein adsorption on chromatographic media has been thoroughly investigated over the past decades, in terms of surface properties, influence of pH and/or ionic strength as well as protein characterization in single and multicomponent systems. The aim of this work is to better understand the binding mechanisms of proteins on adsorbents using Molecular Dynamics (MD) simulations. Indeed, MD simulations are a powerful tool and allow the study at the atomic level without requiring microscopic experimental techniques. The steric mass action (SMA) model [1], which accounts for the steric hindrance of the protein, is widely used to describe single adsorption isotherms and depends on different parameters such as the characteristic charge of the protein, the steric factor and the equilibrium constant. These parameters were obtained both experimentally and through MD simulations [2][3] for a protein (α-chymotrypsin) and a well-known resin (SP Sepharose FF) chosen as models. It allows validating the relevance of microscopic simulations to predict the protein adsorption behavior in adsorbents and then avoid long and costly experiences. This, in turns, enables simulation-based improvement of protein purification process which may have strong industrial impacts.

2. Methods

Experiments and molecular dynamics simulations were performed to study the ion-exchange mechanism from macroscopic and microscopic scales. Breakthrough curves measurements were performed by loading a protein solution, at controlled pH and ionic strength, into an IEC column, for determination of experimental adsorption isotherms. The SP Sepharose FF ionic capacity was also measured. Then, fitting of the experimental results by the SMA model allowed for the estimation of the characteristic charge, the steric factor and the equilibrium constant.

MD simulations were run using all-atom model [4]: a simulation box, containing the protonated protein (pH=5), the charged ligands (the agarose matrix is not represented), ions (Na^+ and Cl^-) and water molecules, was created. The protein is free to move in the box and the ligands are restrained to form a layer at the bottom. Then, long simulations (+100 ns) were performed with GROMACS 2018.3 simulation software and analyzed. Different starting orientations of the protein were also investigated and several simulations were run to obtain a reliable set of data.

3. Results and discussion

The results obtained through macroscopic experiments (presented in Figure 1.a) and microscopic simulations, especially the characteristic charge and the steric factor, were compared. Figure 1.b. shows an example of simulation box at initial conditions.

(a) (b)

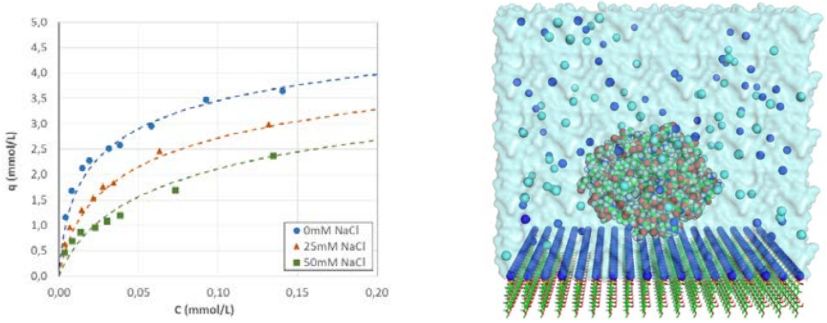

Figure 1. (a) Adsorption isotherms of α-chymotrypsin on SP Sepharose FF (pH=5): experiments vs SMA model (dotted line). **(b)** MD simulation box at initialization. Charged sites are represented at the bottom of the box (324 ligands); positively and negatively charged ions are colored in blue and cyan respectively.

All MD simulations led to an adsorption of the protein on the chromatographic surface, with exchange of Na^+ counter-ions, and the binding residues were also identified. Moreover, free binding energies of interaction were calculated and used to highlight the most favorable binding sites of α-chymotrypsin.

4. Conclusions

α-chymotrypsin and SP Sepharose FF were used to investigate the adsorption mechanism at the atomic scale, combining macroscopic experiments and MD simulations. The two parameters from the SMA model (charge and steric factor), obtained through the simulations, are in good agreement with those obtained from experiments. Thus, MD simulations seem to be a reliable tool to predict the protein retention with a chromatographic surface, in a single-component system. The influence of ionic strength, pH or ligand density is still under investigation, as well as the proteins behavior in multi-component system.

Highlights

- Thermodynamics of physical adsorption from 25 to 100 °C
- Determination of isosteric heats of adsorption
- Fitting of diffusion coefficients by mathematical modelling
- Investigation of chemical adsorption by temperature programmed desorption experiments

1. Introduction

Sources of mercury pollution such as coal-fired power plants, cement plants and waste incineration plants are subject to tightening of regulatory limits. In addition, a stronger focus is given to mercury emission from discontinuous processes e.g. in metal refining or crematoria. While in continuous processes, established technologies like absorptive gas scrubbing or flue gas adsorption are applied, for discontinuous emissions only fixed-bed adsorption with activated carbon is suitable from an economic point of view. For the design and optimization of such processes, a good knowledge of the adsorption thermodynamics and kinetics is necessary. Measurement of mercury adsorption is difficult because mercury is toxic, adsorbs chemically on the surface of many materials (e.g. metal surfaces of pipes and valves) and reproducible supply of mercury vapor requires thorough experimental care. Accordingly, only few data of mercury adsorption has been published.

The aim of this work is to better understand the mechanisms involved in the adsorption of mercury. This understanding particularly applies to the interactions of mercury with the surface of the adsorbents and the influence of the pore size distribution on equilibrium and kinetics.

2. Methods

The adsorption of Hg^0 from a N_2 carrier gas stream is studied on commercial activated carbons. Single and cumulative breakthrough curves are measured in a fixed bed at temperatures of 25 °C to 100 °C and mercury concentrations of 50 to 1000 µg/m^3. From the measured adsorption isotherms isosteric heats of adsorption are determined. In addition, desorption experiments are conducted to distinguish the contributions of physisorption and chemisorption. A dynamic simulation of experimental breakthrough curves yields diffusion coefficients which are discussed with respect to the concentration and temperature dependence of diffusion mechanisms in mercury physisorption. For detailed investigation of mercury chemisorption temperature programmed desorption (TPD) experiments employing activated carbon loaded with mercury are

carried out. During the experiments, the adsorbents are heated from 30 to 500 °C with a constant heating rate of 5 °C/min.

3. Results and discussion

The activated carbons AC 01 and AC 02 are good examples to investigate in detail the dynamics and equilibria during pure mercury physisorption. The measured equilibrium isotherms almost show Henry behavior. A significant increase in capacity is observed when temperature decreases and/or concentration increases. This pronounced temperature and concentration dependence is typical for physisorptive adsorption mechanisms. The calculated isosteric heats of adsorption of Hg^0 only amount to 50 % of the enthalpy of evaporation. This shows that the adsorption of Hg^0 is exothermic, but the interactions of mercury with the surface of the activated carbon are significantly weaker than the interactions between mercury atoms in the condensed mercury phase. This phenomenon can be explained by the strong forces in liquid mercury. At room temperature, liquid mercury forms strong van-der-Waals clusters, whose bonding energies lie between dispersion interactions and covalent bonds [1]. The experimental breakthrough curves can be described by dynamic simulations with good accuracy. The results demonstrate that surface diffusion is the rate-determining diffusion process. Surface diffusion of Hg^0 on the activated carbons exhibits no concentration dependence but a strong dependence on temperature typical for activated processes.

Both, physisorptive and chemisorptive mechanisms play a role in mercury adsorption on non-impregnated activated carbons AC 03 and AC 04. Ultimate analysis proves a high oxygen content of AC 03 and a high chlorine content of AC 04. The type and number of oxygen-containing functional groups are determined by Boehm titration. It is assumed in literature that the presence of oxygen-containing functional surface groups and chlorine favors chemisorption [2,3,4]. Therefore, TPD experiments are carried out to investigate the desorption kinetics and to obtain information on the surface chemistry of chemisorbed mercury. For AC 03, concentration peaks are detected in the temperature range from 120 to 350 °C, which can be assigned to individual functional oxygen groups. The results for AC 04 show a single peak at 420 °C and above. The reaction order and adsorption enthalpy can be determined by dynamic simulations.

4. Conclusions

The physisorptive and chemisorptive adsorption and desorption behavior of four commercial activated carbons was systematically investigated by experimental measurements and dynamic simulations.

Highlights

- Innovative separation of co-products by membrane filtration
- Applicability to aqueous and organic solvent systems
- Polyamide membranes favorable in aqueous solvent systems
- Low MWCO membranes required for separation in organic solvent systems

1. Introduction

Homogeneous catalysis offers high yields and selectivity at mild reaction conditions but requires the challenging separation and recovery of the valuable homogeneous catalyst. In previous work, it was shown that a combination of thermomorphic multiphase systems (TMS) and organic solvent nanofiltration (OSN) enables effective catalyst recovery in the hydroformylation of long chain olefins [1]. In this combination, a TMS of at least two solvents, which are homogeneous at high temperature in the reactor, forms a two-phase system at lower temperature. This system is first separated by a decanter into a catalyst-rich polar phase and a product-rich apolar phase, which is further processed by OSN to recover remaining catalyst and recycle it back to the reactor.

This contribution focuses on an alternative membrane-assisted TMS concept, which addresses the separation of polar co-products, such as water in hydroaminomethylation (HAM) reactions. Due to its high polarity water accumulates in the polar catalyst phase. Since this accumulation can influence the phase stability of the mixture and thereby negatively affect the reaction as well as the subsequent phase separation, the water content should be controlled. For this purpose, the implementation of a second pressure-driven membrane separation in the recycle stream is proposed. However, the specific type of membrane separation and membrane material selection depend on the TMS for the HAM. This consists of different solvents, depending on the substrates, which are two organic solvents, if the substrates are rather non-polar [2], or an organic solvent and water if more polar substrates are used [3]. In the case of an organic system, OSN is a possible choice, whereas reverse osmosis (RO) represents a suitable choice in case of the aqueous system. The current work presents the results of dedicated membrane-screening experiments for organic and aqueous solvent systems. For a range of solvents, which were selected based on literature data [2 - 4], a number of membranes were screened based on high rejection of the catalyst and selective water removal.

2. Methods

Concentrations of the catalyst and the co-product were estimated based on literature data and mass balances. Several commercially available membranes were selected. The experiments were conducted in cross-flow pressure cells. At least three different membrane sheets were measured for each membrane. For the organic system, dimethylformamide (DMF) and methanol (MeOH) as polar solvents were investigated, while a combination of water as the polar and 1-butanol (1-BuOH) as the non-polar solvent was investigated for the aqueous system. The applied ligands were the comparatively small triphenylphosphine (TPP) and tri-sulfonated triphenylphosphine (TPPTS), respectively.

3. Results and discussion

For the aqueous system, TPPTS rejections above 99% were measured for all membranes in water. Rejections decreased slightly when 1-BuOH was present in the mixture (Fig. 1a). Membranes made of polyamides are preferential for the selective separation of water since they combine a high rejection of TPPTS with a high rejection of 1-BuOH. Cellulose acetate membranes, however, show a negative rejection of 1-BuOH (Fig. 1b). For both membrane types, a high flux decrease was observed when 1-BuOH was present in the system (Fig. 1c). Based on the screening results a suitable PA membrane was identified and can be used for further investigations.

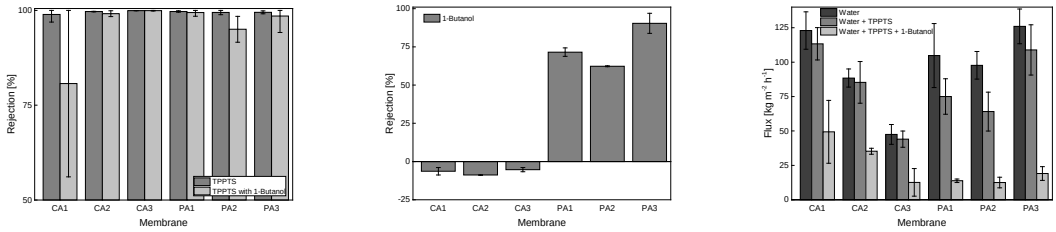

Figure 1. Rejection of TPPTS (a), rejection of 1-butanol (b) and total flux (c) for the aqueous solvent system. Feed pressure p_{Feed}=30 bar, ligand concentration w_{Ligand}=0.003 g g^{-1}, $w_{1\text{-}BuOH}$=0.04 g g^{-1}.

For the organic system, several commercial membranes were screened in a similar way. TPP rejections of 97% and higher were observed for a polyimide membrane with a molecular weight cut-off (MWCO) of 150 Da. The same membrane showed the best results in MeOH as well as DMF. Furthermore, selective water separation was possible with water rejections down to – 50%.

4. Conclusions

The current results show high prospect for the realization of the targeted co-product separation in HAM reactions in aqueous and organic solvent mixtures. Different OSN and RO membranes were suitable in the corresponding solvent systems. High catalyst rejections and selective water separation were achieved leading to a feasible process concept. Further investigations will focus on the implementation of the membrane separation into a continuously operated miniplant.

Highlights

- Hydrogen introduction inside a liquid sodium loop by permeation through a Nickel membrane
- Set up of an experimental facility for the process analysis and validation
- Measurement of the stationary hydrogen permeation flux through the membrane
- Experimental and modeling approach
- Data reconciliation

1. Introduction

In the framework of SFRs (Sodium Fast Reactors), the contamination of the liquid sodium circulating in the secondary circuit with tritium produced in the core is one main process issue. In order to capture and recuperate this tritium, a certain amount of hydrogen dissolved in liquid sodium is necessary. Until now, the hydrogen is produced by steel corrosion and by hydrazine decomposition inside the steam generator, then it diffuses to sodium through the steel walls; to better control the hydrogen concentration, an external and independent process to introduce safely and in a controlled way a hydrogen flux into liquid sodium is necessary.
The permeation through a Nickel dense membrane has been individuated as the most suitable technical solution. Hydrogen permeation through Nickel has been widely studied when a gas phase is present on both side of the membrane [1]–[4]and some applications based on Nickel membranes were developed for SFRs to detect the hydrogen content inside sodium [5]. However, a more detailed study on hydrogen transfer from a gas phase to liquid sodium is necessary, considering not only the permeation through a Nickel membrane but also the mass transfer inside gas and sodium phases as main influential phenomena.

2. Experimental results

In this study, a device constituted by four Nickel tubular membranes (or “permeator”) is designed to transfer a continuous hydrogen flux from a gas mixture (Ar+H_2 at 3% molar) circulating inside the tubes to the external side of the tubes (shell) by permeation. The permeator is installed on a closed sodium loop, with the capability to purify sodium and to warm it up to a temperature of 450 °C. The permeator is tested at different temperatures, gas pressures and flowrates in order to obtain different hydrogen permeation fluxes, depending on the operating conditions. It is tested both in a gas-gas configuration (i.e. shell maintained under vacuum) and in a gas-sodium configuration (i.e. sodium circulating inside the shell), in order to identify the sodium resistance effect on the global hydrogen mass transfer.

Measurements of the main process parameters (pressure, temperature, flowrate) are carried out, as well as a hydrogen concentration measurement on the gas retentate side by a gas chromatograph. Moreover, a measurement of hydrogen concentration inside the sodium loop takes place, by means of a second Nickel membrane coupled to a mass spectrometer.
A data reconciliation method is applied to adjust the values of raw measurements, taking into account the system redundancy and the instrumentation uncertainties, in order to generate reconciled data which satisfy the hydrogen mass balance.

3. Simulation results

Under the hypothesis of steady state conditions, a simplified model of the permeator is set up in COMSOL Multiphysics®, as an instrument supporting the experience design. It includes the permeation Richardson's law[6] for the Nickel membrane, the hydrogen mass balances and the convective mass transport into the gas and liquid sodium phases. Thanks to this model, preliminary results can be produced by simulating the overall process.

4. Conclusions

The reconciled data allow comparing the calculated and the experimental hydrogen permeation flux under given operating conditions. Therefore, it is possible to validate the main hypotheses at the basis of the model and to evaluate the real influence of the operating parameters on the permeation.

Highlights

- Modeling of filtration performance of depth filter
- Investigation of fiber diameter distribution of depth filter media
- Influence of fiber diameter distribution on pressure drop and filtration efficiency
- Improved prediction of filtration performance

1. Introduction

The separation of particles from gas streams having low to medium loadings is an essential task in various civil (e.g. cabin air filters) or industrial (e.g. particulate air filter for clean rooms in aseptic production areas) applications. A high efficiency combined with a low pressure drop is desired to realize cost- and energy efficient separations. For the task of optimization the filter media, knowledge about the connection of macroscopic parameters of fibrous depth filter (e.g., pressure drop and filtration efficiency) to their microscopic properties (e.g., fiber diameter distribution or porosity) is evident [1]. In recent simulations, the fiber diameter distribution (FDD) within the filter media is often neglected and replaced by a medium or averaged value [2]. In this work, the impact of this parameter is in focus.

2. Methods

The FDD of a fine filter (F7, Trox GmbH, Neunkirchen-Vluyn, Germany) based on glass fibers (Filter A) and a coarse dust filter (TH 300-T2, Afprofilter GmbH, Bönen, Germany) based on polyester fibers (Filter B)were investigated using scanning electron microscopy (SEM), (H-S4500 FEG, Hitachi High Technologies Europe, Krefeld, Germany). The FDD was analyzed by digital image analysis. For that purpose, the open source software diameterJ [3] was used. 24 SEM-images of each material at clean- and raw-gas side were considered and the fiber diameter at around 20.000 positions in each image was evaluated. Those data were implemented in an in-house developed model for calculation filtration performance which is computed using Matlab (Matlab 2016a, The Mathworks, Nivack, USA). Filtration performances were measured according to the VDI 3926 using aluminum oxide as test dust (Pural NF, Sasol, Brunsbüttel, Germany).

3. Results and discussion

The FDD of both considered filter media was obtained by digital image analysis. The spans of the distributions, as well as the medium fiber diameter (MFD), were derived from these data. Since no significant deviations between the raw- and clean-gas sides were found, a constant FDD inside the filter was assumed for calculations. Calculations of the filtration efficiency were carried out and results are compared for using the MFD and the FDD (figure 1). A high influence of the FDD on the calculation of the filtration efficiency can be figured out. It is shown that implementing the FDD increases the calculated filtration efficiency (up to more than 50%) in comparison to using the MFD. Furthermore, it was found that this parameter becomes more significant in the region were inertial deposition of the dust can be assumed than in the diffusional dominate region at smaller particle diameter. Also, an influence on the pressure drop was figured leading to higher values for both filter media by considering the fiber diameter distribution. A comparison to experimental data results in an improved prediction of filtration efficiency. This emphasizes the importance of this parameter regarding investigating the filtration of particles in fibrous depth filter.

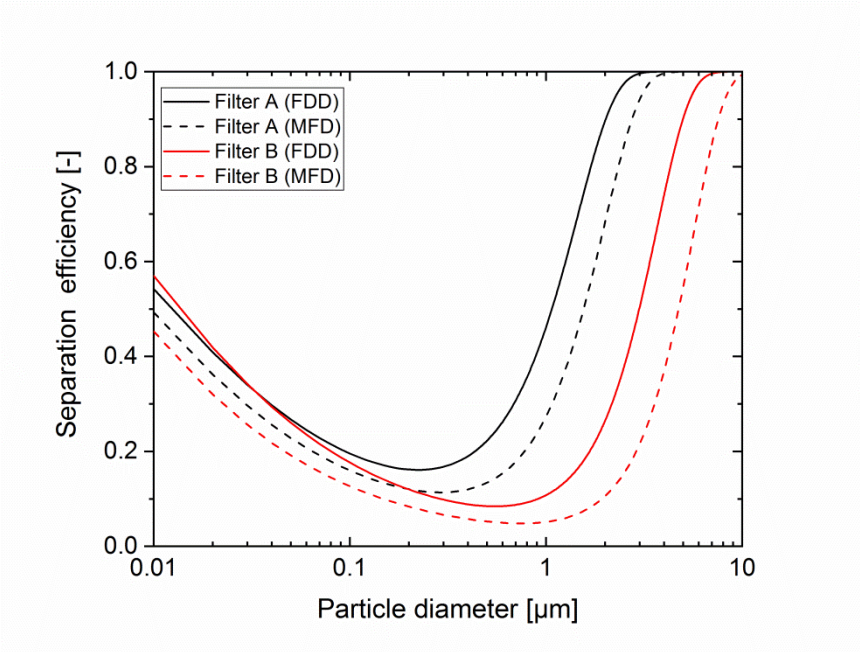

Figure 1. Calculation of filtration efficiency with and without considering the fiber diameter distribution

4. Conclusions

The FDD of two fibrous depth filter media were successfully determined combining SEM and digital image analysis. The influence of that parameter was theoretical investigated, implemented into an in-house developed model and compared with experimentally determined filtration efficiencies and pressure drops. From those results the importance of considering these data in modeling the filtration efficiency was emphasized.

Highlights

- Magnetic bead separation from human whole blood is analyzed
- CFD approach is used for modeling magnetic bead magnetophoresis from blood
- Effect of fluid flow rates in the recovery of magnetic beads is modeled
- We report the rational design of magnetophoretic microfluidic devices

1. Introduction

The removal of disease-causing agents from bloodstream is considered to be the most direct conceivable treatment for infectious illness such as sepsis. In this regard, the coupling of functionalized magnetic microparticles and continuous flow microfluidic devices has attained outstanding attention for the extracorporeal toxin and pathogen isolation from blood. The laminar flow pattern developed in microfluidic devices allows co-flow of parallel streams with stable interface, while the magnetic beads provide the selective adsorption of the target substance on their surface and promote their recovery by external magnetic fields generated by rare-earth magnets [1, 2]. Nevertheless, the performance of such magnetophoretic-microfluidic devices has not been addressed yet because of the complexity of their mathematical description.

2. Methods

The current study presents both the experimental and computational based design of a two-phase continuous-flow extracorporeal magnetic blood cleansing microdevice for maximizing bead recovery while keeping impaired blood quality. In such system, a suspension (0.2 $g{\cdot}L^{-1}$) of fluorescent magnetic microparticles (4.9 µm) in Human Whole Blood (HWB) and a buffer solution are continuously injected through different inlets of a Y-Y shaped glass microchannel. The deflection of the particles and their collection in the buffer stream is achieved through the application of an external magnetic field by a permanent rectangular (10 x 5 x 3 mm^3) neodymium (NdFeB) magnet parallel to the microchannel. Experimentally, the use of fluorescent beads allows the quantification of the particle recovery by fluorescence microscopy, using a custom Matlab code for image analysis. For the numerical analysis, a Computational Fluid Dynamics (CFD)-based Eulerian-Lagrangian approach, using the commercial software FLOW-3D, linked to a Fortran code for magnetic field and forces calculations was employed. The numerical method reported here involves magnetic and fluidic models that describe the motion of the beads and can be used to

study critical details of the separation process, including the trajectories of individual particles and the stability of the blood/buffer interface.

3. Results and discussion

The complete bead recovery and fluids separation at the channel outlet requires a careful study of both magnetic and fluidic forces. For that purpose, a dimensionless number (J) that relates the variables that affect such forces (i.e. bead and fluids properties, magnetic field applied, selected flow rates) was employed.

The influence of fluids flow rates on both flow patterns and capture efficiency of the microseparator, expressed as particle recovery, is illustrated in Fig. 1. Because of the rheological properties of HWB, low flow rates of approximately 0.005 $\mu L \cdot s^{-1}$ are required to obtain high recovery (higher than 90%). This flow rate leads to similar values of magnetic and fluidic forces (J-value of 1.2) and corresponds to an average velocity of 0.65 $mm \cdot s^{-1}$ and a residence time of 3s, which is low enough to prevent diffusion of blood components to the buffer stream, thus ensuring that these low flow rates can be safely used since the properties of the blood are not affected. The experimental results fitted adequately to simulated data provided by the theoretical model (error lower than 10%).

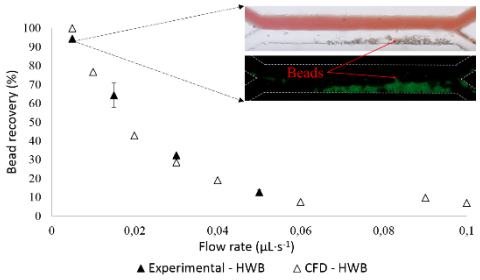

Figure 1. Magnetic bead recovery (experimental and theoretical approaches) from human whole blood as a function of the applied flow rate.

The improvement of the system performance requires the treatment of high contaminated blood volumes. Thus, several channel lengths (2, 5 and 10 mm) and cross sections were computationally tested in order to find the best geometrical conditions that allow the use of higher flow rates while achieving high bead recovery.

4. Conclusions

The theoretical and experimental methodology developed in this work provide insight into the design of magnetophoretic-microfluidic devices for biomolecules separations and can be adapted to a broad range of magnetically-enabled microfluidic applications.

Highlights

- Membrane hydraulic and selectivity properties modified by lysozyme
- Lysozyme suffers changes in the hydrodynamic radius after filtration
- Denaturated form of lysozyme present after filtration

1. Introduction

With a growing market for them, proteins are intensively used in industry where they undergo different operations of separation, concentration and purification. A classical process used for such necessities is the membrane process.

Membrane processes use mild conditions of operation, have low energy consumption, no need for additives and can operate continuously. A key point to all the mentioned advantages is the possibility to modify the membrane properties to fit the need or demand of the industry. Thus, depending on the final outcome of the industry, membrane processes can give higher quality of the processed products. Nevertheless, membrane processes performances can be jeopardized by membrane fouling. Membrane fouling is a phenomenon in which, molecules from the liquid phase start to deposit or adsorb at the surface of the membrane or inside its pores. Fouling influences the membrane performances and in consequence, can affect the outcome of the process - economically and quality.

Our work consists in analyzing how proteins behave in membrane processes taking into account the evolution of the membrane performances and the transformation of the protein molecule.

2. Methods

Filtration of protein solutions was performed in a laboratory pilot-plant [1] using a tubular, ceramic asymmetric ultrafiltration membrane. In order to focus on the effect of the constrains generated by the change in pressure, temperature and flow rate are maintained constant.

The membrane performances after protein filtration were asset by determination of the selectivity (rejection rate) and of the hydraulic properties (permeability) using a neutral solution of Vitamin B12.

The possible change of the protein conformation after filtration was asset by High Performance Liquid Chromatography (HPLC) study, an analysis based on size-exclusion.

3. Results and discussion

A pre-established sequence of filtration was used in the current work as presented in Table 1. Between the lysozyme filtration tests series, neutral solution of Vitamin B12 followed by pure water filtration were performed to analyze the evolution of the membrane performances. It was found that the selectivity of the membrane increase with each filtration test while the permeability decreases. This behavior is specific to the phenomenon of adsorption. Thus, the lysozyme molecule could be adsorbed at the surface of the membrane or in the pores of the membrane. Further tests confirm this hypothesis.

Table 1. Sequence of filtration test with respective concentration, observed rejection rate and hydraulic permeability

Protein Solution	**Concentration (mM)**	**R max (%)**	**Lp ($10^{-14}m^3.m^{-2}_{memb}$)**
VB12	9,22E-03	40	5.7
Lysozyme I	0,025	90	4.7
Lysozyme II	0,025	95	4.5
Lysozyme III	0.025	97	4.0
VB12	9,22E-03	73	4.0

Analyses on the retentate (fraction of the feeding solution rejected by the membrane) and permeate (fraction of the feeding solution passing through the membrane) by HPLC confirm the change of the hydrodynamic radius of the molecule after passing through the membrane. Peak fitting performed on the HPLC chromatograms shows the different forms of lysozyme present in the permeate (native and denaturated) as opposed to the retentate, which shows only one form (native).

4. Conclusions

The current study gives a frame on the evolution of the membrane properties when using a protein solution, taking into account the protein behavior after filtration. The study confirms the adsorption of the lysozyme molecule in the pores, while making a further observation on the change of the protein molecule after filtration.

Mass Transfer in Bacterial Cellulose Synthesis and Their Use as Oxygen Vectors in Bioreactors

Tanase DOBRE

University Politehnica of Bucharest, Department of Chemical and Biochemical Engineering,

Bacterial Cellulose (BC) is a very interesting biodegradable biopolymer with very important mechanical, physical and chemical properties. It is a versatile polymer that could be changed or by biosynthesis or after that. It could also be used to obtain composite materials. B C and its composites are currently being studied for use in various biomedical applications, but bacterial cellulose shows considerable potential for other technical applications as well, electronic paper, transparent composites, conductive and resistive membranes, bio molecularly imprinted polymers, special membranes, etc. Most of these applications are still looking. In this work it is given results which show the use of the specific methods of chemical engineering in many directions characterizing the synthesis and use of bacterial cellulose. For synthesis of the bacterial cellulose he attracted attention with several statistical models developed to identify the culture medium composition and the operating conditions to have static reactors in work with good productivity [1]. The importance of oxygen transfer is not completely elucidated. Here, in BC synthesis the simplex regular method is illustrated for optimization of drum reactor where the process kinetics depend of over 6 factors . The problem of swelling of membranes and composites based on bacterial cellulose, contained in some proper work [2, 3], is analyzed using a new model, capable of finding the most common models. In intensification of oxygen transfer in aerobic bioreactors various strategies has been used in order to obtain a good efficiency of aerobic fermentation processes. The paper focuses on studies concerning the influence of solid carrier addition in the liquid phase on oxygen volumetric mass transfer coefficient in a stirred and aerated tank bioreactor. The selected oxygen carriers (vectors) can be easily separated and they have no harmful effect on the microbial population implied in bioprocesses. Fine particle of activated carbon, silicon oil impregnated activated carbon, bacterial cellulose, magnetite, and bacterial cellulose-magnetite composite were used as oxygen-vectors. An enhancement of oxygen transfer was indicated by an increase in volumetric mass transfer coefficient, k_la, which was determined by a dynamic method. A significant improvement of oxygen mass transfer in the presence of magnetite and bacterial cellulose-magnetite composite was highlighted. Important correlations was obtained. The experiments of aeration of active mud from polluted water shows that the biocellulose magnetite composite improves the efficiency of this bioreactor types.

Highlights

- Modelling of electrodialysis for multi-ionic solutions.
- Estimation of multicomponent membrane properties.
- Assessment of membrane properties effect on multi-ionic systems

1. Introduction

Membrane desalination processes play a crucial role in the current scenario of drinking water production. In particular, electrodialysis (ED) is currently spreading as a viable alternative to other membrane desalination processes, so that plenty of modelling and simulation works have been published in the last few years [1–3]. However, most of modelling and experimental works assume that the feed solution contains dissolved NaCl only. In fact, real feeds always contain additional ions that can substantially affect process performances [4].

When multiple ions systems have to be modelled, the estimation of a much larger number of parameters related to membrane properties is required. Therefore, in this work a simplified approach for the modelling of an ED system operating with multi-ionic solutions is presented. The main parameters required to fully characterize the system and the criticalities arising in their experimental determination are highlighted. In particular, salt diffusion permeability, membrane resistance and transport numbers are discussed.

2. Methods

A hierarchical semiempirical model for ED process operating with multicomponent solutions is developed. The low-hierarchy of the model (i.e. the cell pair) has a one-dimensional structure and incorporates the main transport phenomena occurring through membranes. Each ion flux is described, accounting for the salt back diffusion as well as for water transport. In addition, cell pair voltage is estimated through both Ohmic (i.e. membrane and channels resistances) and non-Ohmic (i.e. membrane potential) contribution. Particular attention is given to the expression of the membrane potential that changes significantly compared to the single-salt scenario. The high-hierarchy model (i.e. the stack) links a series of cell pairs with the electrodes and it is devoted to computing the main performance parameters (i.e. energy consumption, current efficiency, water productivity…). In addition, a geochemical database (PHREEQC, *USGS*) is used for the estimation of

the main thermodynamic parameters, such as activity coefficients, conductivities and saturation indexes of potential solid phases.

Empirical information on membrane properties are purposely collected via laboratory-test rigs: (i) salt diffusion permeability is estimated through batch diffusion dialysis experiments; (ii) membrane resistance is assessed via indirect measurement through an ED stack equipped with only one type of membrane (either anion or cation exchange membrane).

Finally, membrane transport numbers have been estimated through ED measurements according to Hittorf's method [5].

3. Results and discussion

Figure 1 shows, as an explanatory example, simulation results for an ED unit fed with a NaCl, $MgCl_2$ and $CaCl_2$ ternary solution. A preliminary estimation of transport numbers and diffusion permeabilities is used as simulation input. The figure shows the concentration profile of the cations along the channel length. It is worth noting how the membrane properties can strongly affect the magnitude of each ion removal, resulting in this case in a much larger removal of sodium ions.

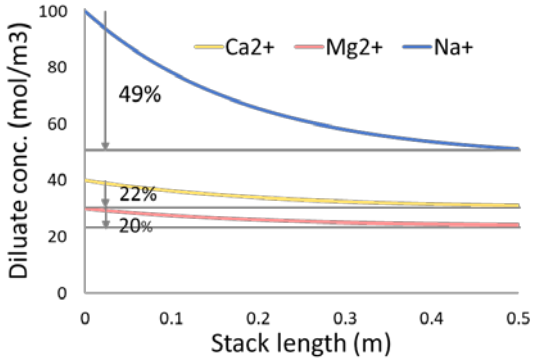

Figure 1. Concentration profiles inside a 0.1 x 0.5 m^2 electrodialysis stack desalinating a solution containing Na^+, Mg^{2+}, Ca^{2+} and Cl^-. Channels 270 µm thick, 2A current, 1 cm/s flow velocity. Transport numbers in cation exchange membrane: 0.25 (Ca^{2+}), 0.15 (Mg^{2+}), 0.55 (Na^+) and 0.05 (Cl^-). Transport numbers in anion exchange membrane: 0.01 (Ca^{2+}), 0.01 (Mg^{2+}), 0.03 (Na^+) and 0.95 (Cl^-). Salt diffusion permeability are assumed equal to $4 \cdot 10^{-12}$ m^2/s for each salt.

4. Conclusions

The development of an efficient simulation tool for multi-ionic ED results into the possibility of estimating the effect of multiple components in the feed solutions. The effect of the characterization-parameters as the membrane properties is crucial for a reliable prediction of the system performance, thus justifying the need for properly estimating them.

On the potential of adsorption processes for low-carbon hydrogen production with carbon capture

Anne Streb[1], Mijndert van der Spek[1], Matteo Gazzani[2], Marco Mazzotti[1*]

1 ETH Zurich, Zurich/Switzerland; 2 Utrecht University, Utrecht/the Netherlands

**Corresponding author: marco.mazzotti@ipe.mavt.ethz.ch*

Highlights

- Adsorption processes developed for the simultaneous production of H_2 and CO_2
- Process intensification achieved: single stage for two separation tasks
- Competitive energy consumption
- Suitable for a variety of multicomponent feedstreams

1. Introduction

Carbon neutral hydrogen is expected to play an important role in future energy systems, especially in industry, transportation and heating applications. Today, hydrogen is used at large scale in many industrial processes, e.g. ammonia and methanol production and oil refining. However, it is mainly produced through conversion of fossil fuels, e.g. via steam methane reforming (SMR) followed by water gas shift (WGS) and pressure swing adsorption purification (PSA), resulting in high CO_2 emission intensity. Adding carbon capture and storage (CCS) to fossil fuel based H_2 production is a means to produce large amounts of low-carbon H_2 in a timely manner thereby paving the way towards an energy system where H_2 plays a pivotal role as low carbon energy carrier. We have developed a promising process integrating both H_2 purification and CO_2 separation within a single adsorption cycle. This option does not require an additional separation stage potentially reducing capital cost and energy requirement compared to the alternative of a separate downstream CO_2 separation process.

2. Methods

We have developed various cycles for integrating the production of high purity H_2 and CO_2 based on heuristics and on the use of a non-isothermal one-dimensional model for an adsorber column. The model was validated for a variety of conditions and cycles [1,2]. The feedstream composition, pressure and temperature are representative for the outlet of a WGS reactor consisting of mainly H_2 and CO_2 with CH_4, CO and N_2 as relevant impurities. The most promising cycles in terms of the key performance indicators, namely the purity and recovery of hydrogen and CO_2, the productivity and the energy consumption, are optimized by combining the use of the simulation tool with that of a multi-objective optimization routine [3].

3. Results and discussion

For all cycles, there exists a tradeoff between H_2 purity and recovery at a given CO_2 purity and recovery (and vice versa). Notably, three of the developed cycles can purify hydrogen to greater than 99.97 %, as required for fuel cells for transportation, with a recovery of > 90 % while coproducing CO_2 at > 90 % recovery and > 96 % purity, as required for CO_2 transportation and

storage. The cycles are flexible regarding the feedstream composition: the specifications given above can be reached for a feedstream with a high CO content (~5 %) representative of the outlet of a high temperature WGS reactor as well as for a feedstream with a lower CO content (< 0.5 %) representative for the outlet of a low temperature WGS reactor.

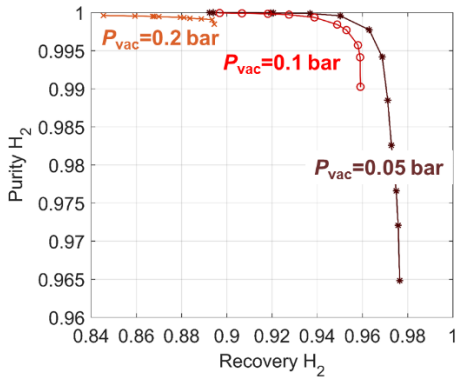

Figure 1. Optimized separation performance for a vacuum pressure swing adsorption cycle at different evacuation pressures, inlet: SMR + HT-WGS, coproduction of CO_2 at > 90 % recovery and > 95 % purity

To achieve the separation requirements, a subatmospheric pressure is required to withdraw CO_2. Lowering this pressure enhances the separation performance and increases the productivity at the expense of a higher energy consumption. The required hydrogen purity is another important factor: the minimum energy consumption increases with higher required hydrogen purities while the productivity decreases. For a hydrogen purity of 99.97 % with a recovery > 90 % (coproduction of CO_2 at > 90 % recovery and > 96 % purity), a minimum energy consumption for the separation of below 0.4 MJ/kg CO_2 separated (below 2.3 MJ/kg H_2 separated) can be obtained. This energy requirement is significantly lower than the energy required for pre-combustion capture using absorption, e.g. with MDEA, which is in the range of 2 MJ/kg CO_2 [4]. The energy required in the latter, however, is mainly steam whereas the former requires electricity for vacuum pumps. The equivalent electricity consumption for both processes assuming a conservative conversion efficiency of 20 % from steam to electricity is similar, but the adsorption process only requires a single process instead of two.

4. Conclusions and outlook

Advanced adsorption processes show promise for process intensification in the context of hydrogen production with CCS. Several cycles have been developed for the coproduction of high purity CO_2 and hydrogen. The equivalent electricity consumption is similar to commercial processes but an entire separation stage is now avoided. Moreover, the cycles are particularly promising due to a high flexibility towards different feedstream compositions. Layering of different adsorbents or the use of advanced adsorbent materials like MOFs leaves room for further process improvement.

Utilizing the photo-induced hydrophilicity of TiO_2 to enhance permeate flux of composite membranes

Duc-Trung Tran, Julie Mendret*, Jean-Pierre Mericq, Catherine Faur & Stephan Brosillon

IEM (Institut Européen des Membranes), UMR 5635 (CNRS-ENSCM-UM), 34095 Montpellier, France

**Corresponding author: julie.mendret@umontpellier.fr*

Highlights

- Photo-active PVDF-TiO_2 composite membranes were prepared by NIPS method.
- Membrane WCA decreased upon UV irradiation due to photo-induced hydrophilicity of TiO_2.
- Permeate flux increased during filtration with UV irradiation (photo-filtration).
- Photo-filtration method offers potential benefits in operating cost.

1. Introduction

Other than being a photocatalyst for chemical reactions, TiO_2 also possesses an important property called photo-induced superhydrophilicity, in which its surface can become extremely hydrophilic upon UV irradiation [1]. As such, composite membranes containing TiO_2 nanoparticles have become very attractive prospects due to their excellent anti-fouling and self-cleaning properties. In addition, when membrane filtration is coupled with UV irradiation (photo-filtration), the permeate flux can be further enhanced thanks to said photo-induced effect [2]. In this study, that phenomenon was comprehensively investigated to explore the mechanism behind such flux enhancement and estimate the potential benefits in cost/efficiency balance of this new filtration method.

2. Methods

PVDF-TiO_2 membranes were prepared by the nonsolvent-induced phase separation (NIPS) method. The PVDF concentration was 20 wt% while the mass ratio of TiO_2 to PVDF was 1:5. The distribution of TiO_2 on membrane surface was characterized by energy-dispersive X-ray (EDX) mapping, while the water contact angle (WCA) was measured for membranes before and after UV irradiation. Photo-filtration tests were performed with pure water, humic acids (HA) and sodium alginate (SA) solutions in a crossflow filtration cell built with a Quartz window on top, so that the membrane could be irradiated by a 365-nm UV lamp. Filtration was performed in constant pressure mode, while irradiation mode was varied in terms of UV cycle (UV on/off time ranging from 15 to 90 min) and irradiance (I = 0.04-1 $mW.cm^{-2}$). The advantages of photo-filtration was demonstrated by comparing the behavior of normalized flux (the ratio between the flux at a given time (J) and the initial flux at the beginning of the test (J_0)) when UV was and was not utilized.

3. Results and discussion

Via EDX mapping, it can be seen that TiO_2 nanoparticles were dispersed uniformly on the surface of the membranes (Fig. 1a), suggesting photo-induced effects could occur once the membranes

were exposed to UV irradiation. Indeed, as the WCA was 77.4±1.2° for the membrane in normal condition (Fig. 1b), as opposed to 68.2±1.8° after it was irradiated by UV for 30 minutes (Fig. 1c). The decrease in WCA indicates an increase in membrane hydrophilicity, which was believed to be responsible for the rise in pure water flux during photo-filtration, as shown in Fig. 2.

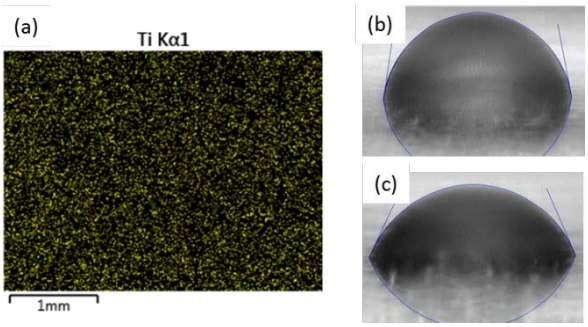

Figure 1. (a) Distribution of Ti on membrane via EDX mapping; and WCA of membranes in (b) normal condition and (c) post-UV-irradiated condition

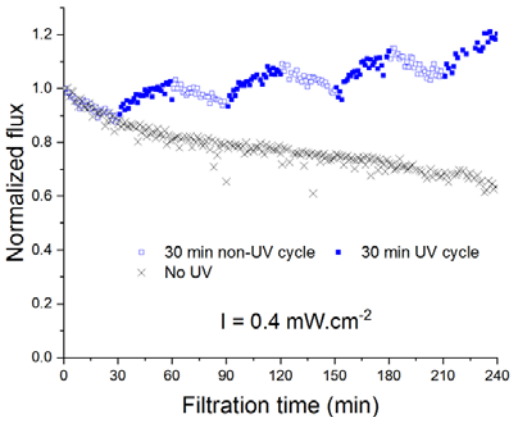

Figure 2. Permeate flux of water during photo-filtration with 30-min on/30-min off UV cycle

Despite that the membrane suffered an inherent flux decline due to compaction, every time UV was activated, a considerable rise in pure water flux could be observed. Even if UV was only utilized for 50% of the filtration time, a significant increase in water output could be achieved for the photo-filtration method compared to normal filtration, thanks to the flux "memory effect" in which the flux remained higher than usual even after UV was deactivated (Fig. 2). The permeate flux increase was also obtained for photo-filtration tests of HA and SA solutions, given the foulant concentration did not exceed 5 ppm for HA and 50 ppm for SA, with a rejection rate of 64% for HA and 90% for SA. Although UV irradiation increases energy consumption, the total operating cost for the whole process could be reduced, taking into account the extra water output. By varying the irradiation mode, several photo-filtration conditions were tested with pure water at lab scale, and the obtained experimental data were extrapolated to a large-scale water processing system (capacity 3000 m^3/day). It was estimated that, to achieve the same water output, utilizing photo-filtration in appropriate modes (for example, a moderate UV irradiance of 0.4 $mW.cm^{-2}$ and UV irradiation cycle of 30 minutes) could reduced the daily total operating cost up to 8.3% compared to normal filtration.

4. Conclusions

When PVDF-TiO_2 composite membrane was irradiated by UV, its hydrophilicity increased thanks to the photo-induced hydrophilicity effect of TiO_2, which led to a steady increase in permeate flux during photo-filtration. Thus, photo-filtration proved to be a promising method to improve the cost/efficiency balance of the filtration process in terms of water output, let alone the benefits from photocatalysis.

Highlights

- Carbon hollow fiber membranes were developed from sustainable cellulose.
- 239 Barrer CO_2 permeability and 186 CO_2/CH_4 selectivity were obtained.
- The membrane exhibited attractive performances in 10% CO_2 -90% CH_4 mixed gas.

1. Introduction

Membrane systems are expected to apply in different gas separations such as oxygen recovery from air, natural gas sweetening and CO_2 capture from flue gas, thanks to the small footprint, low energy consumption, low capital and operating cost and process flexibility. Among different membrane materials, carbon molecular sieving (CMS) membrane is one of the most promising materials due to its high separation performance and good compatibility in some harsh operating situations (such as high pressures, high temperatures). Different polymers, like polyimide[1], cellulose acetate[2] and cellulose[3], have been employed as precursors for CMS membranes. Cellulose, as an inexhaustible and biorenewable material, could be a suitable precursor for large-scale producing CMS membranes. In this work, cellulose-based carbon hollow fiber membranes (CHFMs) were developed from cellulose/ionic liquid system.

2. Methods

Microcrystalline cellulose (MCC) was dissolved in 1-Ethyl-3-methylimidazolium acetate (EmimAc) and dimethyl sulfoxide (DMSO) solution at 50 °C with mechanical stirring in a glove box as a dope solution for spinning. Then, the defect-free cellulose hollow fiber precursors were fabricated by a dry-wet spinning, as shown in Figure 1a. The dried cellulose hollow fibers were carbonized in a tubular furnace by applying a specific carbonization protocol for preparing the CHFMs. Single gas permeation data were determined at room temperature with a feeding pressure of 2 bar. CO_2/CH_4 separation performance was evaluated by mixed gas tests (10% CO_2/90% CH_4) at different temperature and pressures.

3. Results and discussion

XRD and FTIR characterization confirmed that a crystalline structure transition from cellulose I (MCC) to cellulose II (cellulose hollow fibers) occurred during the cellulose dissolution and spinning process. Additionally, due to the transition of crystalline structure, the cellulose hollow fibers retained a higher carbon yield of 22.9% than the MCC after carbonization[3]. Single gas (e.g., CO_2, O_2, N_2, and CH_4) permeation testing indicated that the molecular sieving mechanism is dominating the gas transport through the CHFMs. In addition, the CO_2 permeability and CO_2/CH_4 selectivity of 239 Barrer and 186 were obtained in the single gas permeation, which presents a high separation performance cross the 2008 Robeson Upper Bound as shown in the Figure 1b. Moreover, it maintains attractive CO_2/CH_4 separation performances in 10% CO_2 -90% CH_4 mixed gas permeation testing at increasing temperatures and raising pressures.

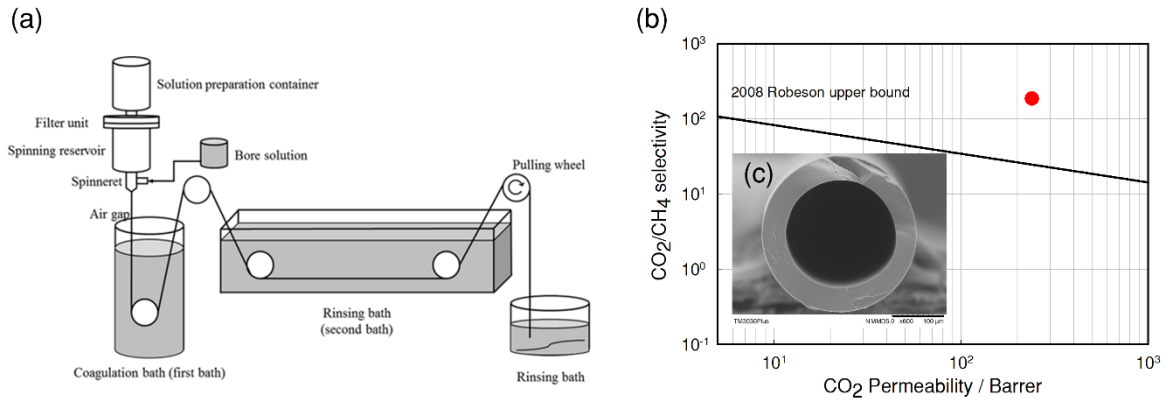

Figure 1. Schematic diagram of the spinning process, b) Gas permeation results for CO_2/CH_4 in prepared CHFM and comparison with the 2008 upper bound plot, c) Cross-sectional SEM images of a fabricated CHFM.

4. Conclusions

This study provides a suitable way to directly fabricate CHFMs using cellulose hollow fiber precursors spun from cellulose/(EmimAc + DMSO)/H_2O ternary system. The developed novel CHFMs shows attractive separation performance especially CO_2 removal from high pressure natural gas, as well as provides a new way for fabricating CMS membranes from sustainable and green materials.

Supercritical water desalination (SCWD) for treatment of multicomponent brine streams.

Surika van Wyk[1], Aloijsius G.J. van der Ham[1], Sascha R.A. Kersten[1]

1 Sustainable Process Technology. Faculty of Science and Technology, University of Twente, Drienerlolaan 5, Posbus 217, 7500 AE, Enschede, The Netherlands

**Corresponding author: s.vanwyk@utwente.nl*

Highlights

- Desalination of multicomponent waste streams with zero liquid discharge.
- Phase behavior of various multicomponent brines under supercritical conditions.
- Selective removal of different salts from multicomponent brines.

1. Introduction

Supercritical water desalination (SCWD) is a promising zero liquid discharge (ZLD) technology that utilizes the non-polar nature of water under supercritical conditions (T > 374 ºC, Pressure > 22.1 MPa). SCWD is based on the formation of vapour-liquid equilibrium (VLE) where a supercritical water (SCW) phase (< 750 ppm NaCl) is separated from a concentrated liquid brine phase (30 – 40 wt.% NaCl). This approach to desalination has been investigated on both laboratory and pilot plant scale for different feed concentrations of NaCl (3.5 – 16 wt.%)[1]. Most large scale studies have been done with aqueous type I salt solutions such as NaCl and $CaCl_2$, however, in industry brine streams contain multiple salts. Different salts exhibit varying phase behaviour under supercritical conditions such as VLE or vapour (fluid) - solid equilibrium (VSE)[2]. As stated, VLE needs to be established for SCWD and therefore the formation of VSE could be problematic as this will lead to plugging and equipment failure. A manner in which this can be overcome, is to dissolve the formed solids in the brine originating from the presence of a type I salts[2,3]. In this manner VLE can be re-establish. This presentation will focus on the separation and treatment of typical brine waste streams found in industry namely, NaCl (type I) -Na_2SO_4 (type II) -H_2O (mining industry), NaCl (type I)-$CaCl_2$ (type I)-H_2O (desalination waste) and NaCl (type I)-KCl (type I)-H_2O (dairy industry). Firstly, the separation efficiency of water from the concentrated brine streams will be investigated. Subsequently, the feasibility of separating different salts from the multicomponent concentrated brine streams will be studied. The solubility of different salts in supercritical water can be easily manipulated by varying temperature and pressure and could therefore be used for the selective removal of certain salts from multicomponent brines.

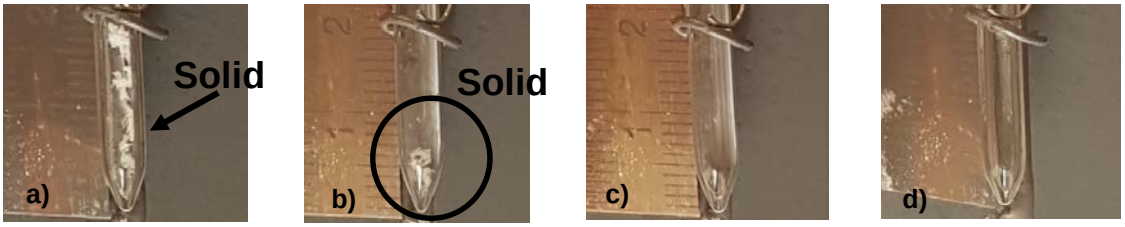
2. Methods

The experimental procedure is divided into two steps, namely qualitative (step 1) and quantitative (step 2) analysis. Qualitative experiments are performed using quartz capillaries to ensure that all the solids are dissolved in the brine during separation, so as to avoid plugging of the system. Once it has been ensured that a VLE system will be obtained at the selected separation conditions (250 – 350 bar; 370 – 450 ^{o}C) for the given mixtures, quantitative phase equilibria measurements are

done, using a laboratory scale SCWD unit [4]. During the quantitative analysis salt composition and concentration of each phase is measured and the separation efficiency for each step is calculated.

3. Results and discussion

The qualitative capillary results for different NaCl:Na_2SO_4 ratios are shown in Figure 1.



T_{wall} = 427 ºC
(P~ 376 bar)
Na_2SO_4 - 3.5 wt.%

T_{wall} = 431 ºC
(P~ 320 bar)
NaCl: Na_2SO_4 – **6:4**
Total salt - 3.5 wt.%

T_{wall} = 431ºC
(P ~ 316 bar)
NaCl: Na_2SO_4 – **7:3**
Total salt - 3.5 wt.%

T_{wall} = 429 ºC
(P ~ 250 – 350 bar)
NaCl - 3.5 wt.%

Figure 1. Phase behaviour of NaCl-Na_2SO_4-H_2O mixtures a) VSE b) vapour-liquid-solid equilibrium (VLSE) c) VLE d) VLE

The results show that for NaCl-Na_2SO_4-H_2O mixtures with mass ratios of 7:3 (NaCl:Na_2SO_4) 8:2 and 9:1, VLE is achieved. The quantitative results show that under supercritical conditions, Na_2SO_4 remains in the concentrated liquid phase and that the SCW phase has a low concentration of NaCl (400 - 1100 ppm) and trace amounts of Na_2SO_4. In general, the SCW concentration and recovery is comparable to that for NaCl-H_2O systems for the given operating conditions. Separation of the remaining concentrated NaCl-Na_2SO_4-H_2O brine will be further investigated. For the other multicomponent streams, the same procedure will be followed *i.e.* qualitative screening to ensure VLE followed by quantitative phase equilibria measurements to determine the separation efficiency of water from brine and that between different salts.

4. Conclusions

The conclusions made based on the experimental results for NaCl-Na_2SO_4-H_2O systems, is that water can be separated from the brine solutions, using the currently developed SCWD process for the treatment of brine streams with ZLD. An additional step will have to be added to separate certain salts for the remaining concentrated brine depending on solubility. The selective removal of salts from multicomponent brine could present an additional benefit to SCWD and could be an alternative method of separation to retrieve certain salts.

Olefin-Paraffin Separation with Customized Amorphous Fluoropolymer (CAF) Facilitated Transport Membranes

William Charlton, Hannah Murnen, Sudip Majumdar, Ken Loprete, Ken Pennisi

Compact Membrane Systems, Newport, DE, U.S.A.

Highlights

- The silver containing Facilitated Transport Membranes has shown high flux and olefin/paraffin selectivity in the laboratory over a period of >600 days.
- Facilitated Transport Membrane stability have been evaluated and proved stable in the presence of known poisons.
- Over the past year, CMS has been operating a pilot utilizing these silver based Custom Amorphous Fluoropolymer membranes on a refinery distillation column.
- CMS is partnering with an industry leader to field test commercial scale membranes in a petrochemical facility.
- CMS has expanded research to include C_4 separations, with initial results showing good performance and longevity.

1. Introduction

Ethylene and propylene are major chemical industry raw materials and consume a great deal of energy in their production. The separations of these materials are some of the costliest, most energy intensive, and most technically difficult separations in the industry due to the very similar size and nature of the molecules being separated. The technology currently employed for the separation of ethylene and propylene from paraffins is distillation and is estimated to consume 250 trillion BTU/year of energy.

A membrane based olefin-paraffin separation process would provide substantial economic benefit to petrochemical processes and drastically reduce the energy required. Membrane processes utilizing facilitated transport membranes for separating ethylene/ethane or propylene/propane have been extensively studied and described in the literature. While separations have been demonstrated in the laboratory, problems with membrane stability have prevented development of commercial systems.

Compact Membrane Systems has developed a customized amorphous fluoropolymer (CAF) facilitated transport membrane (FTM) containing silver ions that selectively transport olefin molecules from a mixture of olefin and paraffin that has shown stable performance in both laboratory testing and field pilot trials.

2. Methods

Over the past year, CMS has been operating a pilot utilizing these silver based CAF membranes on a distillation column at the Delaware City Refining Company. The Delaware City pilot is operated on a low concentration olefin stream (i.e., 10-20 wt% propylene in the feed) with the goal of achieving an HD5 quality propane (<.05 wt% propylene) and an enriched propylene stream. In addition, CMS has entered into a project with Dow Chemical through RAPID, a manufacturing institute funded by the U.S. Department of Energy. The goal of the work with Dow is to operate at the other end of the concentration spectrum where the feed is greater than 80% propylene and the target is an upgraded olefin-rich stream from the permeate. A pilot unit is installed in a Dow facility and we will share the latest results from our tests there.

3. Results and discussion

The silver containing FTM has shown high propylene flux and propylene/propane selectivity in the laboratory over a period of >600 days. Similar results were also obtained with ethylene and ethane gas mixtures. We have also evaluated membrane stability in presence of known process poisons such as hydrogen sulfide, acetylene, MAPD and hydrogen and will provide guidance on the appropriate concentration of these species for membrane applications.

CMS will also discuss initial results on laboratory testing of butane streams. This includes mixed gas separation of n-butane and 1-butene. We will share results for a number of operating conditions and will highlight several exciting C_4 separation applications including those with isomer streams. CMS will also provide an overview on the results of our pilot field trials with the Delaware City Refinery Company and the Dow Chemical Company.

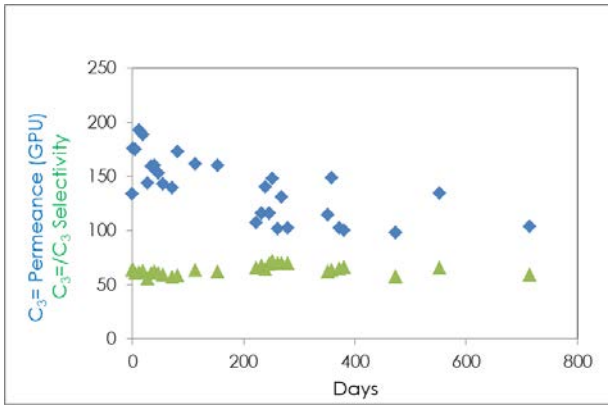

Figure 1. Long term Facilitated Transport Membrane aging study

4. Conclusions

A membrane based olefin-paraffin separation technology has the potential to provide substantial economic benefit to petrochemical industry and drastically reduce the energy required to complete these essential separations. In addition, membrane systems are scalable, allowing their implementation for smaller, stranded streams where distillation columns have not previously been installed due to limited economic value.

Aromatic/aliphatic separation by liquid-liquid extraction with ionic liquids: an overview process analysis with the COSMO-based/Aspen Plus approach

Pablo Navarro[1], Daniel Moreno[1,2], Marcos Larriba[3], Julián García[3], Francisco Rodríguez[3], Roberto I. Canales[2], José Palomar[1,*]

1 Universidad Autónoma de Madrid, 28049 Madrid, Spain; 2 Pontificia Universidad Católica de Chile, 8331150 Santiago de Chile, Chile; 3 Universidad Complutense de Madrid, 28040 Madrid, Spain

**Corresponding author: pepe.palomar@uam.es*

Highlights

- More than 100 ionic liquids evaluated in the whole extraction + recovery process.
- Close relationship found between extractive properties and process insights.
- Cyano-based ionic liquids stand as the most potential solvents.
- The separation is enhanced but the costs are increased with the number of cyano groups.

1. Introduction

Ionic liquids (ILs) are non-conventional salts that are liquid below 373 K, showing negligible vapor pressure and an interesting liquid range of use only limited by their thermal stability [1]. Among other purposes, ILs have been frequently evaluated in a high number of separation cases as solvents in liquid-liquid extraction processes [1]. Focusing the attention in the aromatic/aliphatic separation, which is one of the most prolific and hopeful research lines using ILs [2], a feasible process was evidenced in the literature referring not only to the core separation (liquid-liquid extraction) but also including side-separations and purifications to enhance aromatic standards and recycle the solvent [3,4]. The aforementioned claim is supported by experimental data at laboratory and pilot plant scales [3-5] but also by process simulation [6,7]. Although large experimental liquid-liquid equilibrium data is available, vapor-liquid equilibrium data is scarce and simultaneous modelling liquid-liquid and vapor-liquid equilibria was not revealed to be easy; thus, a proper overview process analysis lighting the more convenient IL-based solvents is still not available in the literature.

According to this, a systematic process analysis for the aromatic/aliphatic separation seems to be interesting to evaluate, for this example, the real applicability of these neoteric solvents at industrial scale. To do this, COSMO-based/Aspen Plus methodology was selected because of its outstanding power and availability to deal with more than 100 ILs in a wide range of conditions, all in the framework of a commercial process simulator. After validating COSMO predictions against all reliable experimental data regarding liquid-liquid extraction and distillation units involved in the process, the methodology was deployed to better understand the aromatic/aliphatic separation.

2. Methods

Integrated COSMO-based-Aspen Plus methodology was deployed to simulate the aromatic/aliphatic separation process, which involves the extractor and three flash distillation

units; the first two flashes are destined to purify the aromatics, whereas the last one is aimed at separating the aromatics and the IL. The COSMOSAC property model was selected to calculate the activity coefficients in the simulations, specifically the modification to the Lin and Sandler model (mode 3 of COSMOSAC model) developed by Lin, Mathias et al. (2002) because that approach better represented available experimental data. Regarding the modules, EXTRACT and FLASH 2 were selected in the simulation.

3. Results and discussion

After properly selecting the input/output matrix and executing more than 5000 simulations, the results were summarized and analyzed. As exemplified in Fig 1 to representative ILs, it is difficult to find an IL with good performance in both aromatic recoveries and purities, even more complex considering recycling streams. Although [4mbpy][TCM] shows a very competitive performance in the more realistic conditions, the direct proportionality between aromatic distribution ratio and utilities costs makes the analysis even more complex. Taking into account process simulation performance, utilities costs and typical ILs' limitations as viscosity and thermal stability, cyano-containing ILs stand as the more potential ILs nowadays.

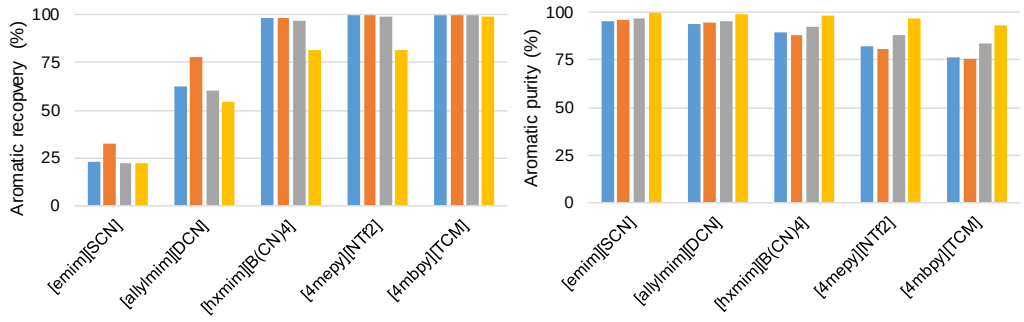

Figure 1. Aromatic recovery and purity with selected ILs in several scenarios. Toluene/n-heptane separation: only extraction, blue; whole process, grey. BTX removing from pyrolysis gasoline: only extraction, red; whole process, yellow.

4. Conclusions

The overview process analysis of the aromatic/aliphatic separation by liquid-liquid extraction with ILs has provided a useful guide to evaluate the global and partial impact of the extractive and physical properties related to available and future IL species on relevant process insights. A clear correlation between ILs features and process simulation insights, such as utilities costs, recoveries and purities, has permitted to give recommended standards for the solvents that will easy the search of even better solvents than cyano-containing ILs for the petrochemical industry.

Confined liquid distribution in structured packings: Study of liquid films around a perforated topography

Manasa IYER[1,2], Hervé DUVAL[1], Joel CASALINHO[1], Jacopo SEIWERT[2], Mikael WATTIAU[2]

1 Laboratoire LGPM, CentraleSupélec, Université Paris-Saclay, Gif-sur-Yvette, 91190, France ;

Highlights

- Film thickness profile over a perforated plate.
- Characterisation of different flow regimes.
- Critical flow rate at which the fluid fills the perforation.

1. Introduction

Falling films on structured packings are extensively studied because of their increased application in the distillation and absorption industries. A class of structured packings consists in stacks of metal sheets. These sheets usually comprise of various complex geometrical intricacies such as corrugations, perforation of various shapes that play a significant role in the local fluid redistribution. The unique flow paths of the liquid and the gas phases over the structured packing, caused by their complex geometry, gives motivation to investigate the physics of the fluid distribution over these topologies. The presence of a topography perturbs the fluid free surface and in a short time, several instabilities can be observed through the deformation of the free surface. The effect of perforations and micro-texture on liquid spreading over the surface of corrugated packing was examined experimentally by Pavlenko et al. (2017). Zhao & Cerro (1992) performed an experimental work over macro and micro structures in which he characterized the mechanics of the viscous film flows by measuring film thickness profiles, streamline patterns and free-surface velocities. More recently, Xie et al. (2018) have studied the liquid flow patterns over several shaped open window at different flow rates. However, in their experiments, perforated plates are supplied with liquid only on one side whereas supply of liquid is maintained on both sides of the metal sheets in real distillation conditions.

In our experimental study, we focus on the fluid redistribution mechanism specific to these topographies in order to clearly understand its contribution towards the spreading of the liquid over a packing. We aim to measure and characterise the local deformation of the film around the topography over a perforated aluminium plate while the fluid supply is maintained on both faces of the plate. The concept of two-face supply of the fluid over such a topographical plate has not been tested before and thus brings new insights on the film behavior around the topographical surfaces.

2. Methods

The film topology and the film pattern in and around the perforation is visualized by using a high speed camera (Phantom v310). With this method, characteristic flow patterns in the perforation and preferred flow paths around the perforation are qualitatively investigated. To measure the free surface topography, Confocal Chromatic Imaging (CCI) (Kofman et al. 2014) technique is used.

3. Results and discussion

The effect of the topography is studied for various aspect ratio of the perforation (diameter d, thickness t) for a range of Reynolds number Re (2 - 63) using three different liquids (Kapitza number Ka = 3, 63, 342). For each configuration, the flow transition from the state of fluid passing around the perforation to the state of fluid filling the perforation is

observed. For all configurations, we measure the critical flow rate at which the fluid fills the perforation. Regime transition occurs at a critical value of the Reynolds number (built with the critical rate) which depends on the Kapitza and Bond number (built with the perforation characteristic length).

Complete two-dimensional map of the free-surface shape of a liquid film in the vicinity of the topography is being constructed by measuring the film thickness using CCI.

Figure 1. Superimposed image of the thin falling film over a perforated plate seeded with silver coated particles to visualise the free surface streamlines for a low Re flow (Re = 0.5) for silicone oil of ν = 100 cSt.

4. Conclusions

In the present work, flow patterns specific to the perforated topography is investigated qualitatively and quantitatively to gain better understanding of the fluid distribution in microscale flow phenomena that may occur on the structured packing. This permits us to optimise the design of structured packings and thereby it could reduce the pressure drop in the column and thus the energy consumption.

Highlights

- CFD investigation of mass transfer in hollow fiber membranes of helical geometry
- The mass transfer efficiency is positively correlated to the helix curvature
- Mass transfer in highly curved helixes is up to 10 times higher than in straight tubes

1. Introduction

Membrane separation is widely used for the separation of homogeneous liquid or gaseous mixtures, and is one of the most promising intensification technologies for gas-liquid absorption processes. The design and operation of membrane modules have been the focus of many scientific researches aiming to improve the separation efficiency.

The mass transfer in membrane modules can be intensified by using helical pipe geometries instead of classic straight membranes. Indeed, the hydrodynamics in helical geometries is characterized by the occurrence of secondary flows, called Dean vortices, which considerably increase the mass transfer efficiency.

The present study addresses mass transfer in highly curved helical pipes, i.e. helical geometries with small helical radius and pitch. Figure 1 presents the limits of the so-called forbidden region in the (R_H^* , p*) space, where R_H^* and p^* are the reduced helix radius and pitch respectively, both nondimensionalized by the pipe diameter, d. The forbidden region corresponds to the zone where it is not possible to design helical shapes. Its frontier, which equation has been determined by Przybył et al. [1], corresponds to closely packed helices, i.e. helices which pitch cannot be further decreased because the consecutive turns of the helix would intersect/overlap one with/on another. Some helix designs are shown in Figure 1. They illustrate the fact that the helical pipe geometry tends toward that of a straight at three asymptotic limits: (i) when the dimensionless pitch *p** tends to infinity; (ii) when the dimensionless helix radius R_H^* tends to infinity; (iii) when the dimensionless helix radius R_H^* tends to zero.

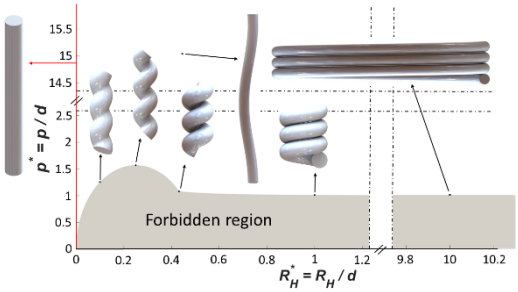

Figure 1: Limits of the forbidden region in the (R_H^* , p*) space (adapted from Przybył et.al [1]) and some representative helices.

2. Methods

In this paper, CFD (Computational Fluid Dynamics) is used to investigate the mass transfer efficiency in helical membranes. Simulations were conducted for various helix designs ($1.25 \leq p^* \leq 15$ and $0.05 \leq R_H^* \leq 10$). The computational mesh consisted of hexahedral cells only, with a boundary layer mesh in the near-wall zone for more accurate calculation of the steep gradients in that area. The commercial CFD code FLUENT 16.0 was used to simulate the mass transfer within the helical membranes. A Newtonian fluid was considered, and the flow, treated as laminar and incompressible, was described using the steady Navier-Stokes and continuity equations. The mass transfer equation was solved assuming a dilute medium and a uniform concentration at the walls.

3. Results and discussion

For each simulation performed, $\mathrm{Sh}_\mathrm{H}^\infty$, the asymptotic Sherwood number (i.e. in the region where the concentration profile gets fully developed) was calculated. Figure 2 shows the contour plot of $\mathrm{Sh}_\mathrm{H}^\infty/\mathrm{Sh}_\mathrm{S}^\infty$ for a Reynolds number of 400 and different Schmidt number values. $\mathrm{Sh}_\mathrm{S}^\infty$ denotes the asymptotic Sherwood number in straight pipes which equals 3.65 under a uniform wall concentration boundary condition.

The contour plots in Figure 2 were obtained using a triangulation-based cubic interpolation of the CFD results. The geometric parameters for which simulations were performed are represented by black dots: at these points, the values of Sh_H^∞/Sh_S^∞ that are displayed on the contour plots are exactly the same than those provided by CFD. Although the interpolated data exhibit some irregularities that are inherent to interpolation, these contour plots provide valuable information: (1) There is a positive correlation between Sh_H^∞ and the pipe curvature. Indeed, highly curved helices involve the highest Sherwood numbers, which is explained by the fact that they engender the most intense Dean-type recirculations. (2) For each dimensionless pitch, p^*, there exists a dimensionless helical radius, R_H^*, at which the Sherwood number is maximal. The ratio Sh_H^∞/Sh_S^∞ tends to one when R_H^* tends to zero or infinity, since the helical geometry approaches that of a straight pipe. (3) The mass transfer efficiency is extremely sensitive to the pitch value in the case of high curved helixes. For an infinite pitch, Sh_H^∞/Sh_S^∞ tends to one since the helical geometry tends to a straight pipe. (4) The mass transfer enhancement is the highest in the case of highly curved helixes and increases when the Schmidt number is increased.

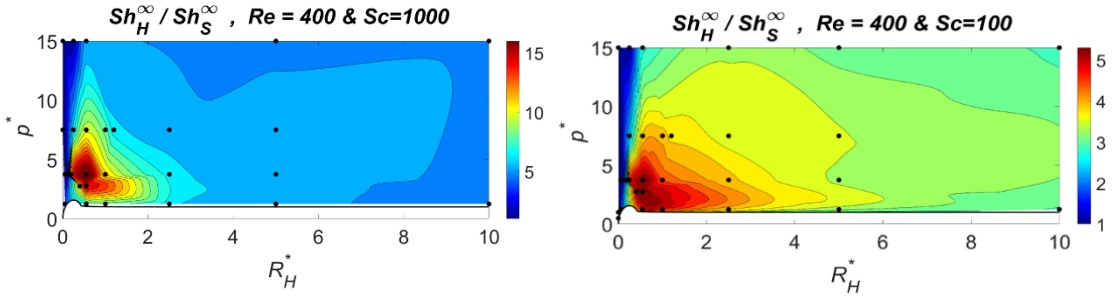

Figure 2: Contour plots of $\boldsymbol{Sh_H^\infty}$ to $\boldsymbol{Sh_S^\infty}$ ratio at different Schmidt numbers and a Reynolds number of 400. The data is interpolated from CFD results marked with black dots.

Highlights

- Expert knowledge was used for formulating a process design optimization problem
- Expert knowledge makes easier the choice of relevant optimization objectives
- Causal map of optimization's objectives is an easy-to-understand graphic representation

1. Introduction

Modelling and optimizing food processes is a complicated task due to the high complexity of the food product itself, the lack of knowledge concerning mechanisms limiting process performances [1], and to the heterogeneity of the involved variables (ordinal, cardinal, discrete or continuous variables). This is the case for skim milk crossflow microfiltration with 0.1 µm pore size (MF 0.1 µm). This operation is commonly used in dairy industry to separate proteins: native casein micelles (retentate) are used in cheese making while serum proteins (permeate) are mainly used in food formulations for specific populations (elderly people, infants, etc). Despite the high interest in MF in the dairy sector, this process is not optimized by considering the different conflicting objectives of the industry such as maximizing protein recovery in the permeate fraction while minimizing economic costs. The choices of membrane configurations, processing designs and operating conditions are based on the know-how of operators and the available expert knowledge. This knowledge is partial and does not take into account links between the process operating variables, product state variables and optimization objectives. When the optimization of MF 0.1 µm is performed, it is often described as mono-objective and empirical problem [2] or as study cases showing the influence of one variable on a group of chosen variables [3]. This article presents a methodology for collecting, collating and representing expert knowledge necessary to the design of food processing multi-objective optimization problems focusing on skim milk MF.

2. Methods

The proposed methodology has four steps: formulation of the multi-objective optimization problem, modelling optimization objectives as functions, optimization of objective functions and choice of a solution to implement [4]. In this work, the focus is on the problem formulation. The

MF 0.1 µm optimization problem is multidisciplinary and the knowledges necessary to formulate and solve the problem are shared between several experts. By dividing the problem domain into domains of knowledge, the identification of experts and the knowledge collection are easier [5]. The semi-structured interview was used to elicit know-how and knowledge from experts. The influence relations between variables and objectives were collected from the interviews and represented as causal maps. Graphical representation allows expert to exchange easily about influence relations. After validations, maps of the same knowledge domain were merged, discussed and validated by the group of the domain experts. Maps represent the knowledge models to use for formulating the optimization objectives as functions from the literature or experimental data.

3. Results and discussion

In this work, the operational objective is to be able to compare optimized microfiltration systems within a global process that can accept different membranes, processing designs and operating conditions. Optimization objectives were defined with the stakeholders: ten experts and decision makers. First, ten objectives were defined and reduced to six regarding industrial issues (maximization of the retentate composition, permeate composition, permeate protein recovery and stability of the permeation flux and minimization of the investment cost and operating cost). The MF 0.1 µm optimization problem domain was divided into nine knowledge domains: membrane properties, performance of the filtration, operating variables, permeate fraction, retentate fraction, process design, costs and environmental impacts. Each knowledge domain benefited from two to seven experts. Knowledge was collected during 36 interviews representing 14h30 of audio recording. For each knowledge domain, a causal map by expert was established and the whole merged as the causal map of the domain. After validations, each domain causal maps were discussed and validated by the different domain experts (industrialists, scientists, equipment manufacturers). One very important point of this step was to define a shared glossary and a generic process scheme representative of all the specific schemes. By the end, the extracted causal relations between variables were represented in 9 maps using approximately 250 variables.

4. Conclusions

The optimization problem studied is complex with conflicting objectives and heterogeneous variables. The integration of expert knowledge allows the identification of relevant objectives regarding to industrial issues. The MF process is considered from conception to performances with the identification of lack of knowledge in order to plan new experiments. Causal maps allow an easy to understand representation of the influences between the variables and make it possible to establish which variables influence which objectives. Based on these maps, the objective functions will be formalized allowing to perform the optimization.

Highlights

- Modelling of heat transfer in metallic open-cell foam.
- New network approach based on Port-Hamiltonian Systems.
- Graph representation are obtained using *X-ray CT* and *iMorph*.

1. Introduction

This paper deals with the modelling of the heat transfer in metallic open-cell foams using their geometric and topological properties. Several works have considered simplified geometries such as regular paving by Kelvin's cell [1] or random cellular morphologies based on the weighted-Voronoi (Laguerre) tessellations [2]. These approaches, however, fail to represent accurately the actual, often non-homogeneous and non-regular, structure of foams and may lead to poor estimation of their effective properties. Another approach is to use, X-ray CT (Computed Tomography) to construct 3D realistic structure which can be used in a CFD software and perform a numerical simulation of the heat transfer equations using finite elements or finite volume methods (FEM, FVM). The main two drawbacks of this approach are (1) the discretization of the computational domain, which leads to numerical models of extremely high complexity (2) the use of staircase boundary approximations, which may lead to inconsistent results.

In this paper, we follow an alternative approach, based on the derivation of two graphs representing the solid and fluid phases obtained using X-ray CT and image analysis [3]. From these two dual graphs, we derive the Port Hamiltonian formulation [4] of the heat diffusion. In a first instance, the work presented here is limited to modelling of the heat transfer in the solid phase.

2. Methodology

From 3D images and using iMorph software [3] (as shown in **Fig. 1**), two graphs are derived. For the graph of solid, one associates nodes to adjacent half-struts and edges to interfaces. For the graph of fluid, one associates nodes with finite volumes and edges to surfaces at the interface of two volumes. Furthermore, some geometrical properties such as strut lengths and diameters, are extracted and associated with the elements of the graph.

The heat diffusion in the solid phase may be formulated as the Port Hamiltonian System $\begin{pmatrix}\frac{\partial u}{\partial t}\\ F\end{pmatrix} = \begin{pmatrix}0 & -div\\ -grad & 0\end{pmatrix}\begin{pmatrix}\tau\\ \phi\end{pmatrix}$ and $\begin{pmatrix}f^b\\ e^b\end{pmatrix} = \mathrm{tr}\begin{pmatrix}\tau\\ \phi\end{pmatrix}$ where u is the internal energy density, τ is the reciprocal temperature, ϕ the heat flux and $\begin{pmatrix}f^b\\ e^b\end{pmatrix}$ denotes the port boundary variables where tr is the trace operator at the boundary of the spatial domain. The Hamiltonian function is the total entropy $H_0 = S$, the state variable is the internal energy density u and the co-state variable is the reciprocal temperature , $\tau = \frac{\delta S}{\delta u}$ corresponding to Gibbs-Massieu equation $ds = \tau\, du$. The heat flux is obeying Fourier's law hence , $\phi = -\frac{\lambda}{\tau^2}F$ with the heat conductivity λ.

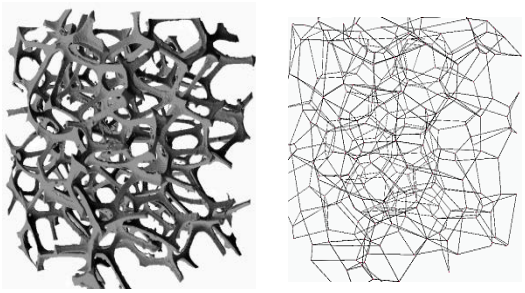

Figure 1. X-ray CT image reconstruction and the solid graph associated (623 nodes and 203 cells).

Writing the set of discrete balance equations, $\frac{d}{dt}\int_{V_i} u_i\, dv = -\int_{\partial V_{ij}} \phi_{ij}\, ds$, for every finite volume V_i associated with node n_i with boundary faces ∂V_{ij} associated with the edges e_{ij}, yields the finite-dimensional Port Hamiltonian Systems [5]:

$$\begin{pmatrix}\frac{du_i}{dt}\\ F_{ij}\end{pmatrix} = \begin{pmatrix}0 & D\\ -D^T & 0\end{pmatrix}\begin{pmatrix}\tau_i\\ \phi_{ij}\end{pmatrix} + \begin{pmatrix}D_b\\ 0\end{pmatrix}\phi_b \quad \text{and} \quad F_b = -D_b^T\tau_i$$

where D and D^T are the incidence and co-incidence matrices of the open graph of the solid. Simulations will be presented in comparison with experimental results [6].

3. Conclusions & perspectives

We have presented the Port Hamiltonian model of the heat conduction in the solid phase of a metallic foam, based on its graph structure obtained by image analysis and tomography. Thereby we take account of the real structure of the foam, the non-regularity of its geometry. Future work will consider the dual graph of the fluid phase and the coupling with the fluid phase and complete the heat transport with mass transport.

Highlights

- PPO-based MMMs can be effectively implemented for CO_2 capture applications.
- Inclusion of selective adsorbents such as ZIF-8 and Zeolite 3A remarkably improved gas transport properties of the glassy polymer.
- Increasing temperature enhanced H_2/CO_2 separation, ideal for IGCC application.

1. Introduction

Membrane technologies represent an alternative to address relevant issues such as global warming and energy efficiency, leaving a smaller footprint than traditional technologies. The use of readily available materials to be combined in Mixed Matrix Membranes (MMMs) to improve the performance for gas separation applications, is one of the solutions to achieve large-scale applications.[1] The use of H_2-selective materials in IGCC plants can reduce the energy consumption associated to post-separation CO_2 compression and provide a hydrogen-enriched stream ready to be used as a fuel for power production.[2] To this purpose, we fabricated robust MMMs based on poly(2,6-dimethyl-1,4-phenylene oxide) (PPO) and different molecular sieves such as ZIF-8 and Zeolite 3A. The membrane preparation was optimized to allow the formation of films up to 45 wt.% of filler. Permeation, diffusion and sorption of He (used as a model for H_2), N_2, CH_4, CO_2 were investigated at 35, 50, 65 °C. Pure and composite materials were characterized from the morphological and calorimetrical point of view. Simple mathematical models were applied to evaluate the permeability of gases in the MMMs.[3]

2. Methods

Membranes were casted by solution casting technique under quick solvent evaporation conditions. MMMs were thermally annealed at 200 °C to remove residual solvent and activate the filler particles. To verify the complete solvent removal from the casting step and evaluate the thermal stability, TGA and DSC experiments were performed. Gas permeation was determined by means of a manometric technique and diffusion coefficients were evaluated with the time-lag method in the framework of the solution-diffusion model.[4] Diffusion coefficients were also evaluated from the diffusion kinetics while measuring sorption isotherms in a pressure decay apparatus. The quality of the adhesion between the filler and the polymer was determined through FEG-SEM images. Density

of membranes was measured by means of the buoyancy method. Maxwell-Wagner-Sillar (MWS) model was used to understand whether the membranes follow an additive rule.

3. Results and discussion

SEM images showed good adhesion between the polymer matrix and filler particles. The dispersion of the filler was homogeneous, especially at low loadings. DSC and TGA analysis revealed that membranes were solvent free after the thermal annealing and thermally stable. Remarkable gas transport results were showed, in particular by PPO/ZIF-8 MMMs, which revealed an increase of He permeability of around 800% with respect to the pure PPO and a He/CO_2 selectivity which was up to 15% higher. Permeability of each gas was successfully described with the Maxwell-Wagner-Sillar model in the range of validity of the model (**Figure 1**). MMMs sorption isotherms followed the additive rule. The effect of temperature further enables the gas separation properties, indeed both He permeability and He/CO_2 selectivity increase sharply with increasing temperature. The activation energy of the permeation and diffusion were evaluated as function of the filler content.

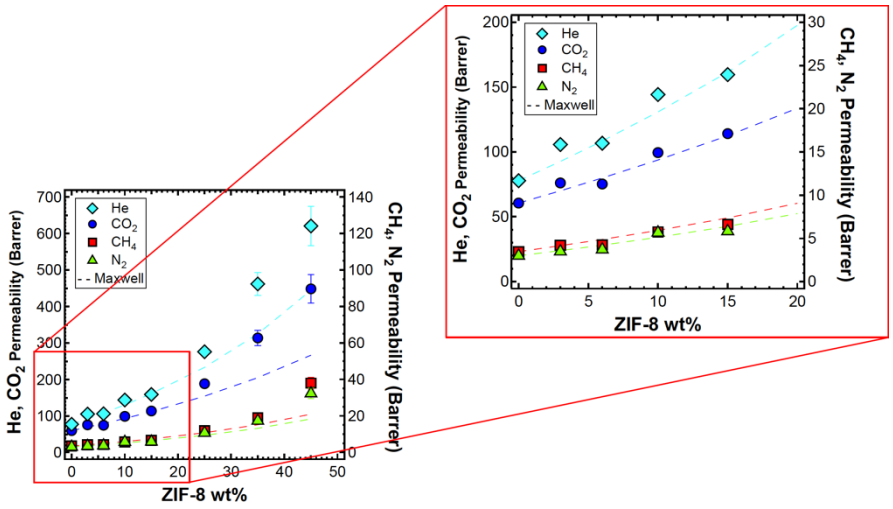

Figure 1. Enhanced gas permeability in PPO/ZIF-8 MMMs. Experimental data (markers) and MWS model (dashed lines).

4. Conclusions

MMMs prepared using PPO and ZIF-8 revealed significantly enhanced transport properties without compromising the processability of the polymer. Density measurements, solubility additive behaviour and Maxell modelling show the ideal behaviour of these MMMs. Higher than ideal permeability at high filler loading may be attributed to percolation phenomenon. Favourable effect on transport properties as the temperature increase make these materials interesting for industrial applications.

Continuous acetic acid extraction from dilute aqueous solutions with supercritical CO_2: experiments and simulation of external extract reflux

Astrid Novella*, Séverine Camy, Jean-Stéphane Condoret

Laboratoire de Génie Chimique, Université de Toulouse, CNRS, INPT, UPS, Toulouse, France

**astrid.novella@ensiacet.fr*

Highlights

- Supercritical fractionation of acetic acid-water mixtures was experimentally studied
- Performances of extraction of AA are low due to thermodynamic limitation
- Simulation of external reflux of extract was performed with Prosim Plus software
- Use of reflux significantly increased the mass fraction of AA in the extract

1. Introduction

Because of emergence of bio-refineries, recovery of valuable products from fermentation broths, such as carboxylic acids, is an important issue to deal with. Conventional purification processes like distillation or solvent extraction present drawbacks that could be alleviated by alternative processes such as supercritical carbon dioxide ($scCO_2$) extraction. $ScCO_2$ was already proposed for purification of alcohol-water mixtures[1] but rarely for recovery of organic acids[2]. Recovery of acetic acid (AA) from dilute aqueous solutions (5% w/w) using a $scCO_2$ countercurrent packed column was experimentally studied at laboratory scale and compared with modelling using a so-called rate-based model[3]. Experimentally, best results were obtained at 40°C and 15 MPa with a solvent-to-feed ratio S/F equal to 11 (according to experimental limits of the set-up), resulting in 43% w/w AA in the CO2-free extract with an AA recovery ratio equal to 36%[4]. This remains low as compared to performances of conventional processes and this is mainly due to the low partition coefficient of AA between CO_2 and water. However, for such systems with unfavorable thermodynamic behavior, use of reflux of extract is likely to allow significant increase of the extract composition. In the present work, performance of this configuration with reflux is assessed by using the commercial process simulation software Prosim Plus (ProSim SA, France), where the column is described as a set of theoretical stages. Thermodynamics of the CO_2-AA-water ternary system is described by an homogeneous approach with Boston-Mathias modified SRK equation of state with PSRK mixing rule and UNIQUAC coefficient activity model (EoS/G^E). For this system, depending on pressure and temperature conditions, so-called type I or type II ternary diagrams can be observed. In this study, design is proposed in terms of reflux ratio and number of theoretical stages for the recovery of AA from water with $scCO_2$, for two sets of operating conditions, corresponding to type I and type II ternary behavior.

2. Methods

Two sets of operating conditions were studied, 45°C and 10 MPa (type I diagram) and 65°C, 12.8 MPa (type II diagram) with and without external extract reflux. From ternary diagrams of figure 1, about 90% w/w of acetic acid in the extract could theoretically be reached at 45°C, 10 MPa, using

external reflux (Fig.1 left) and 100% w/w at 65°C and 12.8 MPa (Fig.1 right). To reach these separation objectives, minimal reflux ratio was graphically determined. Then, value of operational reflux, CO_2 flow-rate and number of theoretical stages were varied to approach these high separation performances.

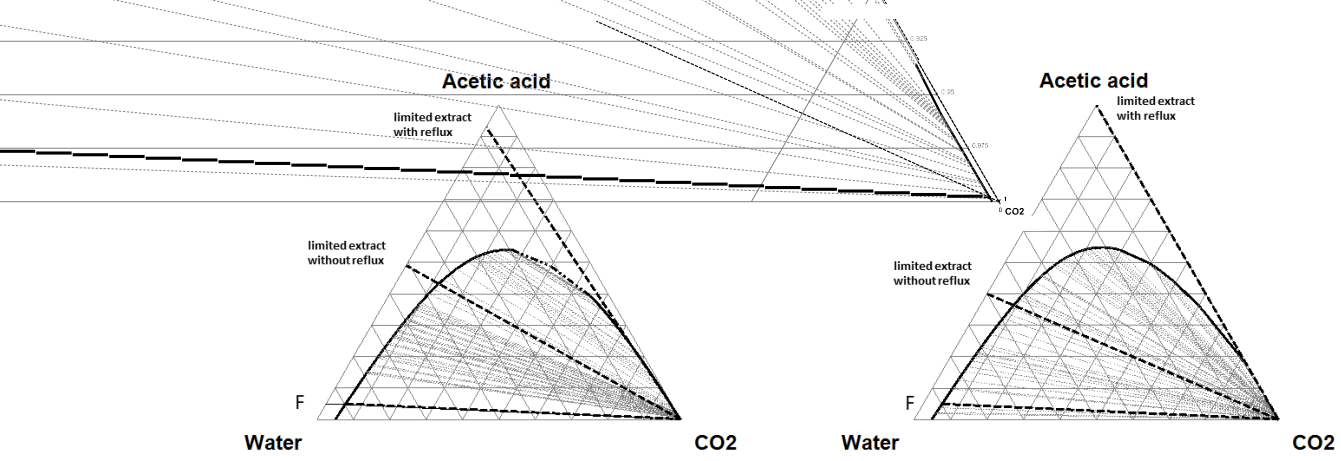

Figure 1. Left : 45°C 10 MPa (type I diagram) & Right : 65°C 12.8 MPa (type II diagram)
Equilibrium curves (solid lines), construction for limited extract in simple and reflux configurations (dotted lines)

3. Results and discussion

At 45°C and 10 MPa, using a S/F=10 with 10 theoretical stages and a reflux ratio=15.5, 87% w/w AA in the extract could be obtained, with a 23% recovery ratio whereas in the conventional extraction without reflux, only 30% w/w of AA in the extract are achieved. At 65°C and 12.8 MPa, 85% w/w AA (with a recovery ratio of 23%) in the extract could be obtained (same S/F and number of stage and with reflux ratio=18.2) whereas only 24% is reached without reflux. These results evidence the theoretical possibility to reach high separation performances for the recovery of dilute acetic acid in water.

4. Conclusions

In this work, supercritical CO_2 extraction for recovery of acetic acid, as an alternative to conventional processes, such as distillation or solvent extraction, was studied. Using conventional configuration of a packed column, *i.e.,* without extract reflux, high purity and high recovery ratio cannot be obtained due to thermodynamic barrier whereas modeling indicated that use of extract reflux could significantly improve separation performances. A larger range of operating conditions has to be considered now to find the optimal design of the contactor (S/F, number of stages, position of feed, reflux ratio). Nevertheless, these theoretical findings remain to be experimentally validated using a lab scale contactor[5]and this work is in progress in our lab.

Novel catalytic distillation processes for a sustainable chemical industry

Anton A. Kiss[1,2]

1 School of Chemical Engineering and Analytical Science, The University of Manchester, Sackville Street, Manchester, M13 9PL, United Kingdom; 2 Sustainable Process Technology Group, Faculty of Science and Technology, University of Twente, PO Box 217, 7500 AE Enschede, The Netherlands

**Corresponding author: tony.kiss@manchester.ac.uk*

Highlights

- Novel reactive distillation processes

1. Introduction

Reactive distillation (RD) is an efficient process intensification technique that integrates catalytic chemical reaction and distillation in one single apparatus acting as a multi-functional reactor. [1] When a heterogeneous catalyst is used, the process is known as catalytic distillation (CD). RD/CD technology has many key advantages such as reduced capital investment and significant energy savings, as it can surpass equilibrium limitations, simplify complex processes, increase product selectivity and improve the separation efficiency.[2] However, reactive distillation is constrained by key thermodynamic requirements (e.g. related to volatility differences and heat of reaction), overlapping of the reaction and distillation operating conditions, and the availability of catalysts that are active, selective and with sufficient longevity to ensure economical operation.

2. Methods

This lecture aims to give an overview of the challenges and opportunities for catalytic distillation processes, the requirements in terms of hardware and catalyst engineering, and it also provides some industrially relevant examples. The potential of reactive / catalytic distillation processes to transform the chemical process industry is assessed from a techno-economic and sustainability perspective. Moreover, the role of the chemical engineering community in enhancing the applicability range of catalytic distillation technology will be addressed and discussed.

3. Results and discussion

The detailed examples presented in this study show that catalyzed RD processes can drastically improve the production of important chemicals such as: acrylic and methacrylic monomers, unsaturated polyesters resins, alkyl ethers (dimethyl ether, di-n-pentyl ether), fatty esters, and other short chain alkyl esters. Various RD configurations can be used, as illustrated in Figure 1. [3] The main drivers for such novel reactive distillation applications are: economical (large reduction of costs and energy use), environmental (lower CO2 emissions, no or reduced waste) and social (improved safety and health due to lower reactive content, reduced footprint and run away sensitivity). Hence RD technology strongly contributes to all three pillars of sustainability in the chemical process industry.

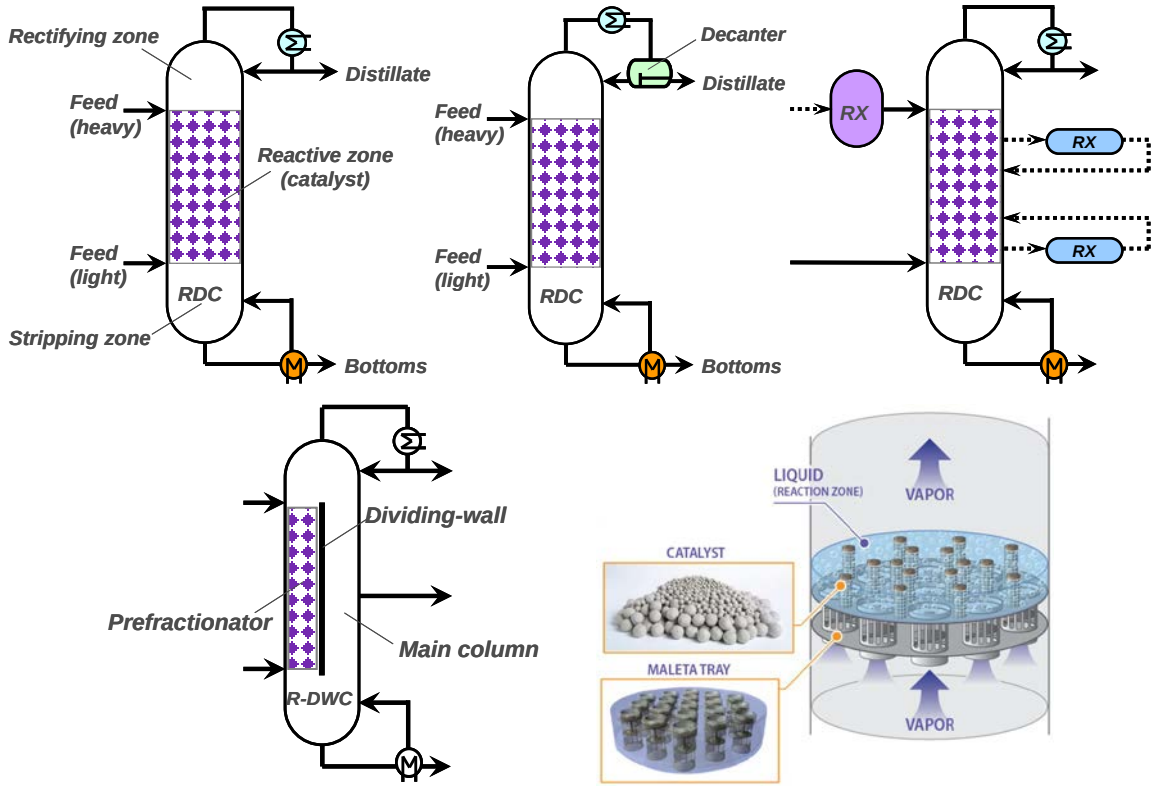

Figure 1: Configurations of reactive distillation processes: classic RD, azeotropic RD, RD with pre-reactors and side-reactors, reactive dividing-wall column (R-DWC), catalytic cyclic distillation internals (Maleta trays).

4. Conclusions

Despite the relatively complex design, control and equipment, RD remains one of the best process intensification technologies that fulfils all the principles of green engineering: design for separation, maximize efficiency, use renewable vs depleting sources, prevent instead of treat, meet need and minimize excess, integrate local material and energy flows, output-pulled vs input-pushed, and design for a commercial afterlife. RD offers key unique features such as: low number of processing units, enhanced overall rates, overcome unfavorable equilibrium, avoid difficult separations, improved selectivity, reduced energy use, less CO2 emissions, low or no solvent use. Considering the outstanding progress in equipment development, modeling and simulation, design and control strategies, real time optimization, and the rapid pace of exploring new applications, RD remains an important PI technique capable to bring green chemistry and sustainable engineering into the chemical process industry.

Investigating reverse osmosis membrane fouling and scaling by membrane autopsy.

Nishtha Dhunnoo[1], Luiza C. Campos[2], Pablo García-Triñanes [1]

[1] *Flow, Heat and Reaction Engineering Group (FHRENG), School of Engineering, University of Greenwich, Medway, ME4 4TB, United Kingdom;*
[2] *Department of Civil, Environmental and Geomatic Engineering, University College London, Gower Street, London WC1E 6BT, United Kingdom*
**Corresponding author: p.garciatrinanes@gre.ac.uk*

Highlights

- The study involved performing membrane autopsy and carrying out a series of tests to investigate the mitigation of fouling and scaling.
- Diatoms, pseudomonas and polysaccharides were the main biofoulants identified.
- Analysis revealed aluminium, calcium and silica as the main elements contributing to inorganic scaling.
- The findings pointed out flaws in pretreatment system of the household water treatment equipment.

1. Introduction

Population bloom, economic growth, industrialisation, climate change and water mismanagement are contributing to diminution of water globally. Many countries have adopted seawater reverse osmosis (RO) desalination to cope with increasing water demand [1]. However, fouling and scaling are crucial problems in the implementation of desalination which increases the cost of running this technology. Reduced efficiency is experienced in terms of a decrease in product output and permeate flux, high energy demand, increased operating pressure and reduced membrane lifetime [2]. The purpose of this research involves the study of proactive methods to mitigate RO membrane fouling and scaling.

2. Methods

This research involves investigating a desalination equipment used in household water treatment. Visual inspection was first carried out to observe the physical integrity to visually identify potential foulants. This step is important in determining subsequent analyses. Scanning electron microscopy (SEM) analysis was then performed to determine the topography and morphology of samples. This was conducted in conjunction with Energy Dispersive Spectroscopy (EDS) to identify and quantify the composition of the sample based on its element. Fourier Transform Infrared (FTIR) spectroscopy was then carried out to compare the wavelength of the foulant to identify the chemical bonds present. This was followed by three microbiological tests, namely catalase test, gram stain and API (Analytical Profile Index) test, to identify the bacteria causing biological fouling.

3. Results and discussion

Through visual inspection, Reverse Osmosis (RO) membrane fouling was visible as an irregularly distributed, thin and watery fouling layer. Scanning Electron Microscopy (SEM) characterization showed inorganic scaling in the form of salt crystal deposits. Different types of diatoms were also identified. Energy Dispersive Spectroscopy (EDS) analysis showed high concentration of Oxygen (O) and Carbon (C) suggesting deposits of organic and biological materials, with composition of C varying from 3.7% to 52.2% while that for O varying from 17% to 60% in the first membrane. Inorganic elements identified in the fouling layer through EDS are Al, Ca and Si. The spectrum obtained from Fourier Transform Infrared (FTIR) characterisation is shown in Figure 1. Amine group, amide group, proteins, polysaccharides, nucleic acid and aromatic compound were identified though interpretation of the frequency bands [3,4]. Different pseudomona species were identified through microbiological test analyses, confirming bacteria as one of the main causes for biofouling.

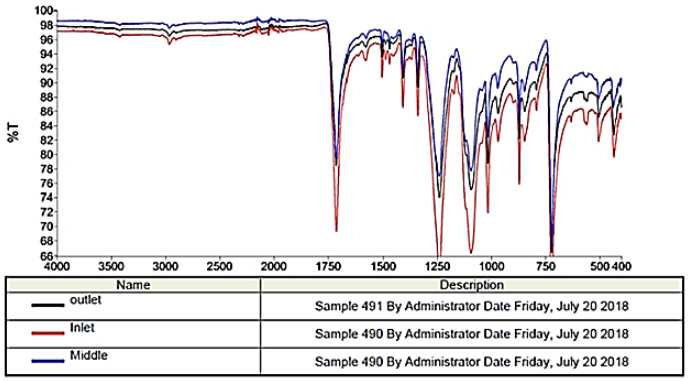

Figure 1. FTIR spectrum of membrane for outlet, middle and inlet sample.

4. Conclusions

Conclusions drawn through interpretation of membrane autopsy analyses indicate that biofouling is very pronounced due to the high number of diatoms, bacteria and the presence of carbon and oxygen. Inorganic scaling has also taken place in the membrane. The current pretreatment system being used in the water treatment equipment proves to be inefficient and inadequate. Additional pretreatment is required to protect the membrane from fouling and scaling. This need to be implemented based on the water quality flowing through the equipment.

Separation of SiO_2 Nanoparticles by Preparative Agarose Gel Electrophoresis with and without Limitation by Mesh Size.

Matthäus Barasinski[1], Georg Garnweitner[1]

1 Technische Universität Braunschweig, Institute for Particle Technology and Laboratory for Emerging Nanometrology, 38106 Braunschweig, Germany

**Corresponding author: m.barasinski@tu-bs.de*

Highlights

- Size fractionation of SiO_2 nanoparticles (10-300 nm) by agarose gel electrophoresis
- Particle migration is observed following a limited and an unlimited regime:
  - Limited migration of particles for sizes similar to gel mesh size
  - Unlimited migration of smaller particles according to zeta potential

1. Introduction

Monodisperse nanoparticles (NP) with completely uniform properties regarding size and morphology are essential already today e.g. for optical (plasmonic) applications. In future, such particles will be necessary for use in further areas, for example all complex nanosystems involving self-assembly processes. There these uniform NP promise structures with highest precision.
Since the required narrow particle size distribution or monodispersity typically is not reached after the synthesis at industrial scale, purification steps are needed. In most cases the high diffusion rates of NP are problematic for a practicable separation with conventional methods. For this reason, we investigate the use of gel electrophoresis for preparative purification, which provides the opportunity of a highly selective separation of synthesized NP by size and morphology. Thereby, the NP are spatially separated in an appropriate gel according to their different electrophoretic mobilities, with the gel matrix substantially reducing the NP diffusion. In principle, the mobility can be simply calculated by the measurement of zeta potential and utilization of the Henry formula.

2. Methods

The movement of the NP is traced during the migration by a simple camera and subsequent image processing, for correlation of the experimental data to the calculated electrophoretic mobility. Besides this, the separation of NP with regard to size and morphology is evaluated with SEM, TEM and small angle X-ray scattering (SAXS) inside the gel.

3. Results and discussion

After the Stöber-synthesis of silica NP under different ammonia concentrations, sizes and zeta potentials ζ were measured via DLS. The measured data show that bigger particles have greater absolute values of zeta potential. Once the voltage was set on, particles start to migrate from gel pockets through the gel from cathode to anode (here: due to negative zeta potential from top down). In Figure 1 different samples can be seen due to scattered light in a 0.2 wt-% agarose gel

after 50 minutes at an applied voltage of 40 V. Two different migration regimes can be distinguished: the unlimited and the limited case. If there is no limitation by too small mesh sizes of the gel, bigger particles migrate faster due to their greater absolute value of zeta potential (samples A and B) than smaller ones. In contrast, sample D is influenced by the mesh size which limits its migration although this sample has the most negative zeta potential. For sample C both cases are valid because the particle size distribution is quite large. Bigger particles within sample C seem to be limited by mesh sizes whereas smaller ones show unlimited and fast migration on the basis of their zeta potential.

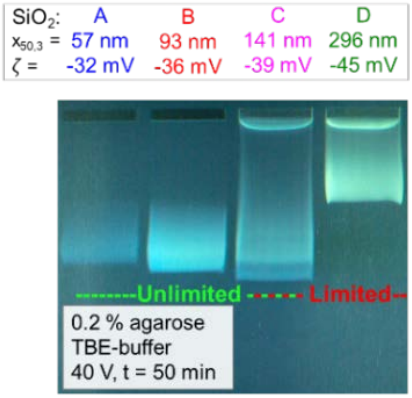

Figure 1. Migration of SiO_2-NP with different sizes in a 0.2 wt-% agarose gel after 50 minutes and an applied voltage of 40 mV.

As an example, in Figure 2 the migration of two SiO_2 samples and a separation of their binary mixture are presented. Sample D with the higher absolute value of zeta potential migrates much slower than sample B, because the mesh size of this specific agarose gel limits its migration speed. Here, the limited case is applied which acts like a sieve to separate the two fractions. After the electrophoretic experiment the particle sizes of the fractions were confirmed with dried gel samples by SEM images.

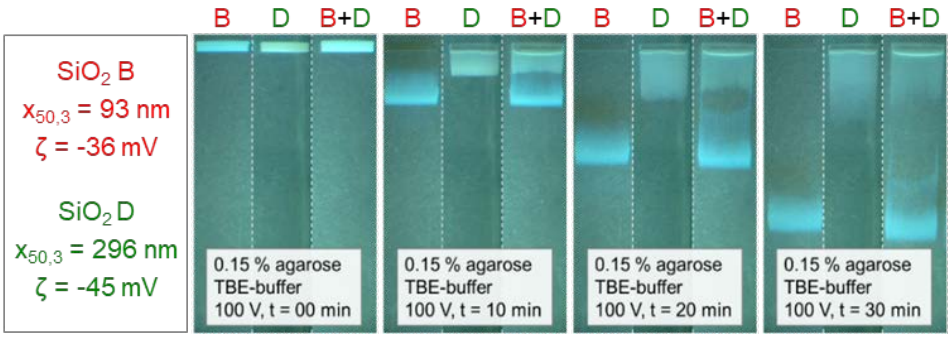

Figure 2. Separation of SiO_2-NP by limitation of sample D (bigger particles) in a 0.15 wt-% agarose gel at 100 V and different times (t = 0, 10, 20 and 30 min).

4. Conclusions

The influence of particle size and zeta potential on the migration behavior of particles inside an agarose gel was investigated and binary mixtures were successfully separated. After the electrophoretic experiment, particles were characterized by SEM, TEM and SAXS inside the gel.

Direct observation of particle accumulation on a model filter: analysis of the morphology of solid particles and yeast cakes.

Alberto Valencia[1], Philippe Schmitz[1*], Christine Lafforgue-Baldas[1], Jeffrey Morris[2]

1 Université de Toulouse, INSA, LISBP, Avenue de Rangueil, 135, F-31077 Toulouse, France;

**Corresponding author: schmitz@insa-toulouse.fr*

Highlights

- A new microfluidic device for direct observation of particle accumulation.
- Use of image processing for particle tracking and concentration profile
- Growth of cakes of spherical solid particles and yeast cells.
- Compressibility effects of the yeast cake.

1. Introduction

Particle transport and capture are widely encountered in many applications, from living to environmental and manufactured systems. In the particular case of filtration of living cells such as microorganisms, the fouling phenomenon, partly related to cell accumulation at the filter surface, should still be better understood to improve the performance of a number of devices. Experiments in model systems have exhibited complex behaviors of the microorganisms due to their specific properties (shapes, mechanical properties, physiological state) that drastically depend on the local environment. A new microfluidic device was thus developed to study the morphology of filtration cakes through the direct observation of particle accumulation. Particle trajectories, velocity and concentration fields were all studied during cake growth.

2. Methods

The setup consists of a transparent photoetched microfluidic device with a rectangular channel (1mm x 20 to 30 µm) having a filtering structure of multiple slots and a microscope connected to a computer (Figure 1A). Different filter geometries were obtained by varying the width of the slots and the pitch (Figure 1B). Two model suspensions were used: monodispersed spherical solid particles (8.2µm) purchased from Thermoscientific, and cultivated yeast cells (mean diameter 6µm). Filtration experiments were performed at low flow rates (1 to 20 µl/min). The images of particle transport and capture and pressure drop were recorded during filtration. Dedicated image processing modules were developed for particle tracking, velocity and concentration fields and fluid/cake interface tracking.

3. Results and discussion

The effect of the filter geometry on the final position of the first arriving particles and the subsequent blockage of the slots was carefully analyzed. First, particles can eventually protect neighbor slots from blockage as function of the ratio between particle size and pitch (Figure 2A).

The same results were previously obtained in the case of microsieves (provided by Aquamarjin) made of regular arrangement of circular pores [1]. Then the permeability of the resulting first layers of accumulated particles depends on the filter geometry.

The mean porosity of the cake was calculated from the cake observed thickness and the mass of particles accumulated, taking into account the time variation of the particle concentration field above the cake. As can be expected it is about 50% in the case of spherical solid particles. However, it is lower in the case of yeast suspensions and slightly decreases with time of filtration, exhibiting a compressibility effects of yeast cakes. This phenomenon was observed as an increase of the cake thickness when the flow rate is stopped (Figure 2B). Analog results were previously obtained and explained by the deformation of the yeast under pressure [2].

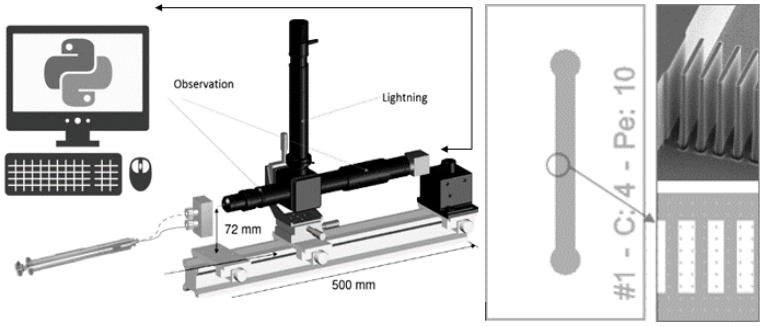

Figure 1. A) Experimental setup. B) Details of the filter geometry

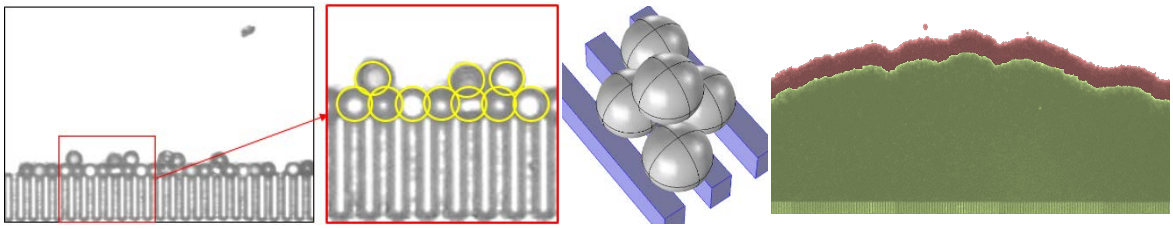

Figure 2. A) Visualization and sketch of first particle layer deposition. B) Compressibility effects of the yeast cake

4. Conclusions

A new microfluidic filtration device was developed to scrutinize the particle accumulation on a model filter. The results allow for better understanding of the first step of cake formation and the morphology of the cake, especially for yeast suspensions. Discussions should be strengthened by future experiments with non-spherical solid particles (snowman shape, for example) and yeast cells obtained from different states of cultivation.

Simulation of the AMP process for the purification of a flue gas stream from a power plant

Stefania Moioli[1], Ricardo R. Wanderley[2], Laura A. Pellegrini[1], Hanna K. Knuutila[2]

1 GASP, Group of Advanced Separation Processes and GAS Processing, Dipartimento di Chimica, Materiali e Ingegneria Chimica "Giulio Natta", Politecnico di Milano, Piazza Leonardo da Vinci 32, I-20133 Milano, Italy;
2 Department of Chemical Engineering, NTNU, N-7491 Trondheim, Norway
**Corresponding author: stefania.moioli@polimi.it*

Highlights

- Carbon dioxide removal needs to be applied for climate change mitigation.
- AMP is a sterically hindered amine which can be used for CO_2 removal.
- Simulation of non-precipitating aqueous AMP process for CO_2 absorption.
- Future development of precipitating pseudo-solvents based on literature data for AMP.

1. Introduction

Carbon dioxide is the greenhouse gas which produces the strongest effect on global warming and several methods for its removal have been developed, with chemical absorption (usually by aqueous solutions of alkanolamines) being generally recognized as a suitable technology in particular when applied to treatment of gaseous streams as flue gases from power plants. The formation of solids upon CO_2 absorption is a feature of many alternative amine systems and precipitation may actually be considered advantageous [1], as outlined in studies on potassium taurate [2,3], and by the UNO MK 3 process [4,5]. Notwithstanding these efforts, not enough attention has been paid on methodically outlining which particularities arise when moving from regular monophasic solvents to precipitating solvents. Issues such as increases in equipment complexity and sizing, the handling of viscous slurries, the shifting in rates of absorption upon precipitation are easily overlooked. Furthermore, the main energetic benefits of this process will be wasted if plant designers forget to adapt the typical absorption-desorption process structure to the specific context of precipitating solvents. With the aim of mapping the opportunities and challenges of employing precipitating solutions, a token solvent of aqueous 2-amino-2-methyl-1-propanol (AMP) has been selected. AMP is a sterically hindered primary alkanolamine with a tertiary carbon atom attached to the amino group. It presents good absorption capacity, absorption rate, selectivity and degradation resistance if compared to traditional amines [6]. Recently, Svensson et al. [7,8] have focused a lot of effort in developing a precipitating solvent based on AMP plus N-methyl-2-pyrrolidinone (NMP). For that reason, AMP is a good starting point for this analysis. In order to study this type of solvents, the first step, on which this work focuses, is to provide an accurate process design for a CO_2 capture plant based on aqueous AMP, for which only few papers in the literature [6,9-12] can be found.

2. Methods

ASPEN Plus® has been employed as tool for simulation. The thermodynamic model has been selected considering that the system is strongly non-ideal because of the chemical reactions

occurring in the liquid phase and generating ions and validated by comparison with experimental data. Kinetics and mass transfer have been taken into account for the simulation of the absorption and desorption units.

3. Results and discussion

The purification of a flue gas from a 500 MW coal-fired power plant has been considered for removal of 90% of carbon dioxide. The obtained results show that the profiles of the absorber are characterized by the same trends typical of the ones of traditional amines. Similar trends occur also in the regeneration section, though being the required energy different.

4. Conclusions

This works has focused on the study of AMP for use as solvent for the chemical absorption of carbon dioxide from flue gas of a 500 MW coal-fired power plant, which is removed with the aim of reducing the greenhouse gas emissions to the atmosphere. ASPEN Plus® has been validated and used for the simulation of the system, providing an accurate representation of the system, which can be used as a basis for the future developments of the work.

Strategies to improve the performance of Membrane Distillation.

Alessandra Criscuoli*

Institute on Membrane Technology (ITM-CNR), via P. Bucci 17/C, 87036 Rende (CS)

**Corresponding author: a.criscuoli@itm.cnr.it*

Highlights

- Different Membrane Distillation configurations were integrated.
- Different designs of membrane modules were realized.
- A feed-side heated flat membrane module was designed.

1. Introduction

Membrane Distillation (MD) is a thermal membrane separation technique based on the use of microporous hydrophobic membranes. The evaporation of the liquid feed occurs at the liquid-membrane interface, because of the hydrophobic membrane properties that prevent the liquid phase to permeate, and the vapor moves through the membrane micropores thanks to a difference of vapor pressures (driving force) established across the membrane. Depending on the way the driving force is created, different MD configurations can be obtained. The potential of MD as an efficient separation technique has been demonstrated in many fields (seawater and brackish water desalination, wastewater treatment, purification of physiological solutions, etc.). Complete rejection of non-volatile species can be, in fact, obtained working at lower operating temperatures and equipment size than traditional distillation columns. The high specific thermal energy consumption (ratio between the thermal energy supplied and the permeate produced) is, however, one of the main drawbacks of the technique, that is limiting its implementation at large scale. In this respect, this works aims at presenting some possible strategies to improve the performance of MD, in terms of higher permeate flux and lower energy consumption. In particular, the simplest and most investigated MD configuration, the Direct Contact Membrane Distillation (DCMD), was considered in the present study.

2. Methods

Three strategies were investigated to improve the performance of DCMD:

1. The coupling of the DCMD unit with an Air Gap Membrane Distillation (AGMD) unit, where the feed exiting from DCMD was heated up in AGMD [1];

2. The realization of new DCMD flat membrane modules presenting baffles at the feed side [2];

3. The design of a feed-side heated DCMD flat membrane module.

For each case, experiments were carried out by varying operating temperatures and flow rates, and the best conditions were identified.

3. Results and discussion

The investigated approaches allowed to reach positive results, like:

1. lower specific thermal energy consumption and higher permeate production for the integrated MD system;
2. better heat transport and higher permeate flux for the new DCMD designs.

4. Conclusions

The results obtained in this work confirmed the validity of the proposed strategies to improve the efficiency of DCMD. As future research, the combination of the three approaches could be explored to further enhance the performance of this promising separation technology.

STRATEGIES FOR PARACETAMOL WITH 4'-CHLOROACETANILIDE PURIFICATION AND CRYSTALLIZATION

Leila Keshavarz, Rene Steendam, Lian Blijlevens, Patrick Frawley

The striking ability of impurities to significantly influence crystallization processes is a topic of paramount interest in the pharmaceutical industry. Despite being present in small quantities, impurities tend to considerably change a crystallization process as well as the final crystalline product. In the present work, the effect of two markedly different impurities 4-nitrophenol and 4'-chloroacetanilide on the solubility, nucleation and crystallization of paracetamol are described. In the first part of this work, the fundamentals are outlined and show that although each impurity led to a small increase in solubility of paracetamol, their effect as a nucleation inhibitor was much more pronounced. Induction time experiments were used in conjunction with the classical nucleation theory to show that the impurities did not affect the solid-liquid interfacial energy but instead significantly reduced the kinetic factor, overall resulting in reduced nucleation rates. Intriguingly, both impurities influenced the solubility and nucleation of paracetamol in a similar fashion despite their significant differences in terms of molecular structure, solubility and ability to incorporate into the crystal structure of paracetamol. In the second part of this work, the incorporation of 4'-chloroacetanilide into the solid phase of paracetamol was investigated. The presence of 4'-chloroacetanilide in the solid phase of paracetamol significantly increased the compressibility of paracetamol, resulting in improved processability properties of paracetamol. The compressibility efficiency of paracetamol could be controlled using the amount of incorporated 4'-chloroacetanilide. Therefore, an experimental design space was developed and utilized to select the most important process parameters for impurity incorporation. Intriguingly, the number of carbon atoms in the aliphatic chain of the alcohol solvent strongly correlated to the impurity incorporation efficiency. As a result, it was feasible to accurately control the compressibility and the amount of 4'-chloroacetanilide in the solid phase of paracetamol by simply choosing the required alcohol as the solvent for crystallization. Thus, the present work comprehensively shows how different impurities impact the key crystallization mechanisms and properties of a pharmaceutical product. Rational process control over the incorporation of impurities and additives allows for advanced manufacturing of products with tailored specifications.

Improved FOS fractionation using inhomogeneous membrane cascades

Zulhaj Rizki[1,*], Anja Janssen[1], Remko Boom[1] and Albert van der Padt[1]

1 Wageningen University, Food Process Engineering Group, the Netherlands

**Corresponding author: zulhaj.zulhajrizki@wur.nl*

Highlights

- Inhomogeneous filtration cascades fractionated FOS into 3 fractions vary in sizes.
- Separation was improved using more stages and altering configurations.
- Optimizing the process considering all performance indicators was done using a multi-criteria decision making approach.

1. Introduction

Fractionating fructo-oligosaccharides (FOS) into multiple fractions that vary in degree of polymerization (DP) is beneficial to produce prebiotics with different functionalities. Membrane separation becomes a favorable option for fractionating FOS due to its mild condition and high selectivity. However, a single stage membrane can only produce 2 fractions at a time and its maximum achievable purity is limited. Using a cascaded multi-stage membrane system overcomes that purity limitation and opens a possibility to extract multiple products at once. We used an inhomogeneous membrane cascade system to fractionate FOS into 3 different products rich in monosaccharides (DP1), DP3 and DP≥5 simultaneously using a side-stream approach (Figure 1.a). Differentiating from the firstly introduced ideal cascade [1], the inhomogeneous cascades allow us to use different set up at each stage [2] resulting a better separation performance. Having an independent system and multiple products raise new design questions: Which set up to use at each stage? And which (product) parameter should be optimized? Aided by a mathematical model, we simulated various possible setups and developed a method to select the best setup using a multi-criteria decision making approach.

2. Methods

A model based on characterization of 3 types of membranes (GE, GH and GK from GE Osmonic, USA, model 1812) was developed to predict the performance of single stage membranes. Such model was later expanded for cascaded systems [3]. A set of combinations was used to simulate the purities, yields and separation factors of products that are rich in DP1, DP3 and DP≥5. The simulated values were then used to develop an optimization procedure to select the best setup with compromised performance. Applying this procedure, we optimized the process by using 4 and 5 stages and altering the configurations (S- and L-strategies) while keeping the stage number at 3.

3. Results and discussion

The fractionation cascades with side stream approach were able to fractionate FOS into 3 different products with enhanced purity compare to the feed having maximum purities of 66% for DP1 (from 9%), 33% for DP3 (from 24%) and 54% for DP≥5 (from 34%). These maxima were achieved by using

a 4-stage design. The 4-stages designs create asymmetric configurations towards the top or bottom region resulting in a more specific separation. Similar considerations were used in the S- and L-strategies to improve the purities further while keeping the stage number at 3.

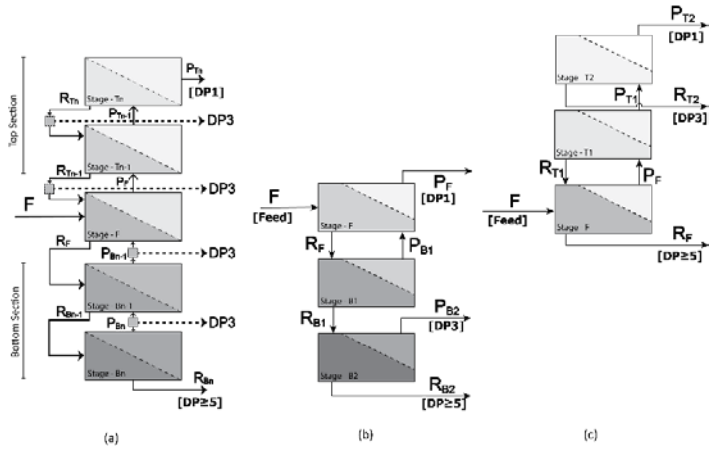

Figure 1. Configuration of (a) generalized fractionation cascades with side streams and example modification with (b) S-strategies and (c) L-strategies for 3 products.

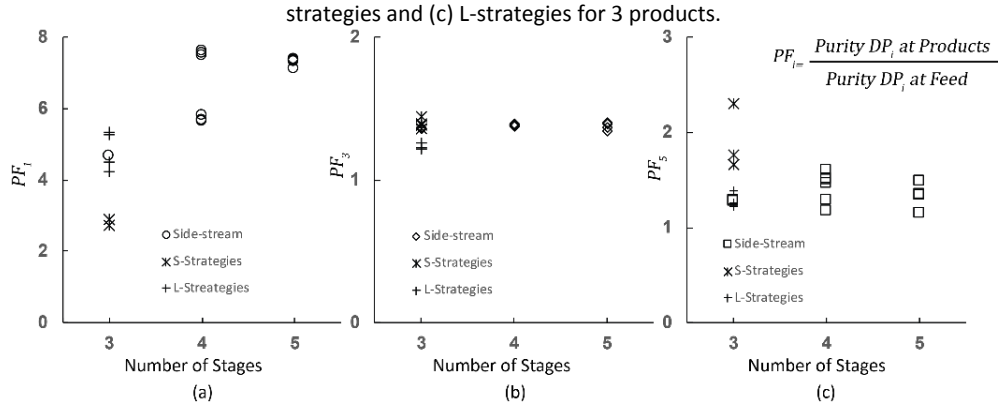

Figure 2. Maximum purification factor of (a) DP1, (b) DP3 and (c) DP≥5 achieved by membrane cascade system using side-stream approach for 3, 4 and 5 stages and modification of 3 stage cascades with S- and L-strategies.

Achieving those maximum purities could only be done by sacrificing the purities of other components or the yields. Using the multi-criteria decision making approach, a setup that is giving compromised performance indicators (purities, yields and separation factors) could be chosen.

4. Conclusions

Fractionating FOS into 3 products was performed using membrane cascaded systems. The system was improved by using more stages and altering the configuration. The approach to improve and optimize a fractionation process that we described here is applicable for other processes (not limited to membrane systems). A predictive model for a single process is required. This single stage model has to be expanded in the comprehensive model to predict the whole system. This comprehensive model needs to be used for optimization.

Highlights

- High-quality vaporization of liquid water in millichannels is studied experimentally
- Dedicated test bench is used to study influence of flow rates, temperatures and pressure
- Flow regimes, vapor quality and heat-transfer coefficients are estimated
- High-quality vaporization is reached at low flow rate and large temperature difference

1. Introduction and context

Steam is largely used in industry as an energy vector and is currently generated in large tubular heat exchangers coupled to a vessel in a thermosiphon system. Process intensification mainly aims at increasing the process efficiency by reducing the size of the equipment: the smaller the size, the better the control of the operating conditions, for instance the heat transfer. The case of the water vaporizer in hydrogen production is the focus of the present study. However, the results of this study could be used in other applications as long as heat has to be valorized, such as in the case of hot gases outgoing from the reactor of the Steam Methane Reforming (SMR) process.

The intensification of this process could enable to reach total vaporization of the water flow and a significant simplification of the installation. A plate milli-channel heat exchanger is studied in this work, although some other technologies could have been used in this application such as brazed plates-and-fins exchangers.

The main goal of this work is to develop a sizing tool for intensified vaporizers in order to meet the expectations of the steam production needs on SMR plants. It is developed thanks to an experimental study of the hydraulic and thermal phenomena occurring during phase change in the milli-structured device.

2. Test Bench and Methods

A test bench has been set up for this study. Convection of hot oil was chosen as the heating mode for the water vaporization to avoid the risks induced by a hot gas convection loop at lab scale. The test bench presents three different loops of fluids: one for the process water, another one for the hot oil and the last one for the condensation of the produced vapor. Several parameters are measured, namely, the flowrates, the temperatures of fluids and the absolute and differential pressure inside the vaporizer for the water. A particular attention is given to the wall temperature between the oil and the water, measured at six positions along the millimeter-size channels. The semi-circular cross section of the channels was chosen to enable the visualization of the boiling

fluid, through a 1 cm thick borosilicate window. Unfortunately, the vapor quality cannot be directly measured; nevertheless, it can be estimated using a heat balance on the vaporizer. A specific study on the heat losses was performed to minimize the uncertainty related to this heat balance.

3. Results and discussion

The vaporizer has been operated under various operating conditions: the water flowrate varied between 0 and 6 L/h, the oil flowrate between 0.5 and 4.5 L/min, the inlet temperature of oil between 100 and 190°C and the pressure on the water side between 1 and 5 bars. The resulting vapor quality (Figure 1.b), the pressure drop and the hydraulic regime, highlighted by image analysis of high frequency movies, are studied for all operating conditions. This work presents an analysis of this experimental campaign, completed with high-speed visualization, to characterize properly the "two-phase" thermal transfer coefficient in milli-structures (Figure 1.a), which is one of the keystones to design a vaporizer.

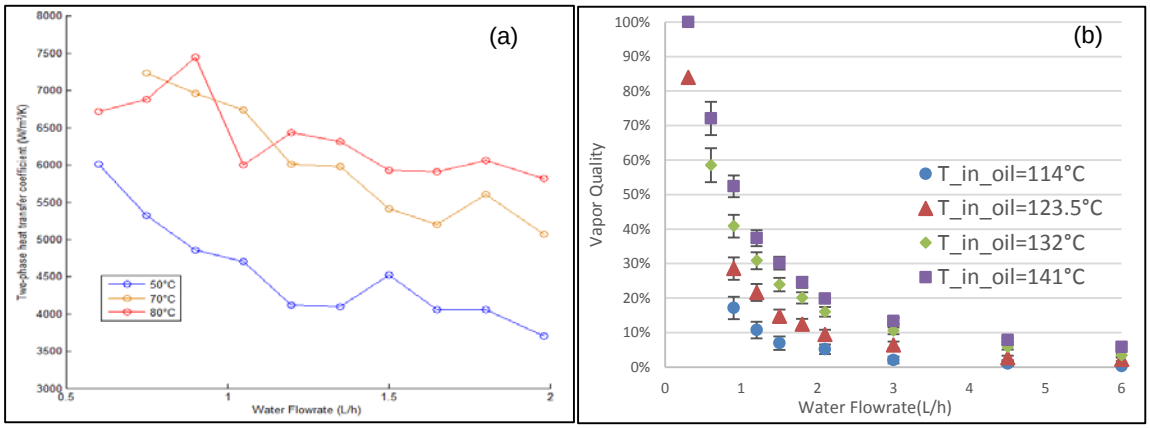

Figure 1. Influence of the pre-heating temperature on the two-phase heat transfer coefficient (a), Influence of the oil flowrate on the vapour quality (b)

The magnitude of the "two-phase" heat transfer coefficient ~~estimated in the milli-channels~~ is similar to what can be found in the literature [1]. Since the boiling in the vaporizer creates a high frequency oscillating flow, further investigations are needed to validate the evolution of these coefficients. Concerning the vapor quality, the geometry of straight milli-channels is not able to produce high quality at "high" water flowrates. However, it has been shown that the thermal gradient between the oil and the boiling water is the main way to step up the vapor quality.

4. Conclusions

The vaporizer studied enables the production of steam by heat recovery from a hot flow. The vapor quality produced is improved by low water flowrates and high differences of temperature between the hot and water flows.

KRAFT, BCTMP and TMP dewatering in a screw press: A statistical modeling.

Bouchaib El idrissi[1*], Éric Loranger[1], Robert Lanouette[1], Jean-Pierre Bousquet[2], Mark Martinez[3]

1 UQTR, Trois-Rivières. Canada; 2 Valmet, Montréal. Canada; 3 UBC, Vancouver. Canada

Highlights

- The pulp behavior is very similar regardless the type of the pulp.
- The behavior is predicted statistically with a good approximation.
- The screw rotational speed is the most significant factor.

1. Introduction

Screw presses are used for solids/liquids mechanical separation. As dewatering is one of the most important unit operations in the pulp and paper industry, this study was conducted to establish a statistical relationship between the operational parameters and the main outputs of the screw press.
The objective of this study was to analyze statistically the main outputs and try to find a predictive model of the screw press.

2. Methods

For this study, we used JMP from SAS for experimental design and statistical analysis.
The screw press used in this study is a Thune SP23 screw press from Voith. Four pressure sensors and fourteen filtrate baskets were installed along the screw press to track the pressure variation and filtrate characteristics.

3. Results and discussion

- At first, the designs were including the quadratic effects. After analysing all the data on JMP, the design can be reduced in most cases to having just the interactions parameters.
- For Kraft pulp, the R squares varied from 0.89 to 0.97 in the interactions model. The BCTMP model gives R squares from 0.85 to 0.98, and for TMP the R squares varies from 0.72 to 0.97.
- JMP allows us to see the effect of the parameters using a profiler for each pulp. In our case, we have chosen to observe the effect on the pulp outlet consistency and inlet flow; the filtrate consistency and flow rate; the screw press production; the pressure in the basket 4 near to the discharge end and finally the screw torque.
- The outlet consistency is mainly affected by the screw rotational speed. For the three-pulp studied, the outlet consistency decreases with increasing the rotational speed. Increase the rotational speed implies a reduction in the residence time, thus not enough time for the pulp to dewater, especially in the first section of the press. Comparing the three pulps, the rotational speed effect is more pronounced for BCTMP and TMP compared to KRAFT. This can be explained by the fact of the fibres size, the KRAFT fibres are almost twice longer than those of TMP and BCTMP, thus, the filtration process is faster and even when increasing the rotational speed, the filtration stage is less affected.

The other difference is for BCTMP, the outlet consistency increases more when increasing the freeness, by knowing that both KRAFT and TMP fibres are softwood and BCTMP fibres are hardwood, we can expect this difference is due to the fibres inner properties. The fiber length, the quantity of fines and the flexibility of the long fibers are to be considered.

- The filtrate flow rate increases with increasing the screw press and the feed pressure. This flow increase was observed to happen at the same rate for the three pulps and it can be explain by the fact, when increasing the rotational speed and the pressure, the pulp moves faster, giving a dilute suspension behind the screw flights, allowing the pulp to drain faster in the first section of the press. The drainage is more important when operating with higher freeness, so in this case the inlet flow increases when increasing the freeness, this was observed for KRAFT and TMP, for BCTMP we do not notice any variation. As mentioned before, KRAFT and TMP are softwood, and TMP is a hardwood, this can explain the difference observed when varying the freeness. On the other hand, when increasing the consistency, the pulp is more compact, and the fibres form a network that slows the drainage, thus giving a lower filtrate flow rate.
- The filtrate consistency increases with increasing the rotational speed, since when increasing the rotational speed, the perforated barrel is rapidly cleared off by the screw moving flights, allowing the fines and some fibres to slip from the screw press. The filtrate consistency is influenced by the feed consistency as well, increasing the feed consistency will give a more compact suspension rapidly, thus blocking the fines and fibres from sliding out of the press. The KRAFT and TMP response to the parameters variation is similar, whereas, the BCTMP is more sensible to the parameters variations, the slop is more important.
- It is obvious when increasing the rotational speed, we increase the inlet flow. On the other hand, when feeding the screw press with a more concentrated suspension, the inlet flow is lower for a same production rate, increasing the consistency will increase the shears in the screw press, thus implying a lower screw linear advance and lower inlet flow rate. These observations are the same for the three pulps studied, the only exception is the freeness, where it has no effect for the BCTMP.
- The screw press production increases with increasing the rotational speed, the pressure, the freeness and the feed consistency. The behavior is identic for the three pulps studied.
- The pressure does not change much in the screw press, only near to the discharge end where we have a noticeable increase. The rotational speed is the most significant factor, increasing the rotational speed implies a less important pressure near to the discharge end. Increasing the rotational speed pushes the pulp faster to the discharge end, thus the pulp drains by filtration and we do not have enough time for pressure build up. The three pulps react the same way to each variation.
- The screw press torque decreases when operating with high rotational speed because the shear is lower. The degree of variation is the same for the all the pulps studied.

4. Conclusions

- The rotational speed is the main factor that has the biggest influence in the screw press.
- The pulp behavior is very similar in the screw press for the three studied pulps. There is only a slight difference when changing the pulp type (softwood or hardwood) or fines or short fibers content.
- JMP analysis shows that the screw press outlets can be predicted with a very good approximation for each pulp.

Dewatering of Cellulose Nanofibrils (CNF) Suspensions using Centrifugation

Jennifer Astorsdotter[1], Eva Ålander[1], Maria Sedin[1]

1 RISE Bioeconomy, Stockholm, Sweden; 2 Affiliation and address

**Corresponding author: maria-sedin@ri.se*

Highlights

- It is possible to dewater CNF using centrifugation with industrial relevant *g*-forces.
- Addition of NaCl or decreased pH improves the dewatering of carboxymethylated CNF.
- Final concentrations achieved was 5.3 w% for enzymatic CNF.
- Final concentrations achieved was 4.4 w% for carboxymethylated CNF using NaCl.

1. Introduction

Dewatering and thickening of cellulose nanofibrils (CNF) suspensions are challenging. Traditional filtration-based dewatering processes are very time-consuming. Once the solids of the suspension start forming a network, the permeability is very low due to small size-scale of the particles and the compressibility of the fibre network. In centrifugation the dewatering flow counteracts the compression of the network, thus maintaining a higher permeability during the thickening process. Therefore, centrifugation may be a viable alternative separation method.

2. Methods

Two qualities of CNF were produced by passing either enzymatic pre-treated (CNF1) or carboxymethylation pre-treated (CNF2) pulps through a high-pressure homogeniser yielding CNFs at 2 w% with different size distributions and charge densities [1, 2]. An analytical centrifuge [3] was used to study the dewatering behaviour. The height of the supernatant was determined during centrifugation from *in-situ* light transmittance measurements at 25°C and the average sediment concentration was calculated. The influence of *g*-force, initial concentration, pH and ionic strength were investigated.

3. Results and discussion

The average concentration of the sediment at 2320*g* is shown Fig. 1 for CNF1 and CNF2. In the figure it can be seen that for CNF1 a final concentration greater than 5 w% could be achieved whereas the final concentration for CNF2 could not be increased if the initial concentration was greater than approximately 0.5 w%. This is due to the highly charged particles, 600 μeq./g, attained with carboxymethylation. For comparison CNF1 has a total charge of approximately 60 μeq./g. The time required to reach the final concentration is given in Fig. 1. For CNF1 the time was about 30–60 s but CNF2 required at least 2 min or more if the separation was possible.

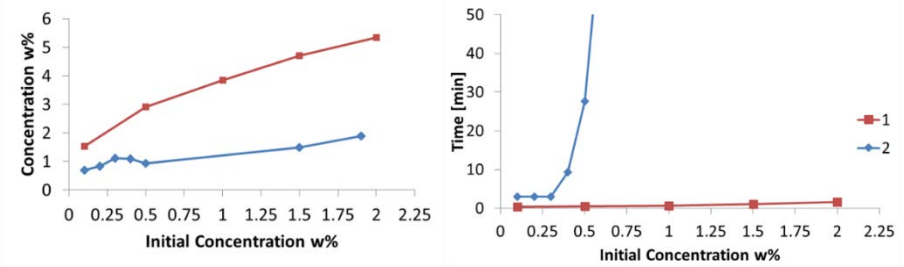

Figure 1. Effect of initial concentration on final concentration and separation time at 2320*g* for CNF1 and CNF2.

To improve the separation of CNF2, the pH and ionic strength of the suspension were changed. In Fig. 2 the effect of decreasing the pH is shown for 1.5 w% CNF1 and CNF2 suspensions. pH has a negligible effect for CNF1 on final concentration and separation time. On the other hand, the pH affects CNF2 significantly if the pH is less than 5; the final concentration is almost 4 w% and the separation time is comparable to CNF1 or even less. This is due to the protonation of the carboxyl group introduced in CNF2; pK_a approximately 4. Decreasing the pH will therefore reduce the electrostatic repulsion between CNF2 particles and improve the separation. The effect of adding NaCl to the suspension showed the effect of shielding the charges on the particles. At 0.1 and 0.5 M NaCl the final concentration at 2320*g* was 3.7 and 4.4 w%, respectively, for CNF2 whereas NaCl had a negative effect on CNF1. The effect of pH and NaCl on CNF2 was also visible in the light transmittance measurement: a zone with a concentration gradient was observed for CNF2 but not for CNF2 with NaCl added or pH adjusted.

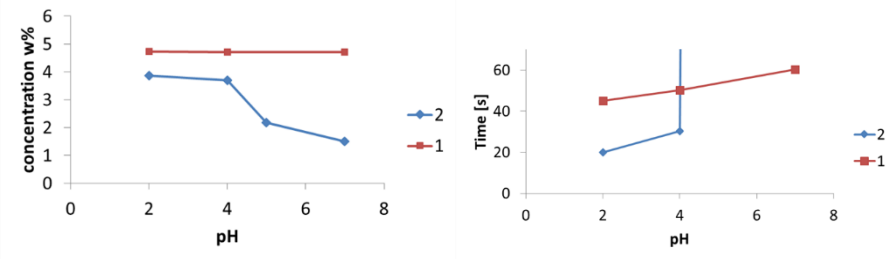

Figure 2. Effect of pH on final concentration and separation time at 2320*g* for CNF1 and CNF2 with initial concentration of 1.5 w%.

4. Conclusions

With centrifugation it is possible to increase the concentration of CNF1 (enzymatic) to more than 5 w% with a separation time of less than 60 s at 2302*g*. At an initial concentration above 0.5 w%, it is not possible to dewater the carboxymethylated CNF2, but with addition of electrolyte (shielding of charges) or decreasing the pH (protonation) 4 w% and a comparable separation time as CNF1 is reached.

Highlights

- Uranium(VI) extraction from nitric acid by TBP 30% with contact time lower than 50 ms.
- Estimation of the chemical mass transfer constant using the microfluidic device: over 4.2 10^{-4} $m.s^{-1}$.
- Difference between the results and a 2D COMSOL model: presence of an acceleration factor?

1. Introduction

Kinetic constants in reactive liquid-liquid extraction processes are generally determined using constant interfacial area methods such as the single drop method the Nitsch cell or the Lewis cell. These techniques only allow reaching the overall kinetics of the process that is the result of two basic phenomena: the intrinsic reaction and the overall mass transfer of the components that participate to the reaction. The determination of the intrinsic kinetics of the reaction is necessary for the design and extraction process modelling. Mass transfer limitation is quite hard to be restrained in a device to determine intrinsic chemical kinetics since molecular diffusion contributes in majority to the overall mass transfer resistance. Hence, the field of microfluidic devices appears as an interesting way to study such kinetics by reducing the molecular diffusion. In this context, our study considers the well-known solvent TBP 30% in TPH used to reprocess nuclear spent fuels as a reference solvent to study mass transfer kinetics [1-4].

2. Methods

The extraction of uranium(VI) in nitric acid by tributylphosphate (TBP) diluted at 30% in TPH (hydrogenated tetrapropylene) was carried out using a Y-Y microfluidic chip with a 1.25 cm straight microchannel (dolomite). Two stratified flows in co-flowing configuration were generated with high fluid velocities to aim chemical kinetics constant determination, thanks to both diffusive length reduction and fine flow control in the microfluidic technology. Liquid-liquid stratified flow configuration with a centered interface avoids any tangential convective movements. Therefore, the hydrodynamics in the device is perfectly controlled and predictable using CFD codes, as for the mass transfer phenomenon. The experimental hypothesis of a centered interface along the microchannel depth was validated thanks to confocal experiments.

3. Results and discussion

First, the influence of inlet uranium concentration and total fluid velocity on the extraction yield has been studied as shown in Figure 1. The observed extraction yields are quite good considering the short contact time inside the microchip (lower than 0.05 s).

Then the results have been exploited to determine if diffusion still occurs in such conditions thus allowing the estimation of the chemical mass transfer constant (k_e), which is expected to be over 4.2 10^{-4} m.s^{-1} for a 0.12 M U(VI) aqueous solution. The results hardly fit with a preliminary 2D COMSOL model even by increasing the supposed k_e twice and the U(VI) molecular diffusion coefficient (DU) by a decade. Another solution to fit the experimental results consists on taking into account an acceleration factor, provided whether from a Hatta acceleration or from Marangoni instabilities.

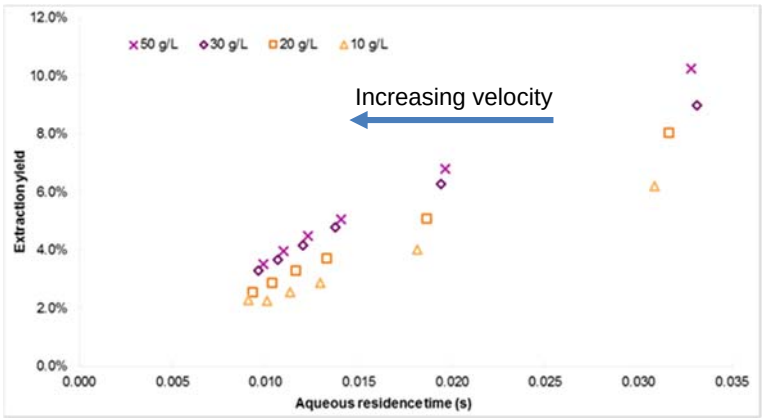

Figure 1. Comparison between the extraction rates of uranium(VI) in HNO_3 3M extracted by TBP 30% in TPH.

4. Conclusions

Attempts to determine the chemical kinetics constant of uranium(VI) from nitric acid by TBP 30% in TPH were carried out by means of microfluidics device at high flow velocities in order to limit the impact of diffusion phenomena on the global mass transfer. The intrinsic chemical kinetic constant was performed thanks to COMSOL modelling. When only chemical phenomenon is taken into account, all the numerical results are below the experimental data in the process modelling. Hence, both reaction and molecular diffusion have to be taken into account in the modelling of the microfluidic experiment through the presence of an acceleration phenomenon enhancing the overall kinetic constant.

Highlights

- Desalination technology is associated with various technological challenges
- Hydrogel composite is used for removal of seawater hardness.
- The characteristics of the composite and performance via adsorption of Ca^{++} and Mg^{++} have been determined.
- The electro-regeneration has been also explored.

1. Introduction

Seawater desalination is becoming a crucial intervention for mitigating water shortage in numerous Middle East countries. Desalination technology is associated with various technological challenges that should be resolved to maintain plant sustainability and performance. For instance, seawater hardness is recognized as a challenge for recent large scale desalination plants. Optional technologies including chemical treatment, adsorption and membrane filtration have been developed for hardness removal and recovery of Ca^{++} and Mg^{++}.

2. Methods

This paper addresses the development and application of a new conductive polymeric hydrogel composite exhibiting electrically tunable characteristics. The developed hydrogel composite comprises especially treated zeolite, polyacrylate, polyaniline, hydrolyzed polyacrylamide and special processing aids. The characteristics of the composite have been determined via scanning electron microscopy, Fourier transform infrared spectroscopy and electric conductivity measurements in addition to swelling ratio. Impact of composition and processing conditions on conventional and electrochemically enhanced adsorption experiments have been presented and analyzed. The electro-regeneration has been also explored.

3. Results and discussion

The promising features of this novel hydrogel composite are elucidated by the removal and recovery of hardness causing elements in simulated seawater and brines.

4. Conclusions

It is concluded that the developed hydrogel is initially qualified for upstream seawater softening. Additional endeavors are still needed for downstream brine management to overcome apparent osmotic effects.

Highlights

- PDMS was chosen as representative membrane for VOC removal from polluted air
- Permeability of representative VOCs were studied in PDMS membrane
- Linear alkane (hexane) was found to be the most permeable in PDMS membrane
- Membrane flux was studied at various experimental conditions

1. Introduction

Gas separation technology is a mature topic, while the vapor permeation (VP) process still needs some development. It can be presumed that VP will become extensively applied in the future, thanks to its economic and ecological advantages. VP can be successfully applied for example for removal of volatile organic compounds (VOCs) from polluted air (Figure 1) [1].

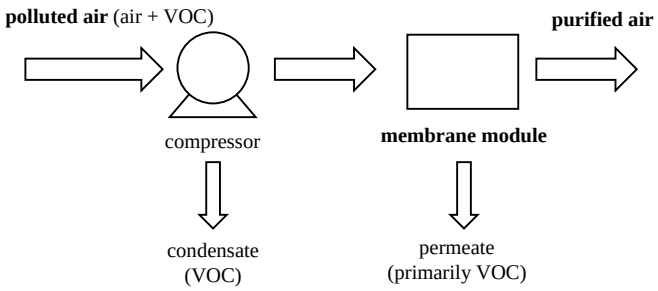

Figure 1. Scheme of VOC separation from polluted air.

2. Permeation experiments

Dense polydimethylsiloxane (Elastosil PDMS, Silicones and more) membrane was prepared by casting-knife method. The membrane thickness was 100 microns. The feed stream contained either pure nitrogen or nitrogen saturated by representative VOC (hexane, isooctane, and ethanol). Permeation experiments were carried out at temperature (25–35) °C and at feed pressure (100–250) kPa while the permeate pressure was always kept at 50 kPa. The basic test apparatus was described previously in a detail [2].

3. Results and discussion

The influence of long-term exposure of representative VOCs was studied at various experimental conditions. The membrane flux was studied for representative VOC to simulate purification of

polluted air by organic vapors (Figure 2A). The highest flux showed the representative linear hydrocarbon (hexane) while the branched hydrocarbon (isooctane) showed significantly lower flux that was less depended on VOC feed concentration. The lowest membrane flux was observed for chosen alcohol (ethanol). The flux of isooctane and ethanol depended similarly on VOCs feed concentration.

The membrane flux always increased with the VOC feed concentration as expected for PDMS membrane. The influence of temperature and trans-membrane pressure was studied for all representative VOCs (see temperature influence for the most permeable hexane in Figure 2B).

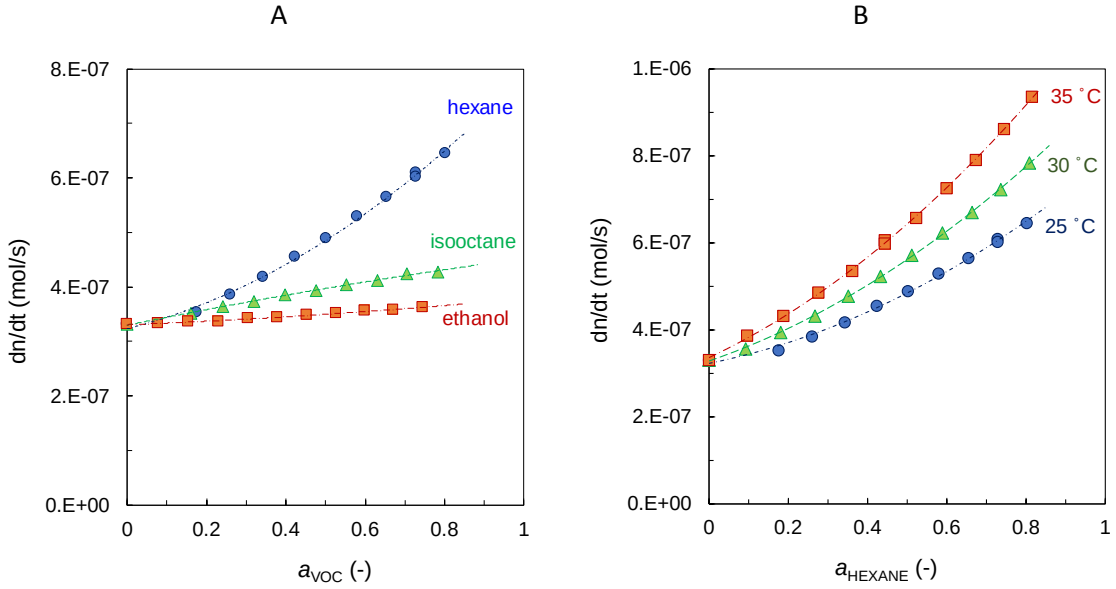

Figure 2. A) Comparison of molar flux of VOC + nitrogen in PDMS membrane as the function of VOC feed concentration at 25 °C and trans-membrane pressure of 150/50 kPa (ethanol – squares, isooctane – triangles, hexane – circles), B) Influence of temperature on hexane + nitrogen flux in PDMS membrane at the trans-membrane pressure of 150/50 kPa (25 °C – circles, 30 °C – triangles, 35 °C – squares).

4. Conclusions

It was found that prepared PDMS membrane is suitable for long-term separation of various volatile organic compounds from polluted air. The influence of input parameters (such as VOC feed concentration, temperature and pressure) has been discussed. Interestingly, the membrane increased with VOC feed concentration while the decrease was observed for a thicker PDMS film.

Highlights

- The retentions of VFAs increase with solution pH
- Separation factor between Ac and Bu increase with pressure and decrease with total concentration
- The best Separation is achieved at pH 8, 20 bar and total concentration of 0.1 M

1. Introduction

Volatile fatty acids (VFAs) are promising chemical building blocks that can be obtained by fermentation of biomass in the biorefinery concept. The present project aims to use Municipal solid waste (MSW), as raw material to produce VFAs. Previous investigations pointed out that the purification of VFAs is still a major challenge since the characteristics of the produced VFAs are similar and the fermentation broth contains many other components [1].

Nanofiltration (NF) is a pressure-driven membrane process, considered as environmentally friendly, that was already successfully used in the separation of many organic solutes like lactate and glucose [2]. Only a few reports concerning VFAs separation have been published [3], showing the necessity to improve the selectivity. The objective of this work is then to investigate the feasibility of NF for the selective recovery of VFAs from a waste-derived fermentation broth.

2. Methods

An experimental study is carried out using a dead-end stirred cell with a Filmtec (Dow) NF-45 membrane. The retention of the solutes is measured and the separation factor is calculated in order to characterize the separation efficiency. Synthetic solutions with various total concentration (from 0.1 mol to 0.5 mol) and pH (from 3 to 8) as well as a real fermentation broth are investigated.

3. Results and discussion

The results show that the individual retention of VFAs follows their molecular weight (acetate < propionate < butyrate) for all the conditions investigated (concentration and pH). The lowest VFAs retention is observed at pH 3 whereas the highest retention is obtained at pH 8, with an intermediate retention at pH 5.6 (*Fig. 1*). This phenomenon is due to the charge effects since the VFAs charge (due to the dissociation) as well as the fixed charges on the membrane surface increase with the pH. Thus, the increase of the electrostatic repulsion between the solutes and the membrane with the pH leads to the decrease of the VFAs transfer through the membrane, i.e. to the increase of their retention.

Separation factor is defined as the ratio of two solutes in the feed divided by their ratio in the permeate. At pH 8, the separation factor between Ac and Bu increase with transmembrane pressure and decrease with the total concentration of the solution (*Fig. 2*). The same trends are observed for the other pH investigated. It is also observed that a higher separation factor is achieved at higher retention.

The separation factor slowly increases as the pH increase from 3 to 5.6. However, a sharp increase is observed from a higher pH *(Fig. 3*). The highest separation factor between Ac/Bu is 2.2, and it is obtained at a total concentration of 0.1 mol, a transmembrane pressure of 20 bar and a pH of 8.

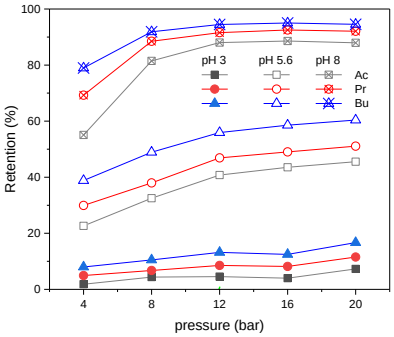

Figure 1 Individual VFAs retention versus transmembrane pressure in ternary solutions (Ac:Pr:Bu=33%:33%:33%, total concentration of 0.1 mol) at different pH

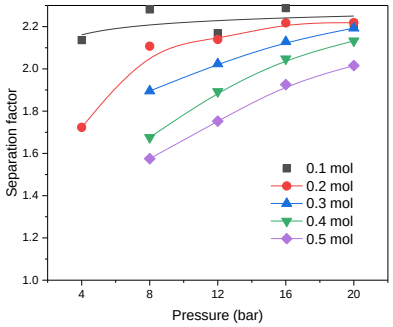

Figure 2 Separation factor of Ac/Bu versus transmembrane pressure for ternary solutions (Ac:Pr:Bu=33%:33%:33%, pH 8) at different total concentration

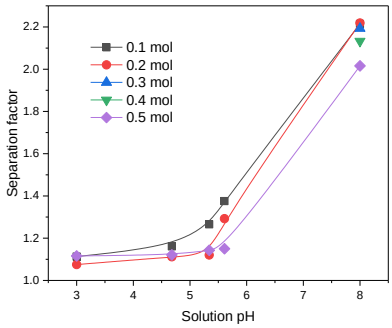

Figure 3 Separation factor of Ac/Bu in ternary solutions (Ac:Pr:Bu=33%:33%:33%) at different pH and total concentration

4. Conclusions

It is proved that NF could be used for the recovery of VFAs from a waste-derived fermentation broth. The selectivity of the recovered fractions strongly depends on the pH and total concentration of the fermentation broth, but further investigation is required to improve the efficiency of the separation.

Highlights

- Adsorption Isotherms of an organic acid for various pH-values.
- Presentation of an easy way to improve adsorption capacities.
- Influence of co-ions on the adsorption process.

1. Introduction

Capacitive Deionization (CDI) is an easy to use method, which is suitable for the separation of ions or charged molecules in solutions. The advantages of this method are that it is already established for desalination and therefore available at low cost. Furthermore, it offers the opportunity to concentrate a charged species in a solution without additives [1]. Therefore, CDI can also be an interesting alternative for the purification and concentration of larger molecules like organic acids, which gained importance e.g. due to their use for the production of biopolymers [2]. Here we present a method to determine an appropriate pH-value and concentration for electrosorption purposes, by investigating the potential free adsorption properties of the carbon material. Furthermore, the influences of co-ions on the adsorption process are described. Afterwards the predicted optimum for the electrosorption of weak organic acids was checked by further experiments.

2. Methods

An organic acid solution with a specific pH-value was pumped through the CDI system without the application of an external electrical potential until an equilibrium between the molecules in the solution and the adsorbed molecules was reached. The moment when the conductivity stopped to change was taken as the state of equilibrium. After a sample was taken an equal amount of a high concentrated stock solution was added to increase the concentration and the process was repeated. Based on the results of the adsorption of the organic acids on the carbon surfaces due to potential free adsorption the best operation conditions for the electrosorption could be derived. For electrosorption experiments a potentiostat was attached to the CDI unit and different experimental series applying constant current or constant voltage mode were conducted.

3. Results and discussion

The adsorption isotherms of an organic acid onto an activated carbon based CDI electrode are plotted in Fig. 1. It shows that the isotherms mainly split into two groups with isotherms representing high capacities at pH-values ≤ 5.5 and isotherms representing small capacities at pH-

values ≥ 6.5. The fast variation of the potential free adsorption capacity in-between these pH-values directly correlates with the second dissociation constant of this organic acid. In the presentation the strong effect of this potential free adsorption onto the achievable electrosorption will be theoretically discussed and experimentally validated.

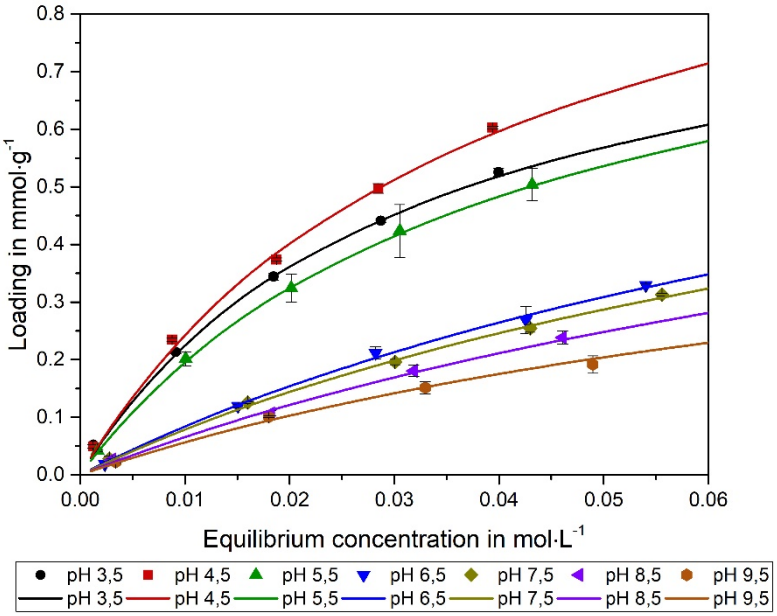

Figure 1. Adsorption isotherms of an organic acid for different pH-values and concentrations, fitted following the approach of Langmuir.

In addition to the pH also the concentration and type of strong electrolytes present, e.g. sodium chloride, show a clear effect onto the potential free and potential driven adsorption of weak organic acids. A generalized, thermodynamics based model will be presented which simulates these effects.

4. Conclusions

The electrosorption of weak electrolytes onto carbon materials shows a strong dependence onto the adjusted pH and the presence of other ions. In order to explain these effects, the dissociation behavior as well as potential free adsorption effects must be taken into account, resulting quickly in a relatively complex network of adsorption and chemical equilibria in combination with electrostatic effects. Detailed investigation of potential free adsorption data and literature based chemical equilibrium constants built the basis to understand this network and predict optimum operation windows for electrosorption processes.

Highlights

- Membrane assisted crystallization (MCr) was utilized for brine exploitation.
- New membranes were tested in MCr process.
- MCr performance was analyzed in terms of resistance to wettability and crystals properties.

1. Introduction

Membrane assisted crystallization (MCr) is an innovative process which combines crystallization process with membrane technology. This operation uses hydrophobic microporous membranes for promoting solvent evaporation from a feed solution thus concentrating it above its saturation limit and attaining a supersaturated environment where crystals may nucleate and grow. In a membrane crystallizer the membrane matrix acts as a selective gate for solvent evaporation, modulating the final degree and the rate for the generation of the supersaturation. Hence, acting on the transmembrane flux, either by changing the driving force of the process or by choosing membrane with proper characteristics, allows controlling the crystallization process very precisely.

2. Methods

The description of the lab scale apparatus utilized for performing the tests can be found elsewhere [1]. In all the tests, solution was charged in the crystallizer and recirculated through the membrane modules. The membrane-crystallization unit aims to induce supersaturation in solution by removing solvent in the vapour phase. The solvent evaporates at the interface of microporous hydrophobic membranes on the warm (retentate) side, diffuses through the pores and condenses on the opposite (distillate) side. In Table 1 the list of the utilized membranes can be found.

Table 1. Membrane utilized in MCr tests.

Membrane material and configuration	Type
Flat sheet Hyflon/PVDF composite membrane	AD40H_010, AD40H_022, AD40H_045
Hollow fiber ceramic membranes	CM-L, CM-S
Hybrid Bi2Se3/PVDF flat sheet composite membrane	Bi2Se3/PVDF

PVDF flat sheet membrane	PVDF

3. Results and discussion

All the tested membranes showed stable performance, without any wetting, during crystallization. Visual observation of the obtained NaCl crystals showed cubic shape whereas the analysis of their crystal size distribution proved their low dispersion (i.e., CV). Moreover, a secondary nucleation was observed which occurred simultaneously with crystal growth due to the contact of the growing crystals with the different parts of the plant. This effect was more evident for the membranes with the highest trans-membrane flux due to the highest rate in achieving supersaturation degree, supersaturation rate, nucleation and secondary nucleation. Furthermore, the inclusion of Bi2Se3 fillers in PVDF membranes, assisted the crystal-growth for NaCl, leading to a faster crystal growth and a higher uniformity of the crystal size.

4. Conclusions

All the analyzed membranes proved their suitability for MCr process whose performance can be controlled acting on the chemical–physical properties of the membranes and process parameters (temperature, concentration, flowrate, etc.). These aspects would be of undoubted benefit because allow modulating the final properties of the crystals produced both in terms of structure (polymorphism) and morphology (habit, shape, size, and size distribution).

Highlights

- Steam induces additional mass transfer limitation in the alumina porous support
- Hydrogen permeation is strongly influenced by steam in the permeate side
- High temperatures reduce the mass transfer resistance induced by steam

1. Introduction

In recent years palladium membranes received increasing interest due to their extremely high selectivity and permeability and for the possibility to integrate into membrane reactors for hydrogen purification and production. There are two possible ways to increase the permeation of hydrogen at fixed feed pressure: decreasing the thickness of the membrane to increase the permeance, at the expenses of the selectivities, or to raise the driving force of the process via either a vacuum or a sweep gas in the permeate side of the membrane. Steam is generally suggested as sweep gas as it can afterward be easily separated by condensation. The effect of steam on the permeate side of a membrane is however not fully understood and it is the topic of this work.

2. Methods

An ultra-thin Pd-Ag membrane was deposited on asymmetric porous α-alumina tubes (100 nm pore size, from Rauschert) using simultaneous electroless plating (ELP) technique [1]. Thicknesses were defined by controlling the time of plating process. The membranes have been sealed and placed in the setup for its permeation characterization. The gases have been fed in the membrane module through mass flow controllers that can work until 10 l/min. The permeate side of the membrane has been analysed with flow meters in order to determine the gas permeances (H_2, CH_4, H_2O, N_2) and with gas chromatographer for measuring the H_2 purity in the permeate side. After a pure gas test to calculate the permeance and the selectivity of the membrane, a mixture of 10% H_2-90% CH_4 was fed in the retentate side while in the permeate side, counter-current sweep gas was applied. A validated model for the description of the membrane, which includes concentration polarization in the retentate, permeate and mass transfer limitation in the porous support was used for comparing and understanding the experimental results [2]. N_2 and H_2O was applied in the permeate side changing the sweep gas flow rate and the steam concentration from 0 to 93.5%.

The working temperature was changed from 350 °C to 500 °C and the retentate pressure between 1 and 5 bar.

3. Results and discussion

As depicted in Figure 1, the negative influence of steam as sweep gas is deduced because of the decreasing hydrogen permeation obtained when steam flow rate is increased. An additional effect apart from the concentration polarization and the mass transfer limitation in the porous support is clearly present in case of steam. Indeed, as shown in Figure 2, the model (that included a dusty gas model for the permeate side) could predict the behavior of the membrane in case of nitrogen as sweep gas but overestimates the hydrogen permeation in the presence of steam as sweep gas. The possible explanation could be found in the adsorption capacity of alumina which it could be relevant even at 400 °C. The XRD of the alumina support sample, moreover shows Si traces, which could represent an additional reason for the adsorption capacity of the support. Therefore, the temperature plays an important role because the lower the temperature, the more remarkable the negative steam effect. At 500 °C the steam adsorption on the alumina support seems to be negligible and indeed the model then predicts well the experimental results.

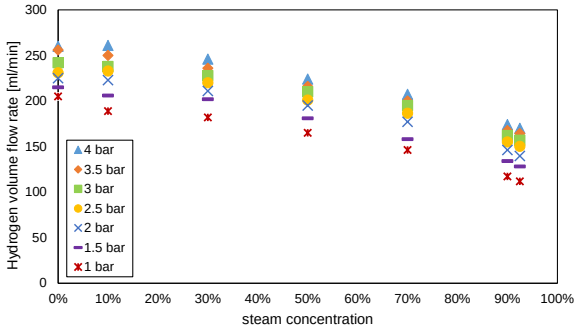

Figure 1. Hydrogen permeation trend with steam concentration

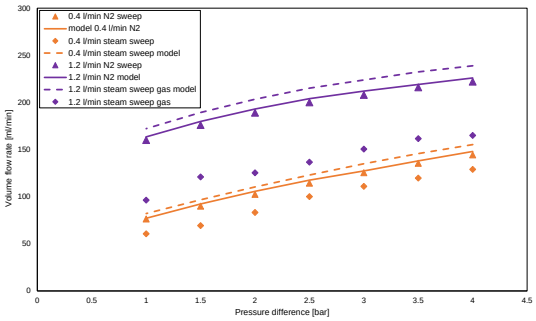

Figure 2. Comparison between experimental and model results in presence of N_2 and H_2O as sweep

4. Conclusions

The driving force of a Pd membrane when feeding steam as sweep gas is decreased between 350-450 °C because of steam adsorption on the support. Indeed the temperature plays an important role on the decreased hydrogen permeation in presence of steam. No influence of the steam on the retentate side was found in the experimental results.

Highlights

- Poly(ionic liquid)s containing anions based on fluorosulfonyl derivatives were synthesized.
- PIL–IL composite membranes were prepared by solvent casting.
- Pure PILs and ILs and their composites were characterized by different techniques.
- The CO_2/H_2 separation through the studied PIL–IL membranes was evaluated.

1. Introduction

Despite the recognized potential of biohydrogen ($bioH_2$) for sustainable development, there are still issues regarding its production and purification, such as the elimination of CO_2, N_2, and other impurities (H_2O and H_2S), so that an enriched H_2 stream can be obtained for efficient energy generation [1].

Ionic liquids (ILs) have been used as a successful platform to design novel task-specific materials for CO_2 separation [2]. In an effort to improve the CO_2 permeability and permselectivity properties of supported ionic liquid membranes (SILMs), we recently reported the CO_2/N_2 separation performance of different ILs based on the $[C_2mim]^+$ cation and different fluorinated-based anions, such as $[TFSAM]^-$ or $[C_4F_9SO_3]^-$. The results showed that both $[C_2mim][TFSAM]$ and $[C_2mim][FSI]$-based SILMs present remarkable CO_2 permeabilities and CO_2/N_2 permselectivities [3]. However, and considering that the long-term stability and industrial operation of SILMs are still compromised due to the risk of IL draining from the membrane pores, different studies have been unveiling that the use of poly(ionic liquid)s (PILs) and their composites (PIL–IL) is a powerful strategy to design improved CO_2 separation membranes [2].

In this work, PIL–IL membranes composed of pyrrolidinium-based PILs with $[TFSAM]^-$, $[FSI]^-$ and $[TSAC]^-$ anions were prepared by the incorporation of ILs containing the same anions. The composite membranes as well as both PIL and IL components were characterized by different techniques (TGA, DSC, FT-IR and RAMAN) and their CO_2/H_2 separation performance was evaluated using the time-lag method at biohydrogen production conditions.

2. Methods

The free-standing PIL–IL membranes were prepared by solvent casting. The 6 (w/v)% solutions were

mixed until complete dissolution of the PIL and IL components and then poured into Petri dishes for slow evaporation of the solvent. The gas permeation properties were evaluated using the time-lag method at *T*=35°C and P_{feed} of 1 bar.

3. Results and discussion

From the thermogravimetric analysis results, and depending of the PIL used, different trends were observed for degradation temperatures of the PIL–IL composites with the addition of free IL, which led to the conclusion that the thermal stability of the studied PIL–IL membranes not always follows a simple mixing rule.

From CO_2 and H_2 permeation results, and taking into account that it was not possible to prepare PIL–IL composites with more than 40 wt% of free IL incorporated, both PIL TFSAM – 40 IL TFSAM and PIL FSI – 40 IL FSI membranes presented higher CO_2/H_2 selectivities (Figure 1) compared to the already reported PIL–IL membranes containing the conventional $[NTf_2]^-$ anion with 60 wt% of free IL.

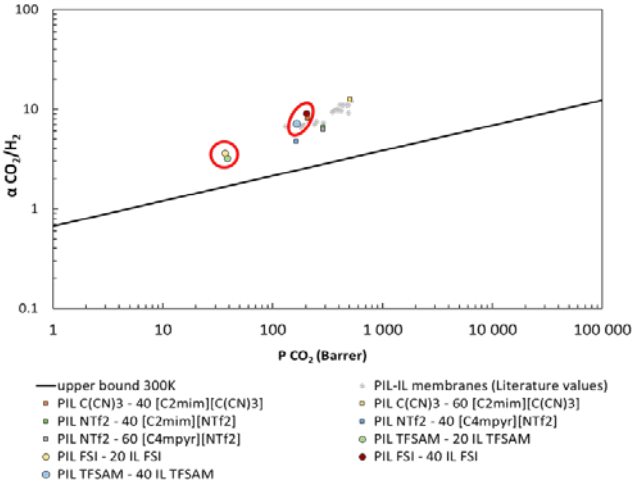

Figure 1. CO_2/H_2 separation performance of the PIL–IL membranes studied.

4. Conclusions

PILs and ILs containing anions based on fluorosulfonyl derivatives were synthesized and characterized. PIL–IL membranes were prepared to evaluate their CO_2/H_2 separation performance. In sum, higher CO_2/H_2 selectivities were obtained for both PIL FSI– 40 [C_2mim][FSI] (α = 9.0) and PIL TFSAM– 40 [C_2mim][TFSAM] (α = 7.1) compared to those of composites containing the conventional $[NTf_2]^-$ anion (PIL NTf_2 – 40 [C_2mim][NTf_2] (α = 6.5) and PIL NTf_2 – 60 [Pyr_{14}][NTf_2] (α = 6.3).

Adsorption of sulfur and nitrogen compounds present in commercial diesel.

Marco Figueiredo*, Luana Baia, Wallace Souza, Cláudia Veloso and André Costa.

State University of Rio de Janeiro, Rio de Janeiro, Maracanã, BRASIL.
* Corresponding author: mgaya@uerj.br

Highlights

- Higher removal of sulfur compounds by silica in isothermal and kinetic tests.
- Clay showed higher affinity for nitrogen compounds.
- The adsorption capacity of nitrogenous compounds was greater than that of sulphides

1. **Introduction**

In order to mitigate the damages caused by man's action on the environment, more restrictive legislation has been created, one of which is to reduce the sulfur content in fuels, in order to reduce the emission of SOx to the environment. This is responsible for the formation of acid rain, besides being directly harmful to human health, particularly in relation to the respiratory tract [1 and 3]. At the beginning of this century, regulations in different countries reduced the sulfur content to 15 mg kg-1 (USA, EU and Japan) [1] and 10 mg kg-1 (Brazil) [2]. The process used to remove sulfur compounds is hydrotreatment which is highly severe in energy and hydrogen consumption. Alternative processes with lower cost are being studied in order to remove this contaminant, being the adsorption one of these processes. In the present work, the adsorption of nitrogenous and sulfur compounds present in diesel samples was evaluated in three commercial adsorbents: silica, clay and coal. Kinetic curves and adsorption isotherms were obtained. In the modeling of the kinetic curves was used mass transfer model and isotherm data were adjusted by the Langmuir-Freundlich Model.

2. **Methods**

The adsorbents were characterized as texture properties, thermogravimetric data, chemical composition and acidity. The kinetic and isothermal tests were performed in a Dubnoff bath, where in the kinetic tests the ratio of diesel volume / adsorbent mass used was 2: 1 (mL / g), at 40 ° C, shaking of 2.5Hz and range of between 30 and 360 minutes. The isotherm tests were performed by varying the diesel / mass ratio of adsorbent between 1.25: 1 and 100: 1 (mL / g), time of 420 minutes and using the same agitation and temperature of the kinetic tests.

3. Results and discussion

The silica sample was the one that removed the largest quantity of sulfur compounds among the studied adsorbents, while the clay was the second adsorbent with the highest removal of this contaminant. In the equilibrium range studied between 1.25: 1 and 10: 1 mL of diesel: g adsorbent, the amount of sulfur compounds removed by silica ranged from 3.03 to 7.74 mmol of sulfur / kg adsorbent for the range studied.

The following sequence for the adsorption capacity of the nitrogen compounds was obtained: clay> silica> coal for the entire concentration range in the studied fluid phase. The ratio of volume (mL) of diesel per mass (g) of adsorbent ranged from 1.25: 1 to 100: 1 and an adsorption capacity of 1.48 to 34.43 mmol of nitrogen / kg of adsorbent was obtained. In order to adjust the adsorption isotherms, the Langmuir-Freundlich model was the most suitable for the treatment of the equilibrium data.

The experimental data for the nitrogen compounds presented a satisfactory fit, while for the sulfur compounds some points showed a greater dispersion. It is observed a greater removal of nitrogen compounds by the clay, while the silica presents a greater removal of the sulphur compounds, as already observed in the adsorption isotherm tests using the same charge and adsorbent. It is also noted that both nitrogen and sulfur compounds reach equilibrium faster in silica than in clay, which may be associated with the higher pore volume of this material.

The results show that the diffusive resistance is higher for sulfur compounds (lower diffusion coefficient) in relation to nitrogen ones, and silica presented the lowest diffusive resistance, in the removal of both contaminants in relation to the clay. This lower resistance to silica adsorption may be due to the fact that this material has the highest pores volume.

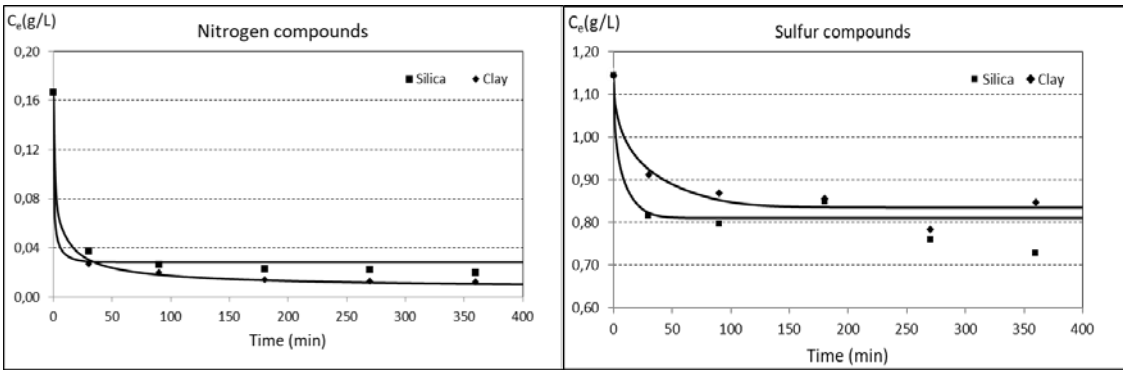

Figure 1. Kinetic curve of adsorption of nitrogen and sulfur compounds.

4. Conclusions

The results showed a higher affinity of the adsorbents for the nitrogen compounds in relation to the sulfur compounds. In equilibrium isotherm tests with diesel, silica and clay removed the largest amount of sulfur and nitrogen compounds, respectively. The effective diffusivity values estimated in the kinetic curves indicated a lower resistance of the sulfur and nitrogen compounds to the diffusion in the presence of silica.

Overcoming the Influence of HMF Reaction Mixture Constituents on Extraction Solvent Performance.

André B. de Haan[1]

1 Delft University of Technology, Chemical Engineering, Van der Maas Weg 9,

2629 HZ Delft, The Netherlands

**Corresponding author: a.b.dehaan@tudelft.nl*

Highlights

- Effect of ionic liquid, deep eutectic solvent and fructose on HMF extraction by MIBK and 2-pentanol was evaluated.
- All reaction mixture constituents decreased extraction performance.
- Monovalent salts can overcome decreased solvent performance.

1. Introduction

HMF (5-hydroxymethylfurfural) is a promising bio-based platform chemical that is obtained from hexose dehydration and can be used to produce biofuels and various chemical products [1]. The hexose dehydration reaction is equilibrium limited, reversible and the HMF formed in this reaction can decompose into levulinic acid (LA) and formic acid (FA).

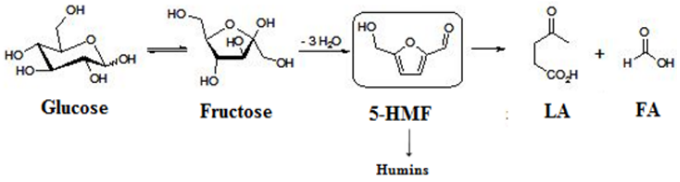

Figure 1. Reaction scheme for HMF formation.

In order to avoid HMF degradation, extensive research has been performed on biphasic systems wherein the catalytic dehydration reaction is coupled with direct extraction of the HMF into an organic solvent to increase the selectivity as well as conversion [2].

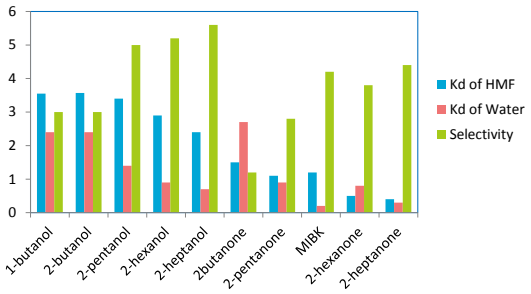

Figure 2. Comparison of various solvents for HMF extraction.

The focus of this work is a systematic study how the constituents of the reaction mixture affect the extraction performance of organic solvents. A solvent screening has shown that in addition to the

widely studied solvent methyl isobutyl ketone (MIBK), 2-pentanol is a promising alternative with comparable selectivity but significantly higher distribution coefficient. Next to water and HMF the reaction mixtures typically contain the hexose substrate (glucose, fructose), salts, catalyst (acid) and co-solvents (DMSO, ionic liquids, deep eutectic solvents) [1]. All these constituents will influence the extraction performance (distribution coefficient, selectivity) of the solvent. However, while using these complex reaction mixtures in studying the effect on conversion and selectivity of the dehydration reaction, there are to our knowledge no studies that have systematically investigated the combined effect of these constituents on the solvent performance.

2. Methods

The study has been executed by determining liquid-liquid phase equilibrium data for the ternary systems HMF, water, and solvent (MIBK or 2-pentanol) at 313.15 K (40^{o}C) and atmospheric pressure. Inorganic salts (NaCl, KCl, Na2SO4, KCl, K2SO4), [EMIM][BF4] as ionic liquid, 1:2 molar ratio mixture of choline chloride/urea as deep eutectic solvent and fructose were added to the aqueous phase. All data obtained were correlated using the NRTL model. The effects on solvent performance (HMF distribution coefficient and the selectivity) were derived from the LLE data.

3. Results and discussion

The results indicated that higher distribution coefficients are achieved in the 2-pentanol-HMF-water system compared to the MIBK-HMF-water system. On the other hand, the separation ability of MIBK is better than that of 2-pentanol. Adding up to 10 wt% inorganic salts to the system enhanced the distribution coefficient of HMF into the organic phase as well as the selectivity up to 2 times confirming the salting-out ability of the studied salts. The addition ionic liquid showed the opposite effect. At 30 wt% [EMIM][BF4] the HMF distribution coefficient as well as selectivity were reduced to 1/3 of the original value. This salting in effect is caused by the specific interactions between the HMF and ionic liquid that is known to increase the reaction selectivity by complexing with the hydroxyl groups of HMF. For the deep eutectic solvent a comparable effect as with the ionic liquid was observed. Also the introduction of fructose in the system reduced the HMF distribution coefficient and selectivity. Typically substrate concentrations up to 30 wt% are applied and at these conditions a significant decrease in solvent performance is observed. Finally it was observed that the presence of HMF and fructose in the system reduced the solubility of especially the divalent inorganic salts.

4. Conclusions

Overall monovalent salts like NaCl and KCl are the most suitable candidates to overcome the negative effects of co-solvents (ionic liquid, deep eutectic solvent) and hexose substrate on the solvent performance.

Experimental Investigation of Mass Transfer in a Miniplant Scale Rotating Packed Bed.

Matthias Hilpert[1], Jens-Uwe Repke[1]

1 Process Dynamics and Operations Group, Technische Universität Berlin, Sekr. KWT-9, Str. des 17. Juni 135, D-10623 Berlin, Germany

**Corresponding author: matthias.hilpert@tu-berlin.de*

Highlights

- RPB miniplant test stand constructed
- liquid side mass transfer coefficient evaluated from O2-stripping from water
- gas side mass transfer coefficient determined by distillation of binary alcohol mixtures

Rotating Packed Beds (RPBs) provide one approach to intensification of absorption and distillation processes by enhancing heat and mass transfer through intensified micromixing and increased effective specific surface area. Furthermore, much higher throughputs can be achieved without flooding. This leads to an up to 10-fold reduction in equipment size and thus lower space requirements and capital expenditure, as compared to conventional packed columns [1]. The RPB consists of packing material in the shape of a hollow cylinder clamped between two plates that rotate at speeds up to about 2000 min^{-1}. As illustrated in Figure 1, liquid is fed in the center near the axis of rotation and flows through the bed at multiples of normal gravity, while gas in countercurrent flows radially inward. The high centrifugal forces and thus the possibility to use high surface area packing that would flood in conventional columns lead to the aforementioned process intensification.

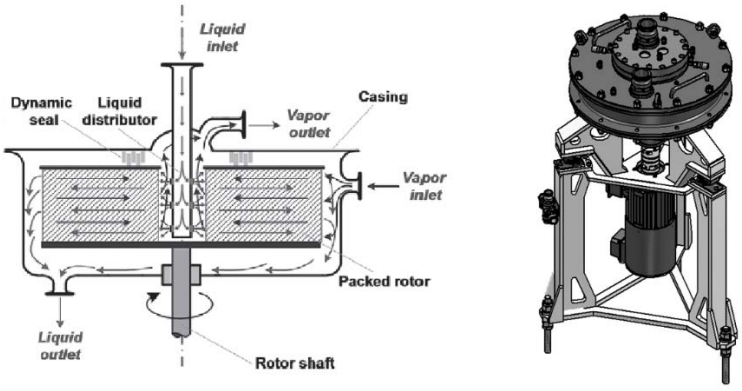

Figure 1. Flow pattern inside a single-stage horizontal RPB (left) [1], CAD-model of the constructed RPB (right).

Despite the potential of RPBs there are still few reported distillation applications in the European chemical industry which is among other factors due to the lack of validated design models for predicting RPB separation performance. While some studies regarding the distillation of binary

mixtures have been published, to the best of our knowledge no publications on multi-component mixtures exist up to now. These however are necessary to validate models of the required complexity. Furthermore, the existing studies report processed results in the form of correlations or specific NTU-values that are of limited use to the development of new correlations. Therefore, a test stand has been built at our institute to generate the required data.

The RPB test stand enables distillation, absorption and desorption experiments over a broad range of operating parameters at a semi-industrial scale. Different bed types, depths and heights, as well as different options for liquid distribution can be employed. Distillation under infinite and finite reflux conditions is possible.

To develop a validated model for multicomponent distillation in the RPB, the following systematic approach is chosen, as illustrated in Figure 2. Mass transfer inside the RPB takes place during the very short residence time of less than 1 s. Therefore, a rate-based modeling approach is adopted, requiring correlations for liquid and vapor side mass transfer coefficients. Liquid side coefficients are determined from desorption of oxygen from water into nitrogen atmosphere. Overall mass transfer coefficients are derived from distillation of binary mixtures of lower-chain alcohols at infinite reflux. Gas side mass transfer coefficients will be back-calculated and correlated using the results. To test the validity of the model, binary and ternary ideal and non-ideal mixtures will be distilled and modeled.

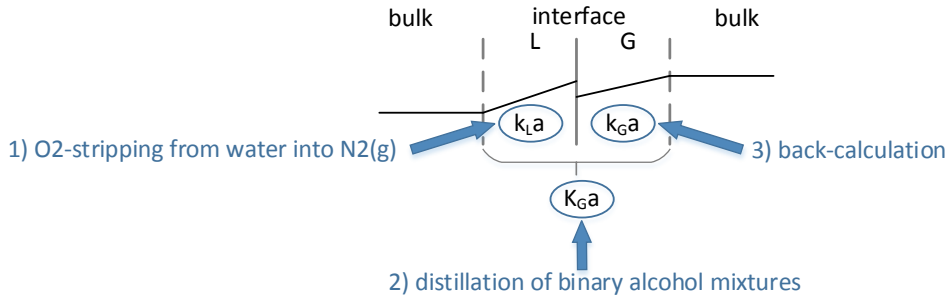

Figure 2. Schematic of approach for determination of mass transfer coefficients.

The contribution presents details of the RPB test stand and the experimental design. Results from desorption experiments and from binary distillation runs will be shown, which form the basis for the development of mass transfer coefficient correlations.

Model Performances Evaluated for Infinite Dilution Activity Coefficients Prediction At 298.15K.

Thomas Brouwer*, Boelo Schuur
University of Twente, Faculty of Science and Technology, Sustainable Process Technology group, PO Box 217, 7500AE, Enschede, The Netherlands.
Corresponding author: t.brouwer@utwente.nl

Highlights

- Eight models were evaluated for infinite dilution activity coefficient prediction.
- The most accurate model depends on each specific solute-solvent pair
- An accurate hydrogen bond description is essential for an accurate prediction
- An extended MOSCED model could be a potential approach for ionic liquids

1. Introduction

The global community relies on the chemical industry for the production of goods from complex raw materials, such as oil and biomass. The separation processes required in these production routes account for up to 50 % of the total energy costs in refineries[1] and improving the efficiency of separations can significantly reduce the environmental impact of the chemical industry. This can only be made by achieved by understanding the separation processes on molecular-level, which includes a good description of thermodynamic equilibria. An accurate description of these equilibria are possible with models like UNIQUAC and NRTL, but require labour intensive experimental data. Alternative predictive models can provide engineers with first estimates for molecular behaviour with less experimental data. In this manuscript, we explore different predictive models in predicting a molecular descriptor, the infinite diluted activity coefficient, γ_i^∞. This descriptor can be used in combination with predictive models to make a first estimate on the thermodynamic behavior in separation processes. Several types of models are known to be able to predict the γ_i^∞, for instance the Hildebrand parameter[2], Hansen Solubility Parameters[3], various Group Contribution Methods (UNIFAC), the Conductor like Screening Model for Real Solvents (COSMO-RS) model[4], Abraham model[5] and the Modified Separation of Cohesive Energy Density (MOSCED) model.[6] The aim of this manuscript is to compare the performance of these fundamentally different approaches in prediction the γ_i^∞ of (a)-polar solutes in (a)-polar (ionic) solvents. The relative performance of all evaluated models will be linked to the fundamental assumption incorporated in the various models.

2. Methods

For all γ_i^∞ predictions a systematic assessment was done at 298.15K and all model specific parameters were imported from literature sources. The overall average relative deviation (ARD) was determined both overall for all models as for specific solute-solvent combinations.

3. Results and discussion

A larger ARD was observed for Ionic Liquids (ILs) than for molecular solvents due to the additional ionic interactions. Overall averaged, the MOSCED model was the most accurate model for the prediction of γ_i^∞ of all solute classes in molecular solvents with an ARD of 16.2±1.35%. The UNIFAC Group Contribution Methods (GCMs), COSMO-RS and the Abraham models perform comparably with ARDs of 24.3-32.2%. Models using the Hildebrand parameter and the Hansen Solubility Parameters are significantly less accurate due to an insufficient description of intermolecular interactions such as hydrogen bonds. For predicting the γ_i^∞ in ILs, the Abraham model is overall the most accurate model with an ARD of 65.1±4.50%. The GCMs are less accurate with ARDs of 86.2-122%, while COSMO-RS is far less accurate with an ARD of 182±16.7%, due to a deficient description of long-range interactions.

Upon classification of solutes and molecular solvents, the evaluating for each of the solvent and solute classes was performed. Each model predicts most accurately, with the exception of the Hildebrand parameter and Hansen Solubility Parameters, the γ_i^∞ for specific classes of binary solute-solvent pairs. Though the accuracy decreases with the polarity of the solute. For ILs, the Abraham model is overall averaged most accurate, though several cations are more accurately described with mod. UNIFAC (Ly) or mod. UNIFAC (Do). The large ARDs from the UNIFAC models and the Abraham model are mainly due to large ARDs for bis(trifluoromethylsulfonyl)imide ($[NTF_2]$), tetrafluoroborate ($[BF_4]$) and the 2-(2-Methoxyethoxy)ethyl sulfate ($[MDEGSO_4]$) anions. Hence, improving the prediction of these anions will greatly increase their overall prediction accuracy. Additionally, the most accurate model for molecular solvents, MOSCED, could not be assessed for ILs. Therefore, an extension of MOSCED towards ILs may become an accurate tool in predicting accurate γ_i^∞ in ILs.

4. Conclusions

Based on the evaluation results, it can be concluded that choosing the most accurate model for estimation of γ_i^∞ depends on both the solute and solvent categories under evaluation. Using a predicted γ_i^∞ for IL screening should be done with caution, as these on average easily exceed deviation of 65%.

Reactive Separation Concept for Valorizing Low Molecular Weight Carboxylic Acids from Aqueous Media.

Andreas Toth[1], Susanne Lux[1], Daniela Painer[1], Matthäus Siebenhofer[1]

1 Institute of Chemical Engineering and Environmental Technology, Graz University of Technology, Inffeldgasse 25C/III, 8010 Graz

**Corresponding author: andreas.toth@tugraz.at*

Highlights

- Valorization of dilute, biobased carboxylic acids is possible.
- Solvent regeneration rates above 75 % are feasible.
- Concept insensitive to residual acid in the regenerated solvent.

1. Introduction

Valorization of low molecular weight carboxylic acids (e.g., acetic acid, formic acid) of biogenic origin is associated with various problems. Originating mostly within biorefinery processes, the carboxylic acids show up at low concentration in aqueous broths. The main problems to be dealt with are (quasi-)azeotropic behavior, high water content and unfavorable combinations of substance properties (e.g., boiling points). While conventional separation technologies struggle with these problems, reactive separation technologies are promising alternatives. [1] For dilute acetic acid in particular and low molecular weight carboxylic acids in general, the concept of chemical conversion in emulsions with in-situ extraction of the products was developed. [2] Homogeneously catalyzed esterification with a higher aliphatic alcohol in the solvent phase (e.g., 1-octanol) addresses the liquid-liquid equilibrium partition by separation of the hydrophobized derivatives of the carboxylic acids. Reactive distillation with transesterification (octyl ester to methyl ester) was investigated for solvent regeneration and product isolation. The surfactant type catalyst 4-dodecylbenzenesulfonic acid accelerates esterification. 4-dodecylbenzenesulfonic acid is also reported to be a potent catalyst for transesterification by Hagen et al. [3]. A proof of concept was performed in batch operation mode.

2. Methods

The laden solvent after esterification was mixed with methanol in a batch reactive distillation column in lab-scale. Laden solvent with and without residual acetic acid from the esterification step was used. The setup consisted of a 500 ml three-neck flask, a 30 cm Vigreux column with a condenser and a reflux splitter. Total reflux ratio was applied until reflux from the condenser was fully developed, then the reflux ratio was set to 10. Distillate was withdrawn from the product funnel every 30 min and analyzed by gaschromatography. The experiments were performed until distillate formation stopped.

For the proof of concept, the molar ratio of methanol as well as the performance of the catalyst were investigated.

3. Results and discussion

Regeneration performance was evaluated via methyl ester yield and amount of volatile residues in the regenerated solvent phase. Figure 1 displays a comparison of methyl acetate yield for different stoichiometric ratios of methanol to octyl acetate. 3-fold excess of methanol allows a methyl acetate yield of 75.6 % and about 1.5 wt.% residual volatile components in the regenerated solvent. While increased excess of methanol is beneficial for yield and regeneration rate, energy demand for excess methanol removal multiplies.

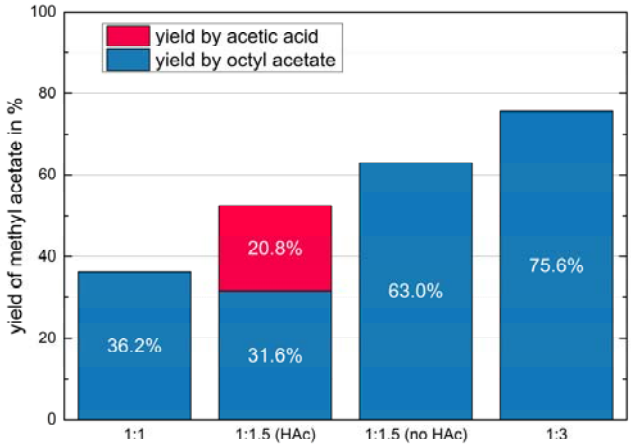

Figure 1. Methyl acetate yield of transesterification in batch reactive distillation

For 1.5-fold excess of methanol the impact of 2 wt.% residual acetic acid in the laden solvent was investigated. As shown in figure 1, less octyl acetate is converted, but more than 99 % of the acetic acid is esterified. Direct esterification (acetic acid to methyl acetate) is preferred over transesterification (octyl acetate to methyl acetate) as a consequence of a lower Gibbs free enthalpy for the esterification. In order to increase the performance a higher excess of methanol is needed, if residual acetic acid is present in the laden solvent.

4. Conclusions

The combination of reactive extraction (esterification in emulsion) and reactive distillation (transesterification) has proven feasible for valorizing low molecular weight carboxylic acids in lab-scale. Solvent regeneration with transesterification in reactive distillation allows regeneration rates in the order of 75 %. The favorable vapor-liquid equilibria between high and low boiling components enable reducing the amount of low boiling residues in the regenerated solvent to below 0.5 wt.%.

Hydrocarbon Mass Transfer in Ionic Liquids.

Noemí Delgado-Mellado[1], Miguel Ayuso[1], Julián García[1], Francisco Rodríguez[1]

1 Department of Chemical Engineering, Complutense University of Madrid, 28040 Madrid, Spain

Highlights

- Determination of hydrocarbon diffusion coefficients at infinite dilution in ILs
- Hydrocarbon diffusion is highly influenced by the ionic liquid viscosities
- A modified Wilke-Chang correlation successfully predicts the diffusion coefficients

1. Introduction

The experimental values of diffusion coefficients are of special importance in the theory of transport properties and to predict the rate-limiting factor for chemical processes and engineering design [1]. Herein, the Taylor dispersion method has been used for the first time to measure the diffusion coefficients at infinite dilution of *n*-heptane and toluene in two ionic liquids (ILs), namely 1-ethyl-3-methylimidazolium dicyanamide ([emim][DCA]) and 1-ethyl-4-methylpyridinium bis(trifluoromethylsulfonyl)imide ([4empy][Tf_2N]). The importance of both ILs lies in their remarkable extraction properties in the aromatic/aliphatic separation process by liquid-liquid extraction [2]. A correlation based on the Wilke-Chang equation has been proposed to estimate the diffusion coefficients that satisfactorily predicts the temperature dependence.

2. Methods

The experimental equipment consists of a KDS Legato 200 metering pump which provides a constant and a laminar flow, a PEEK diffusion tubing (10 m length and $0.375 \cdot 10^{-3}$ m inner radius) located in a thermostatic incubator, and a Refractive Index Detector Agilent 1260 Infinity II which records the concentration gradient signal at the end of the diffusion tubing. The experiments were performed at temperatures between (298.2 and 333.2) K and a constant laminar flow of 50 $\mu L \cdot min^{-1}$ for 20 μL of samples with a hydrocarbon concentration of (0.02-0.10) $mol \cdot dm^{-3}$ in excess.

3. Results and discussion

Toluene presents higher values of diffusion coefficients than *n*-heptane in the [emim][DCA] IL because of the lower toluene molecular volume, meanwhile both toluene and *n*-heptane show similar values in the [4empy][Tf_2N] IL due to high effect of the solvent viscosity on the hydrocarbon diffusion (Figure 1). Meanwhile at a temperature of 298.2 K the [emim][DCA] IL has a viscosity of 15.1 mPa·s, the [4empy][Tf_2N] viscosity presents a much higher value of 34.5 mPa·s [3]. Therefore, the higher [4empy][Tf_2N] viscosity leads to a lower influence of the solute molecular volume on the diffusion coefficients.

It has been observed that the Wilke-Chang correlation [4] does not correctly predict these diffusion coefficients; it tends to underestimate them at low temperatures and overestimate

them at high temperatures, with an average deviation of 17.5%. The association parameter seems to be a nonconstant value influenced by the temperature in ILs, therefore a modified Wilke-Chang equation is proposed and expressed as:

$$D_{12} = 7.4 \cdot 10^{-8} \cdot \frac{(\varphi_{\mathrm{mod}}(T) \cdot M)^{0.5} \cdot T}{\eta \cdot V^{0.6}}$$

being $Æ_{mod}(T)$ the association parameter dependent on temperature as $Æ_{mod}(T)=a_1 \cdot T+a_2$. The modified Wilke-Chang equation correctly represents the temperature effect on the diffusion coefficients and estimates them with an average deviation of 2.6% (Figure 1).

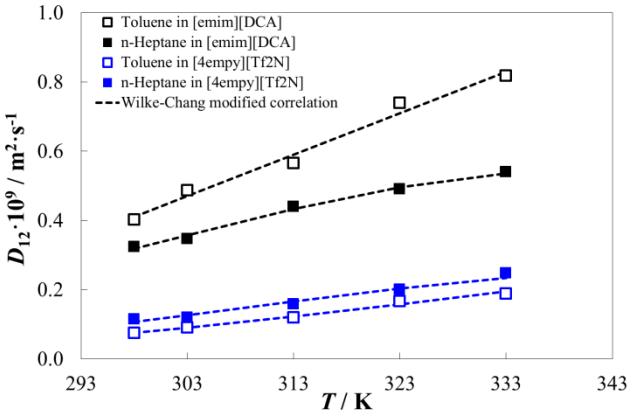

Figure 1. Diffusion coefficient at infinite dilution of *n*-heptane and toluene in [emim][DCA] and [4empy][Tf2N] ILs and dotted lines for Wilke-Chang modified correlation.

4. Conclusions

The hydrocarbon diffusion is faster in [emim][DCA] because of the much lower values of its viscosity, and the difference between *n*-heptane and toluene diffusion coefficients are due to their respective molecular volume. On the contrary, the high viscosity of [4empy][Tf_2N] IL leads to lower and similar diffusion coefficients of both hydrocarbons, prevailing the effect of the viscosity over the effect of the hydrocarbon molecular volume. The Wilke-Chang correlation, the most common one used to estimate the diffusion coefficients, unsuccessfully predicts the temperature dependence with an average deviation of 17.5%. A modified Wilke-Chang correlation has been proposed to properly estimate the dependence of the temperature on the association parameter. This correlation has shown a good fit in the studied temperature range with an average deviation of 2.6%.

Mass transfer intensification in wastewater aeration system with novel conical mixer

Anastasia Grigoreva[1,2], Rufat Abiev[2]*

1 Asterion Ltd, Saint-Petersburg, Russia;
2 St. Petersburg State Institute of Technology, Moskovskii pr.26, 190013, Saint-Petersburg, Russia;

**Corresponding author: abiev.rufat@gmail.com*

Highlights

- New conical mixer has been elaborated and tested.
- New conical mixer has the same mass transfer efficiency as Ruston turbine, but lower power consumption.

1. Introduction

The practice of operating wastewater treatment plants shows that 60-80% of expences depends on the efficiency of the aeration system [1]. This is the most energy-consuming process. Rushton turbine is recognized as the most effective mixer for gas dispersing [2]. We have recently developed aeration system with new type of impeller, which shown in the Fig.1.

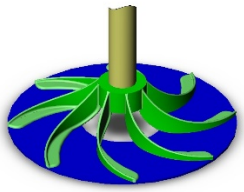

Figure 1. New type conical mixer.

This mixer has more streamlined shape, the blades are rounded, therefore hydraulic losses are minimized.

2. Methods

All tests were hold in plexiglass vessel with volume of 44 litres. In present work we analyzed bubbles' sizes using photographic method. From 5300 to 7300 bubbles were captured and calculated. Mass transfer was determined by method, described in [3]. Sodium sulfite was added to the tap water for deoxygenation. The oxygen content in the liquid was measured with oxygen sensor (Expert, Type 009, Russia). Volumetric Mass Transfer Coefficient (K_La) defined as

$$K_La = \frac{1}{t2-t1} ln \frac{d1}{d2}$$

Where d2 and d1 – oxygen deficiency at the moment of time moments of t2 and t1. Power consumption were measured with stand, which described in [4]. SOTE and SAE were chosen as criteria of efficiency [5].

3. Results and discussion

Oxygen content in the water during experiments shown in the Fig. 2. The main results are presented in the Table 1.

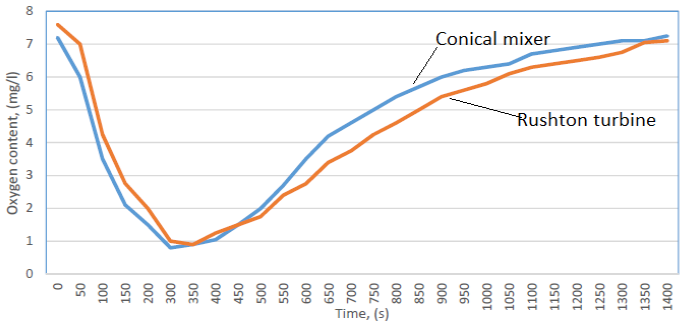

Figure 2. Oxygen content during experiments with conical mixer and Rushton turbine.

Table 1. Mass transfer characteristics of water oxidation

The name of calculated parameter	Rushton turbine	Conical mixer
Volumetric Mass Transfer Coefficient Kla,	11.06	15.62
Oxygen dissolution rate, kg/h	21.25	29.99
Oxygen use percentage SOTE, %	13.60	19.19
The ratio of the amount of oxygen dissolved in a liquid to the amount of electricity used SAE	0.35	0.64

4. Conclusions

Conical mixer shows SAE efficiency 1.82 times more than Rushton turbine. This is because the new type of mixer has a more streamlined shape, contributing to reduced power consumption. The proposed aeration system is a good alternative to the existing pneumatic aeration, especially in shallow tanks (up to 3 meters deep). Installing this kind of mixer will significantly reduce operating costs and avoid problems with clogging of small (approx.. diameter of 0.1 mm) pores in aerators (spargers).

Molecular dynamics simulations of the adsorption of partially hydrolyzed polyacrylamide on kaolinite edge surfaces in saltwater for a range of pH values: Effect of temperature

Quezada GR[1]*, Rozas RE[2], Toledo PG[3]
[1]*Water Center for Agriculture and Mining (CRHIAM), University of Concepción, Concepción, Chile*
[2]*Department of Physics, University of Bío-Bío, Concepción, Chile*
[3]*Chemical Engineering Department and Surface Analysis Laboratory (ASIF), University of Concepción, Concepción, Chile*

The adsorption of partially hydrolyzed polyacrylamide (HPAM) polymer chains on kaolinite particles is key in solid-liquid separation processes that seek to recover water in mineral processing. In this work, computational molecular dynamics is used to study the water-kaolinite interface in the presence of HPAM under conditions of high salt concentration and wide pH range. The salts used are some of the most common in seawater. Water clarification processes occur at very different temperatures at different times of the year, however the effect of temperature has practically not been studied. First, quantum mechanical calculations are used to describe the negative charging on the edge surfaces of the kaolinite at and above its point of zero charge. Then, molecular simulations are used to evaluate the effect of temperature on the adsorption of ions and HPAM chains on the edges of kaolinite particles. The saltwater contains different salts, where the anion is chloride and the cation an alkali metal or alkaline-earth metal, in all cases concentration is as high as 0.6 M. It is also considered a brine that imitates seawater, with an ionic strength of 0.6 M and the simultaneous presence of Cl^-, Na^+, $SO4^{2-}$, Mg^{2+}, Ca^{2+} and K^+. The pH range of the simulations is 7 to 11 and the temperature range is 273 to 313 K. The results show that the ions compete for the edge surfaces of the kaolinite, although water-structure maker ions always adsorb better than water-structure breaker ions. An interesting result is that the adsorption of HPAM is promoted by the salts with maker cations and is hindered by the salts with breaker cations. Temperature has a significant impact. We hope these results can contribute to the decision making in water clarification processes in mineral treatment.

Extraction of Glycyrrhetinic acid from Dried Licorice Root by using Supercritical Carbon Dioxide.

Kohei Wada and Masanao Imai*

Course of Bioresource Utilization Sciences, Graduate School of Bioresource Sciences, Nihon University, 1866 Kameino, Fujisawa, Kanagawa-pref. 252-0880, Japan
**corresponding author: XLT05104@nifty.com*

Highlights

- Glycyrrhetinic acid was extracted by supercritical carbon dioxide from dried Licorice.
- Extracted amount was increased with increasing pressure and decreasing with temperature.
- Extracted amount was correlated with estimated density of supercritical carbon dioxide.
- Lower energy required for extraction led higher extracted amount of glycyrrhetinic acid.

1. Introduction

Licorice is one of major medicinal herbs expecting anti-inflammatory and anti-cancer[1-3]. Pharmaceutical effects have been brought by glycyrrhetinic acid. In the licorice root, glycyrrhetinic acid is contained as an aglycone and glycyrrhizin is also included glycoside. In this work, glycyrrhetinic acid was focused as a target component. Supercritical carbon dioxide ($SCCO_2$) has been anticipated as lowest risk solvent and non-residual character in products. The aim of this study is to measure of effect of temperature and pressure on extracted amount of glycyrrhetinic acid. Extracted amount was correlated with the estimated density of supercritical carbon dioxide. Energy required for extraction was preliminary evaluated and then correlated with the extracted amount of glycyrrhetinic acid.

2. Methods

Licorice root was purchased from Uchida Wakanyaku Ltd. (Tokyo, Japan). Pure glycyrrhetinic acid (98%) was purchased from FUJIFILM Wako Pure Chemical Industries, Ltd (Osaka, Japan). It was used to determine the calibration curves to measure the concentration of glycyrrhetinic acid by high performance liquid chromatography. The mean size of the powdered licorice root was varied from 200 to 990 µm. The $SCCO_2$ extraction apparatus was presented in Fig.1[4]. The extraction was operated as batch mode. Extraction period was 30 min. throughout this study.

3. Results and Discussion

Extracted amount in this study was expressed as [mol-target･(g-dried-sample)$^{-1}$･(mol-$SCCO_2$)$^{-1}$]. Liquid-solid extraction by ethanol was employed as a primary experiment. Extracted amount was 6.0 [mol-target･(g-dried-sample)$^{-1}$･(mol-$SCCO_2$)$^{-1}$] at 303K.

The extracted amount was decreased with increasing temperature (Fig.2). It was remarkably decayed in the range of 313-318 K. The extracted amount was gradually increased with increasing pressure (Fig.3). Density of supercritical carbon dioxide was estimated by Bender's empirical equation[5]. The extracted amount was strongly depended on the density within 0.71-0.93 [g·cm^{-3}]. Energy required for extraction was evaluated from the square of difference of solubility parameters between $SCCO_2$ and glycyrrhetinic acid. Lower required energy led higher extracted amount of glycyrrhetinic acid.

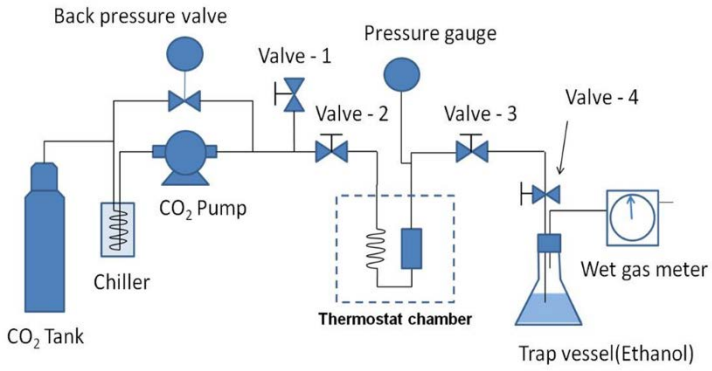

Fig. 1. Schematic illustration of $SCCO_2$ extraction process

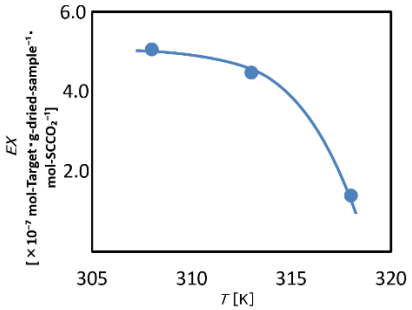

Fig. 2. Effect of temperature on the extracted amount

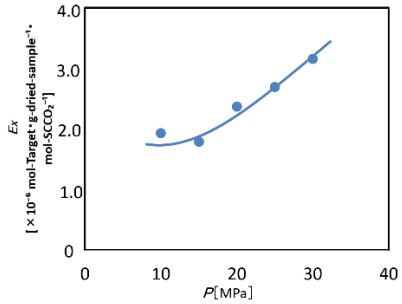

Fig. 3. Effect of pressure on the extracted amount

4. Conclusions

Glycyrrhetinic acid was successfully extracted by supercritical carbon dioxide from dried Licorice root ranging 308-318K and 10-30MPa. Extracted amount was increased with increasing pressure and decreasing with temperature. Extracted amount was closely correlated with the estimated density of supercritical carbon dioxide. Energy required for extraction was estimated from solubility parameter of supercritical carbon dioxide and glycyrrhetinic acid. Lower energy required led higher extracted amount of glycyrrhetinic acid.

Highlights

- Strategies for the complete preparative separation of nadolol chiral drug.
- Optimization of different solvent compositions using chiral and achiral adsorbents.
- Experimental chiral separation by preparative and SMB chromatography.

1. Introduction

Nadolol is a common prescribed pharmaceutical drug for the relieve of several cardiovascular diseases and represents a very interesting case-study of multicomponent chiral separation since it is composed by four stereoisomers, being two pairs of enantiomers. In this way, it introduces the possibility of alternative strategies, using different kind of preparative separation sequences and techniques, the use of different packings (chiral and achiral stationary phases), and the corresponding mobile phase optimization at both normal and reversed-phase modes.

When considering preparative and multicomponent separation, the complexity deeply increases by introducing the necessity of multi-step separation sequences (or a much more complex multi-region separation process), by opening the possibility to combine chiral and achiral stationary phases (when in presence of stereoisomers instead of just one pair of enantiomers) and to combine different separation techniques (fixed-bed and simulated moving bed (SMB) related processes). The design of the complete preparative separation of nadolol stereoisomers asks for a global experimental and simulation methodology considering both the characterization and optimization of each separation step and its sequences to achieve the four nadolol components pure. New strategies using combinations of achiral and chiral stationary phases and sequences of different separation techniques will be presented. Extensive experimental and simulation results for the complete separation of all the four nadolol stereoisomers using Chiralpak IA (chiral) and different Waters C18 (achiral) stationary phases will be presented.

2. Methods

For the analytical measurements, an analytical Knauer HPLC was equipped with one Smartline 1050 pump, a 10 mL pump head and two detectors in series: a Smartline UV detector 2520 a polarimeter detector (Chiralser IBZ, Messtechnik, Germany). These measurements were performed using a Chiralpak IA column obtained from Daicel and a XBridge C18 column obtained from Waters. Both columns have the same analytical dimensions (250 mm L × 4.6 mm ID) and

packed with 5 μm particle size materials. For the preparative measurements, a preparative Knauer HPLC system equipped with a Smartline UV detector 2520, two Smartline 1050 pumps with 50 mL pump heads, was used. Three different preparative columns (100 mm L × 20 mm ID) were used, a Chiralpak IA (particle size diameter 20 μm), a SiliaChrom XT18 and a XBridge C18 column (both with a particle size diameter of 10 μm). The pseudo-binary SMB separation of nadolol stereoisomers was performed on a laboratory-scale SMB unit built on the LSRE group, Faculty of Engineering, University of Porto. The SMB unit was operated using a [1-2-2-1] column configuration. The SMB unit was operated with six Chiralpak IA columns for the pseudo-binary enantiomer separation and six XBridge C18 columns for the binary separation of the two nadolol racemates. Additionally, a commercial Azura Fixed-Bed prep HPLC system obtained from Knauer was also used for the binary separation of nadolol racemates. This system was equipped with two preparative HPLC pumps P2.1L model with 250 mL/min pump heads, one UV detector UVD2.1L model and a unique Waters XBridge prep C18 column (30 mm ID x 250 mm L) with particle size diameter of 10 μm.

3. Results and discussion

An extensive set of experimental and simulation results will be presented (see Fig. 1). Results will include the identification of the stereoisomers present in both nadolol racemates by means of using UV and polarimeter detectors in series. Then, a complete methodology developed during the last years by our group will be explained and applied to scale-up the separation process from analytical to preparative scales [1-3].

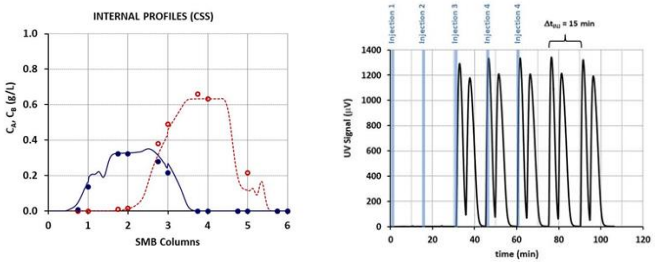

Figure 1. Experimental preparative separations of nadolol racemates using (left) Flex-SMB unit and (right) Fixed-Bed Azura pilot unit, both with achiral adsorbent under reversed-phase mode.

4. Conclusions

The results recently obtained by our research team for this topic clearly support the capacity to enhance the knowledge on the chromatographic separation of chiral pharmaceuticals using fixed-bed and SMB preparative chromatography. In this communication, it will be introduced original and innovative challenges through the real separation of multicomponent (quaternary) chiral mixtures which represents an important step forward for the pharmaceutical industry.

Highlights

- Electrodialysis at overlimiting currents as a way of intensification.
- Investigation of overlimiting mechanisms in a specific cell.
- Electroconvection tracked by particle image velocimetry.
- Water splitting detected mostly at anion-exchange systems.

1. Introduction

Intensification of processes can bring significant savings both economical and ecological. With the advent of techniques allowing the investigation of the overlimiting region at ion-exchange membrane and with better understanding of the occurrence of overlimiting current, the scientist started to work on the development of electrodialysis units working in this high intensity current regime. Until now, these processes have been operated under much smaller currents, which in turn requires much larger units.

The typical current voltage curve (CVC) of ion-exchange systems displays three parts: (i) underlimiting, (ii) limiting, and (iii) overlimiting. The underlimiting region occurs at small current densities. The increase in the current density leads to depletion of ions on one side of the membrane which is manifested as limiting region on the CVC. However, further increase in the current results in the occurrence of physical mechanisms that partially destroy the region of depleted ions. There are two major mechanisms, and these are: (i) electroconvection, and (ii) water splitting. Unlike other separation processes (e. g. pressure driven), the overlimiting region overcomes the limitation given by concentration polarization. For the engineers to be able to exploit this advantage in the industrial applications, they need in-deep understanding of the ion-exchange system behavior in this region. We have developed a special cell, that allows to (i) visualize electroconvection in the system and (ii) measure pH changes associated with the water splitting reaction. Our work should contribute to the proper understanding of aforementioned mechanisms and their dependence on the structure of ion-exchange system and the composition of the desalted electrolyte

2. Methods

We manufacture a fluidic cell that incorporates either a small piece of an ion-exchange membrane or a single ion-exchange resin particle. This cell allows one to characterize the systems electrochemically (current-voltage curves, chronopotentiometric and amperometric curves) and

at the same time observation of the processes that occur at the interface between the ion-exchange system and the desalted electrolyte [1]. The electroconvection is tracked by solid microparticles and the results are evaluated by particle image velocimetry, the extent of water splitting reaction is directly measured by changes in pH of the respective electrolytes.

3. Results and discussion

Figure 1 depicts the results of a single experiment performed on a single cation-exchange particle. In a similar way these experiments can be carried out for any other ion-exchange system or for any other type of the measurement. In this particular case, we show that the underlimiting region is accompanied by formation of ion-depleted zone within which an array of vortices is formed upon reaching the limiting current. With further increase in the polarization current the vortices grow and start to affect the boundary created by the tracking particles. This growth gives rise to the appearance of the overlimiting current (first region), which is characterized by increasing slope. However, upon reaching a certain critical current, the system will transition into a second part of the overlimiting region that is characterized by constant slope of the CVC. This transition will form four large vortices on the system. We also showed that the water splitting is negligible on the cation-exchange particle. Very similar results were obtained for a small piece of a heterogenous cation-exchange particle. By contrasts, the anion exchange systems, although also showing occurrence, are easily prone to the water splitting reaction.

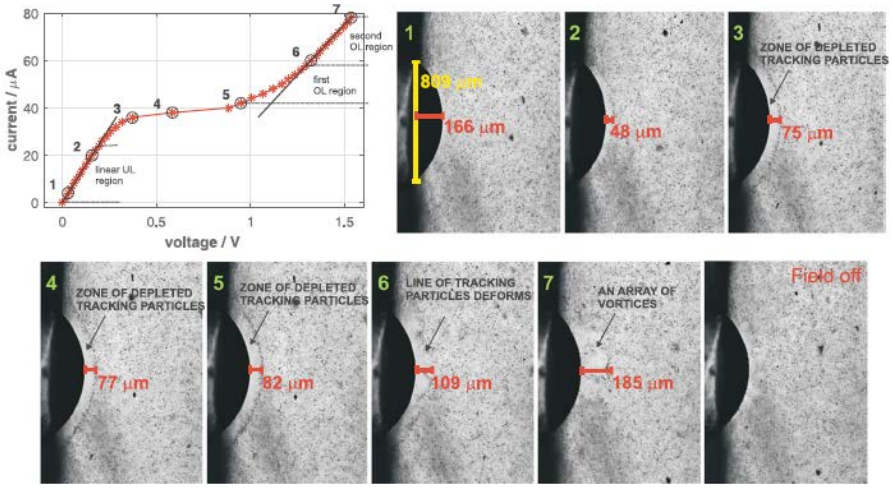

Figure 1. Current-voltage curve measured on a single cation-exchange particle and the set of images capturing the situation at the system-electrolyte interface under various polarization currents [2].

4. Conclusions

We monitored the processes occurring on the ion-exchange systems during polarization. Our observation confirmed the generation of the ion-depleted region followed by formation of the electroconvective vortices that are responsible for the overlimiting current exhibited by these systems. The water splitting reaction was shown to have small effect in cation-exchange membranes and reached much larger extent in anion-exchange system.

Highlights

- Dehydration of organic solvents by pervaporation
- Pervaporation data treatment using solution-diffusion approach coupled with an accurate vapor-liquid equilibrium model
- Comparison of pervaporation and distillation efficiency in terms of separation and energy consumption

1. Introduction

In the modern conditions of constantly growing market demand and product consumption, the world leading industries shift progressively towards the eco design approach. That means a production with an attentive consideration for the environmental impacts of a product during its lifecycle, low material and energy resources consumption and using of the environmentally friendly solutions. Chemical engineering is not an exception. The situation becomes especially sensitive in separation technologies as the chemical waste treatment and recycling remains one of the most important problems of the humanity. For example, in the alcohols and organic solvents dehydration, robust and durable processes, such as distillation, are mainly used. Regardless of its durability and high product output, the overall results obtained by distillation may be far from expected. Its separation efficiency may be limited by the vapor-liquid equilibria (azeotropes, relative volatility etc). The modified processes such as azeotropic or extractive distillation are able to deal with these drawbacks generally at the expense of increased complexity and operational costs. Moreover, one should not ignore the high energy consumption of distillation.

The pervaporation, a membrane separation process, can be an excellent alternative to distillation. Though it is a relatively young technology, the attention of industries towards it increases every year mainly due to its low energy consumption and high separation performance. The main advantage of pervaporation is that the separation efficiency is independent of vapor-liquid equilibria and is only limited by the membrane material and operating conditions. A large number of researches on membrane materials have significantly decreased the costs of membrane modules which makes pervaporation even more attractive for separation of liquid mixtures.

The aim of our work was to emphasize the new horizons of solvent dehydration technology and mark the contribution of pervaporation in process eco design. We have experimentally and

theoretically studied the pervaporation applied to a dehydration of an aqueous mixture of three glycol ethers which are widely used in different chemical industries all over the world. The interest was mainly pointed towards the separation efficiency and energy consumption. The results were compared to those of distillation for the same mixture. The modeling of both processes was also performed in order to optimize operating conditions and increase the efficiency.

2. Methods

A mixture of three organic solvents and containing 10%wt of water was dehydrated by pervaporation using commercial dense membranes with a cross-linked polyvinyl-alcohol (PVA) active layer. The pervaporation was carried out at 30, 50 and 70°C. The permeate fluxes were measured by weighing and the permeate composition was determined by a gas chromatography method. The membrane permeances were calculated by the solution-diffusion approach coupled with accurate liquid-vapor equilibria data. The energy consumption of the process was determined as well.

A dehydration of the same mixture by distillation was carried out in parallel at the pressures of 1.013 bar, 0.2 bar and 0.05 bar. The modeling of the distillation process was made using ProSim Pro software.

3. Results and discussion

Results obtained were encouraging. The permeate analysis has indicated the presence of only pure water which means that the membrane is 100% selective to water and no solvent passed through it. The process was compared with the distillation in terms of separation efficiency and energy costs. While the distillation has offered high product flows, the separation was much less efficient because of the limit in vapor-liquid equilibrium; moreover, the energy consumption was very important.

4. Conclusions

In this work we have shown the potential of pervaporation to replace classic separation methods such as distillation while dehydrating organics. A highest separation rate and low energy expenses were achieved. An ideal permeate flux can be obtained by choosing a membrane module with an appropriate working area. Experimental and modeling results were used for further development of an industrial-scale applied process.

Separation of mixtures containing SO_2, CO_2 a CH_4 using membranes based on polymers with intrinsic microporosity

Petr Stanovsky[1*], Andrea Zitkova[1], Magda Karaszova[1], Pavel Izak[1],
Bibiana Comesaña Gándara[2], Neil McKeown[2]

[1] *Instit. of Chem. Proc. Fund. CAS, Rozvojova 135, 165 02 Prague 6 – Suchdol, Czech Republic;*

**Corresponding author: stanovsky@icpf.cas.cz*

Highlights

- Separation of CO_2 from CH_4 is efficient and overcome the Robeson upper bound 2008
- Permeability of SO_2 and CO_2 is very high but SO_2/CO_2 selectivity is low for industrial use.
- Selectivity of aged PIM membrane increased after testing with pure CO_2.

1. Introduction

Membrane separation of gases offer several advantages compared to common industrial methods as such as energy efficiency, safety and no additional waste production. One of the recent progressive direction in the field of polymer membrane science is a new class of ultrapermeable polymers based on inefficient packing of the two-dimensional chains – polymers with intrinsic microporosity (PIM).

2. Methods

Membranes were made of polymer with intrinsic microporosity based on tetramethyltetrahydronaphthalene combined with triptycene PIM-TMN-Trip (P5) casted from chloroform solution and further treated with methanol. The procedure of membrane preparation is described in detail in publication Rose et al [1].

Permeation of selected gases and its mixtures was tested using two apparatuses. First allows to set SO_2 concentration in mixture of air, N_2, CO_2 [3]. Second apparatus allow mixing CH_4, N_2, CO_2 or real biogas. The both allows analyzing either retentate or permeate stream via set of electrochemical and infrared detectors.

Membranes were tested for different values of SO_2 concentration ranging from 500 to 2500 ppm at temperature 25°C in mixture of 20% vol. CO_2 and dry air under 100 kPa of upstream and 90 kPa of downstream pressure. Further separation of mixture with 1800 ppm under increasing upstream pressure varying from 200 up to 500 kPa. Another tests with single gas as CO_2 and CH_4, their mixtures and real biogas from wastewater treatment plant were done at upstream pressure ranges from 100kPa to 500 kPa and 98 kPa of downstream pressure.

3. Results and discussion

Tested PIM-TMN-Trip membrane has shown superior separation properties for CO_2/CH_4 mixture. Combined ideal selectivity and permeability of single gases (gray circles in Fig. 1) lies above Robeson bound [2]. However, the membrane have shown lower values of permeability for CO_2 than similarly

prepared membrane by Rose [1]. Permeability of CH_4 slightly increase with increasing trans-membrane pressure; on the other hand, CO_2 permeability remain almost constant over all range of trans-membrane pressure. Mixtures of CO_2 with CH_4 and real biogas with traces of H_2S and siloxanes (red triangles and blue diamonds in Fig. 1) have shown the same permeability for CO_2 with mixed gas selectivity higher than ideal selectivity of particular gases similarly as for polymer PIM based on spirobifluorene unit. Mixed gas selectivity decreased with increasing trans-membrane pressure. Moreover, as the measurement was done for mixtures and afterwards for single gases with CO_2 as the last one; we observed afterwards big increase in selectivity without change of CO_2 permeability. This CO_2 sorption-induced ageing improved selectivity of separation considerably (empty circles in Fig. 1).

Separation of SO_2 from dry stream containing initially 1800ppm SO_2 in mixture of air and 20 % vol. CO_2 is rather low (selectivity is approx. 2) and basically similar to our recent results of water-swollen thin film composite membrane Toray [3] in terms of selectivity but it have much higher permeability for SO_2. Permeability of SO_2 decreased with increasing trans-membrane pressure.

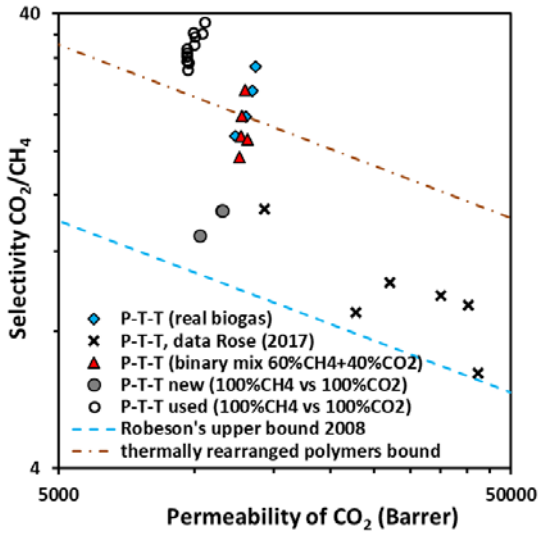

Figure 1. Selectivity CO_2/CH_4 vs permeability of CO_2

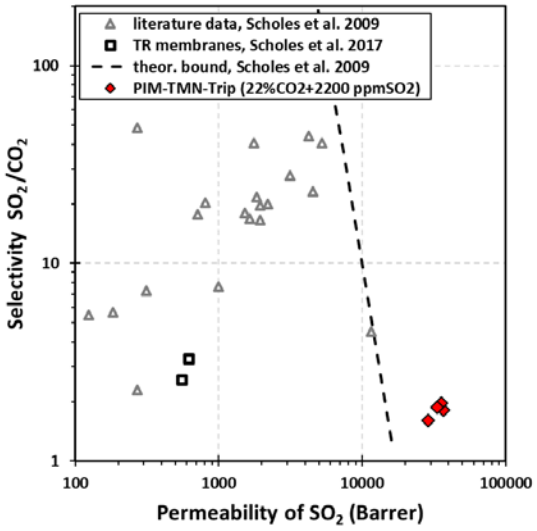

Figure 2. Selectivity SO_2/CO_2 vs permeability of SO_2

4. Conclusions

Tested PIM-TMN-Trip membrane have shown superior separation properties for mixture of CO_2/CH_4 mixture (CO_2 permeability 10-12.10^3 Barrer, selectivity 13-15, selectivity of used and likely aged membrane 30-38). Permeability of SO_2 from air-CO_2 mixture was very high (29-37.10^4 Barrer) but selectivity of SO_2 separation from CO_2 was small (1.6-2.0).

Selective separation of n-butanol from ABE solutions with polymeric inclusion membranes

Carla A. Arregoitia[1], Marcos Fallanza[1], Daniel Gorri[1], Inmaculada Ortiz[1]

[1] University of Cantabria, Santander, Spain;

*Corresponding author: cadriana.arregoitia@unican.es

Highlights

- The addition of IL into the polymeric matrix improves the membrane selectivity
- Permeation fluxes highly depend on the operation temperature
- Fabricated membranes show improved behavior with respect to commercial membranes

1. Introduction

Biobutanol is considered as an attractive commodity and it is used as a solvent for different applications and as a biofuel, it has many advantages [1]. Biobutanol can be produced via ABE fermentation from renewable feedstocks by Clostridia bacteria, the most commonly used microorganism. Yet, the very low yield in final concentration, the severe butanol toxicity to microorganisms and the high-energy consumption are still some challenges that prevent the process from being more competitive over the petrochemical route [2].

Among the many advantages of the Pervaporation (PV) membrane separation technique is the fact that it does not affect microorganisms, and prevents nutrients and substrates loss [3]. Alcohol perm-selective PV membranes are usually composite membranes [4] and are made with a thin and dense active layer on a porous substrate. Ionic liquids (ILs) in membrane techniques have been investigated and although they have a good potential for butanol separation; the application for separation of butanol from ABE solvents by PV has not been fully investigated. This work aimed to develop and evaluate polymeric inclusion membranes made of different amounts of polymer and IL for the recovery of butanol from aqueous solutions by PV

2. Methods

Different composite flat-sheet membranes based on polyether block amide (PEBA) and the ionic liquid 1-Hexyl-3-methylimidazolium tris (pentafluoroethyl) trifluorophosphate (HMImFAP) were prepared by using the TIPS technique (temperature induced phase separation). They were characterized using FTIR and SEM methods. They showed the membranes with the IL fully integrated into the polymer matrix. The resulting membranes were dense flat sheet membranes with an average thickness of 10 μm. Butanol recovery experiments from ABE mixtures (2% butanol, 1% ethanol, 1% acetone) were performed by a PV unit and the transport parameters of the membranes for each component were obtained. Finally, the Pervaporation Separation Index (PSI) allowed a comparison of the performance results between the prepared membranes and the commercial membranes.

$$PSI = J \cdot (\alpha_{i/j} - 1)$$

3. Results and discussion

It was observed that the transmembrane flux is highly dependent on both, membrane composition and operating temperature. Membranes with higher content of ionic liquids are more permeable and the transmembrane flux was observed to increase as the temperature increases.

Based on the obtained results, the addition of a small amount of ionic liquid into the polymeric matrix shows an important decrease of the water flux while the butanol permeation remains almost unaffected. Finally, the efficiency of the membranes prepared in this study for the recovery of butanol was measured in terms of pervaporation separation index (PSI), offering results up to 8 times better than those from commercial membranes.

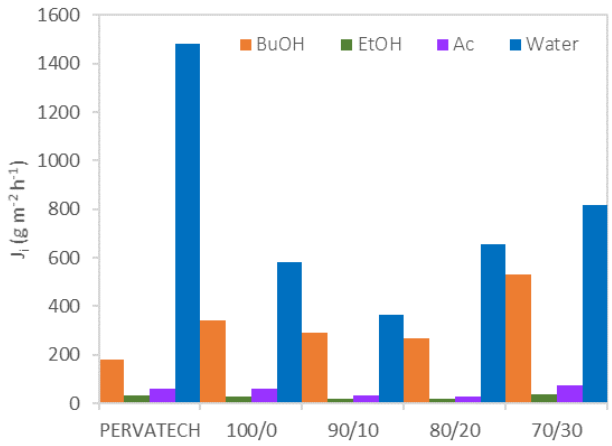

Figure 1. Flux comparison of commercial membrane PERVATECH and PEBAX/ HMImFAP polymeric membrane

4. Conclusions

Polymeric inclusion membranes were made of different amounts of polymer/IL for the recovery of butanol from aqueous solutions by PV process. It was observed that the flux increased as the temperature increased. Adding IL to the membrane showed an improvement by increasing the butanol flux and decreasing the water in the permeate stream. Finally, the influence of the composition of the membranes in the separation of butanol-water mixtures was studied and the performance of the membranes was compared with other commercial membranes showing a significant improvement.

Nano-structural modification of calcium alginate membrane for high performance separation of mono/oligosaccharide

Kaito Yoshida[1], Keita Kashima[1†], Masanao Imai[2]

1 Department of Materials Chemistry and Bioengineering, National Institute of Technology, Oyama College, 771 Nakakuki, Oyama, Tochigi, 323-0806, Japan;

2 Graduate School of Bioresource Sciences, Nihon University, 1866 Kameino, Fujisawa, Kanagawa, 252-0880, Japan

Corresponding author: † keitakashima@oyama-ct.ac.jp

Highlights

- Calcium alginate membrane for mono/oligosaccharide separation was successfully prepared.
- The structure of membrane was modified using polyethylene glycol in low-molecular-weight.
- Improvement of water permeability and sustention of glucose rejection were achieved.

1. Introduction

High-yield purification of monosaccharide and oligosaccharide is still demanded for advanced research in biological chemistry and bioengineering. Separation membrane from calcium alginate known as biopolymer has promising ability for molecular-size-screening of monosaccharide and oligosaccharide. [1-2] This study demonstrates nano-structural modification of calcium alginate membrane using polyethylene glycol in low-molecular-weight (PEG, M_n = 200 Da) for high-performance separation of mono/oligosaccharide.

2. Methods

2.1 Preparation of the calcium alginate membrane

A mixed solution of 10 g L^{-1} of the sodium alginate and 0 to 13 g L^{-1} of PEG was placed in a petri dish (ϕ 90 mm), which was dried at 303 K for 48 h in an electrical drying machine. The dried membrane was immersed in 20 mL of 1 M aqueous calcium chloride solution to cross-link alginate polymer for 40 min. The formed calcium alginate membrane was washed to remove PEG with 100 mL of deionized water at 333 K for 30 min repeated twice within a shaking bath.

2.2 Membrane permeation of aqueous solution of glucose

The prepared membrane was installed in a membrane holder (KST-90-UH, ADVANTEC). 10 mM glucose aqueous solution was permeated to the membrane with an operating pressure of 300 kPa using nitrogen gas. The mass of glucose solution permeated through the membrane was measured by electrical balance and was converted to permeated volume using density. The volumetric permeation flux, J_V [$m^3 \cdot m^{-2} \cdot s^{-1}$] was determined using the following equation (1).

$$J_v = \frac{V}{At} \qquad (1)$$

Where, V, A, and t are the volume of permeated solution [m^3], permeation area [m^2] (A = 0.00453 m^2), and permeation time [s], respectively. In addition, the concentration of permeated glucose solution was quantified through a mutarotase-glucose oxidase method with UV-Visible

spectrophotometer (λ= 505 nm). The rejection of glucose molecules (R [-]) by the calcium alginate membrane was evaluated from the equation (2).

$$R = 1 - \frac{C_s}{C_f} \qquad (2)$$

Where, C_s and C_f are the concentration of permeated solution [M] and the concentration of feed solution [M].

3. Results and discussion

Figure 1 shows the effect of added/removed PEG concentration on the permeation flux of glucose aqueous solution. The permeation flux remarkably increased with the increase of added concentration of PEG when the membrane was prepared. The water permeation was improved by the structural modification of membrane.

Figure 2 depicts the effect of added/removed PEG concentration on the rejection of glucose. The rejection was almost constant although the permeation flux was increased by the PEG modification, which indicates the size of mass transfer channel for glucose permeation was kept as well as the volume of channel increased. Addition and removal of low-molecular-weight PEG performed nano-structural modification.

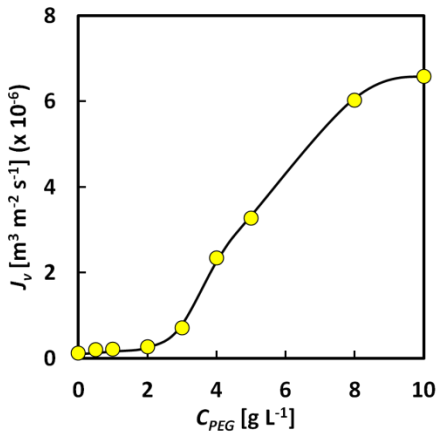

Fig. 1 Effect of the added/removed concentration of PEG (C_{PEG}) on the permeation flux of glucose aqueous solution (J_V)

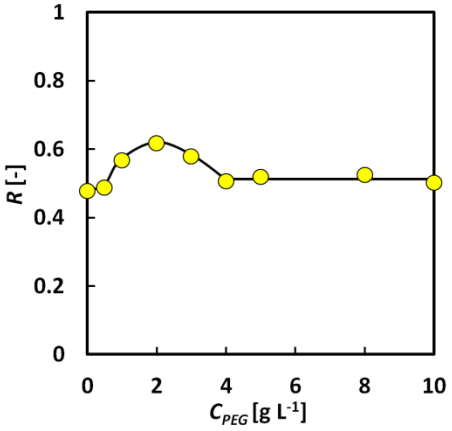

Fig. 2 Effect of the added/removed concentration of PEG (C_{PEG}) on the rejection of glucose molecules (R)

4. Conclusions

The improvement of water permeability and the sustention of glucose rejection were achieved by the nano-structural modification of calcium alginate membrane using low-molecular-weight polyethylene glycol. The modified membrane is expected to exert high performance on the separation of monosaccharide and oligosaccharide.

Highlights

- Solvent extraction La(III) complex using ionic liquid
- Stripping of La(III) complex using carbon dioxide

1. Introduction

Lanthanide elements are comparatively abundant in the earth's crust than other commonly exploited elements but are not sufficiently concentrated to make them easily exploitable. This is due to the similarity in their ionic radio, which makes them interchangeable in most minerals, and are very difficult to separate. In recent decades, lanthanide tris- β-diketones, Ln (β-diketone)$_3$ have attracted a lot of attention because of their spectroscopic properties (Binnemans, 2005). Lanthanum was chosen as an exemplifier of the rare earth (REE) series in this study because it is the most abundant trivalent REE that is found in major host rocks for REE minerals, and it also shows the closest match with respect to trivalent actinides among the other REEs in terms of ionic radio in 6-fold coordination (e.g., rLa 1.13 Å and rAc 1.18 Å) (Fricker, 2006). Solvent extraction (SX) is the most effective method to enrich metal ions, including rare earth. The counter current extraction process permits the separation of substances with different distribution coefficients (Mekki et al., 2006). Since the toxic and flammable characteristics of many organic solvents are detrimental to the environment, eco-friendly substitutes have been investigated. As an example, ionic liquids (ILs). The ionic liquids (ILs) have been considered as alternative solvents for solvent extraction processes because of their properties such as low volatility, low flammability, good chemical stability and adjustable miscibility and polarity (Kikuchi, Matsumiya, & Kawakami, 2014). The synergistic enhancement of the extractability depends largely on the type ligand, in this case, trioctyphosphine oxide (TOPO) was used. The chemical structure TOPO is responsible for its properties. Its strong coordinating abilities result from the presence of a single oxygen atom within the molecule (Anitha, Ambare, Singh, Singh, & Mohapatra, 2015).

There are some studies reported in literature on the extraction of metal ions using supercritical fluids (Wang, 1997) and ILs coupled to supercritical fluids (Mekki et al., 2006). In our previous contribution (Sepúlveda et al., 2017) we have tested an extraction technique to recover Cu(II) from aqueous solutions based on the use of an organic phase formed by an imidazolium-based ionic liquid as solvent and a β-diketone as extractant agent. In this framework, the aim of this work involves the improvement of the extraction and stripping of complex La(III) from an aqueous solution using [bmim][Tf2N] as solvent containing a fluorated β-diketone as extractant and dense carbon dioxide as stripping phase. This study is focused on the effect of the concentration of

extractant, phase contact time, volumetric Organic/Aqueous (O/A) ratio and overall volume of dense CO_2 on the whole process efficiency.

2. Methods

The organic phase was prepared with ionic liquid [bmim][Tf2N], as the solvent and β-diketone (HFOD) as the extractant. The aqueous solution was prepared by dissolving 1.0 g/L of La in deionized water (18.2 mΩ). The desired concentration of the salt was reached by using an analytical balance. The pH of these solutions was measured before and after extraction test using a pH meter. The removal of La(Beta-diketona)$_3$ complex from the aqueous solutions was carried out by means of the same procedure reported in our previous work(Castillo et al., 2014; Sepúlveda et al., 2017). The solvent extraction experiments were conducted by contacting 3 mL of aqueous solution with 3 mL of organic phase, where the phases were mixed in a horizontal mechanical shaker (Jin Yi ® model Hj-4B) at 140 rpm for 40 minutes. Then, the phase separation was achieved by centrifugation (Gemi Industrial Corp® model PLC-01) at 1000 rpm for 40 minutes. After phase separation, the final values of pH in the aqueous phase were measured. All the experiments were conducted at room temperature (25°C). Once these phases were completely separated, the concentration of the La(III) in the aqueous phase was quantified by means of Atomic Absorption Spectrophotometry (AAS) (GBS® Scientific Equipment model SensAA dual beam, equipped with a 4mA lamp (single element) Photron International ®). All the experiments were realized with duplicate samples.

The removal of La(III) complex from the aqueous solutions has been carried out by means of the same procedure reported in our previous work(Castillo et al., 2014). Thus, solvent extraction tests were achieved by contacting 2 mL of aqueous solution with 2 mL of organic phase formed by [bmim][Tf2N], beta-diketone and TOPO for 45 min in order to reach the equilibrium conditions. After phase separation the final values of pH and the concentration of La(III) complex in the aqueous phase were measured with a pH-meter and by AAS, respectively. From the results previously reported in literature (Castillo et al., 2014), it has been verified that the extraction of La(III) complex from an aqueous phase using [bmim][Tf2N] as diluent and beta-diketona as extractant is governed by the following reaction, which describes the cation exchange with formation of a neutral complex La(β-diketone)$_3$TOPO.

$$La^{+3} + 3(\beta\text{-diketone}) + 1\ TOPO \longleftrightarrow La(\beta\text{-diketone})_3TOPO + 3H^{+} \quad (1)$$

3. Results and discussion

This research is still being studied, we do not have data.

Membrane Filtration of Pickering Emulsions for Continuous Liquid/liquid Catalysis – Influence of Membrane Material and Nanoparticle Type

Anja Drews[1], Maresa Kempin[1], Tina Skale[1]

1 HTW Berlin, School of Life Science Engineering, Wilhelminenhofstr. 75A, 12459 Berlin, Germany

**Corresponding author: anja.drews@htw-berlin.de*

Highlights

- Membrane/nanoparticle/solvent combination influences nature of filtration behaviour.
- Gel-forming HDK H20 nanoparticles result in increased permeabilities.
- Suspension filtration can help to explain interactions of solid and liquid phases.

1. Introduction

Water-in-oil Pickering emulsions (PE) are currently receiving increased interest as a promising alternative to dispersions or surfactant stabilized emulsions in two-phase (bio-)catalysis. While batch PE catalysis has been demonstrated for a variety of reactions and catalysts, the separation of the two liquid phases and thus continuous operation has been identified as a main challenge [1]. Since then, the feasibility of using membrane filtration for the retention of catalyst containing droplets has been demonstrated [2-3]. In a proof-of-concept, the biocatalyst was still active after more than 8 residence times with feasible space-time-yields of 0.64 g/(Lh) [4]. After these first results, this works aims at investigating the influences of membrane material and type of stabilizing nanoparticles (NP) to yield more generally valid conclusions and to be able to explain individual interactions of present liquid and solid phases.

2. Methods

The desired amount of silica NP (HDK H20, H18 or H2000 by Wacker AG) was dispersed in the continuous phase (e.g., dodecene, CPME etc.) and PE were prepared by emulsifying the desired water phase fraction using a rotor/stator homogenizer Ultra-Turrax (UT, IKA GmbH) or ultrasonication (US, Branson Sonifier). In addition, NP suspensions were investigated.

A stirred cell (Merck, V_{max} = 91 mL, A_{eff} = $1.23 \cdot 10^{-3}$ m^2) was used for filtration trials. When pressure was applied to a connected surge tank, solvent was continuously transported to the completely filled stirred cell, which displaced permeate at the same rate. Recorded permeate weight was used to calculate flow rate. Membranes were soaked in solvent and pre-pressurized prior to use. Different ultrafiltration and organic solvent nanofiltration (OSN) membranes were used. Microscopic pictures of PE samples before and after filtration were taken and image analysis software (SOPAT GmbH) was used to measure droplet size distribution. Rheology was measured using a MCR 302 rotational rheometer (Anton Paar GmbH).

3. Results and discussion

First results showed that with permeabilities of up to around 40 L/(m² h bar) a large variety of PE could be filtered and concentrated to up to 80% water phase fraction [2-4]. As can be seen in Fig. 1 (left), an unexpected disproportionate flux behaviour with increasing pressure was repeatedly observed for filtration of different PE through a 1 kD PVDF membrane [2-3] which could neither be explained by drop coalescence nor membrane abrasion or swelling. In addition, filtration of a dodecene/H20-PE resulted in higher permeabilities than filtering dodecene alone. This was confirmed for a CPME/H20-PE and a 10 kD membrane [4] and might due to the gel- and network-forming nature of these NP [5]. In contrast, H2000 do not form such networks and result in different behaviour in both emulsion and suspension filtration as well as in rheology.

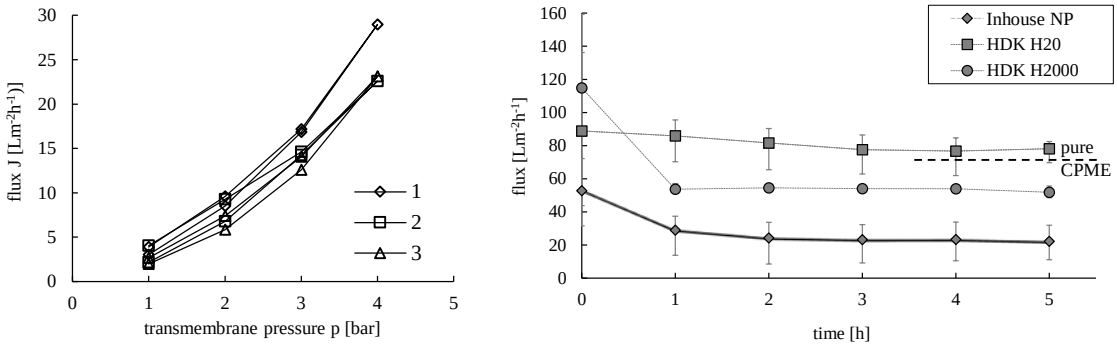

Figure 1. Left: Pressure stepping (dodecene PE, 2 g/$L_{dispersed\ phase}$ HDK H20, US, PVDF 1 kD, [3]). Right: Flux over time for different NPs (CPME PE, UT, PES 10 kD, 2 bar, [4]).

For all suspensions, almost linear flux increases were found. This means that drops add to the interactions, e.g., by adsorbing otherwise unbound residual NP at their interface but also by influencing the rheological behaviour. As opposed to the 1 kD ultrafiltration data shown above, first results indicate that using an OSN membrane with a similar MWCO (900 D) yields feasible permeabilities of around 3 L/(m² h bar), linear relationships and PE fluxes that are lower than pure solvent fluxes.

4. Conclusions

Membrane filtration was shown to be a promising process concept for the separation of aqueous PE droplets from continuous organic phases and thus for continuous liquid/liquid reactions in PE. The gel-forming H20 particles yield unexpected and different filtration behavior than other NP. Separating the influences of all present materials will help to understand individual interactions of all phases which is required for optimum material selection and robust process design.

Highlights

- Interfacial phenomena during liquid-liquid reactive extraction are analyzed
- Dynamic interfacial tension is proposed as an easy method to monitor interfacial reactions
- A mathematical model gives insights in interfacial reaction mechanisms

1. Introduction

3-Hydroxypropionic acid (3-HP) is an attractive platform molecule that can be converted to several materials, such as acrylic acid and biodegradable polymers. Its production by bioconversion has made remarkable advances, but its industrial commercialization is still limited by low productivities caused by product inhibition. *In situ* liquid-liquid reactive extraction assisted by a hollow fiber membrane contactor (HFMC) is a promising strategy to intensify 3-HP bioconversion [1,2]. Several points remain to be better understood, however, to develop a continuous extraction system coupled to bioconversion and maintain a low acid concentration in the medium. 3-HP extraction performed on a hollow fiber membrane contactor occurs at the interface formed inside the pores of the membrane, between two immiscible liquids. Proper interface stabilization is an important factor to avoid emulsions and direct contact of the organic phase with cells. It is also known that extraction rates can be markedly affected by interfacial mass transfer. All this highlights the need to better understand the interfacial phenomena involved during 3-HP extraction. In this study dynamic Interfacial Tension (IFT) was used to monitor concentration of the chemical species at the interface. This allows investigating the mechanisms of mass transfer during 3-HP reactive extraction, by developing a mathematical model that relates IFT with interfacial concentration of species, in addition to usual bulk concentration measurements.

2. Methods

The studied system consisted of 3-HP at 7 different initial concentrations (0 to 50 g/L) in the aqueous phase, and Trioctylamine (TOA) diluted in n-decanol at 20% v/v as the organic phase. For IFT measurement, both phases were put in contact in a Pendant Drop Tensiometer, putting the 3-HP solution in a syringe that creates a pendant drop inside the organic phase. In membrane contactors, mass transfer is mainly controlled by diffusion in the membrane pores. Such a configuration mimics mass transfer conditions at the interface situated in membrane pores. A previously developed mathematical model that successfully describes interfacial equilibrium of the chemical species in the considered extraction system [3] was combined with a mass transfer model

adapted to the geometry and physical conditions of the pendant drop method. Then, the Gibbs equation that relates IFT with interfacial species concentration combined with the Langmuir-Freundlich adsorption isotherm were used to compare model predictions with dynamic IFT measurements.

3. Results and discussion

Dynamic IFT values were chiefly related to interfacial 3-HP/TOA complex concentration formed in reactive extraction, calculated by the model. IFT value of the organic phase with water was 10.24 mN/m, and this value decreased when 3-HP initial concentration increased. The lowest measured value was 6.36 mN/m with an initial concentration 3-HP of 50 g/L. These values are low enough to make potentially difficult the interface stabilization in the pores. Results showed that observed mass transfer in the pendant drop tensiometer could not be explained by molecular diffusion only and involved local convection in the organic phase [4]. The model allows one to estimate adsorption and desorption rates of chemical species at the liquid-liquid interface and the interfacial concentration of the acid-amine complex, the main surface-active species. Insights in the interfacial reaction mechanisms obtained in this study will be useful to determine the rate-limiting mechanisms (adsorption, desorption, reaction, diffusion, convection) in HFMC.

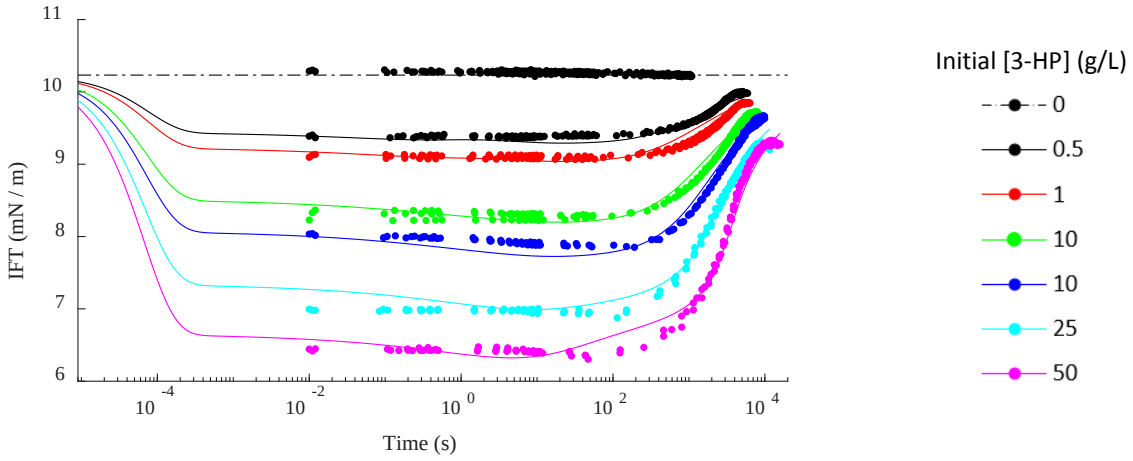

Figure 1. Dynamic Interfacial Tension at different initial 3-HP concentrations. Filled circles: experimental values. Lines: model results.

4. Conclusions

Information obtained from this study validates assumed mass transfer and reaction mechanisms and sets the stage for model-based process optimization in the HFMC configuration.

Highlights

- A 2D TPSA model was developed to separate an industrial scale VCM/N_2 mixture.
- A MTA geometry was used to increase the heat transfer rate of the system.
- A 6-step TPSA system with 3 MTAs was designed for the required separation.
- The system produces VCM with 95% purity and N_2 with less than 8 ppm of VCM.

1. Introduction

Vinyl chloride (VCM) is the main monomer in the production of polyvinyl chloride (PVC), as well as, a toxic and carcinogenic agent. As the polymerization reaction is not complete, the unreacted VCM must be stripped from the polymer, separated, and recycled. Prior art [1,2] details the use of activated carbon for the adsorption based separation of a VCM/nitrogen (N_2) mixture using steam purge regeneration. Drawbacks include a high temperature profile during the adsorption step, a high temperature requirement for regeneration and the creation of a contaminated condensed water stream. A design that overcomes these requirements is one that follows the geometry of a multitubular heat exchanger (MTA), in which the adsorbent material is split up and packed into several tubes, while the heat transfer fluid flows on the outer shell side. In this work, a 2D model of a TPSA system coupled with a MTA geometry will be designed to separate and purify a 40% (v/v) VCM rich mixture in N_2, using the activated carbon Pittsburgh type PCB. This process must produce a VCM stream with high enough purity to be recycled into the reactor feed (95% (v/v)) and a N_2 stream with a VCM composition that complies with the regulated gas emission levels (8 ppm (w/w)).

2. Methods

To simulate a 2D multicomponent TPSA model in a MTA, a set of mass, energy, and momentum balances must be specified, and some considerations must be made: the gas phase follows the ideal gas behaviour; the internal mass transfer resistance is expressed with the Linear Driving Force model; the external mass and energy transfer resistances are expressed with the film model; the column porosity, cross section and particle density are constant along the column; the temperature profile is homogeneous inside the particle; the Ergun equation is valid locally; the header tube arrangement achieves uniform flow distribution; the shell heat transfer performance is similar over all the tubes in the shell cross section; the shell side energy transfer resistance in the neighbourhood of each tube is negligible. Based on these considerations, the MTA geometry can be represented by the translation symmetry of each packed tube. As such, to calculate the performance of the proposed equipment, only the tube side of the equipment needs to be

simulated. The dimensions of this equipment were mostly based on values found in literature, to both guarantee an executable design and to facilitate size and parameter estimations.

3. Results and discussion

As illustrated by Figure 1a, the proposed TPSA cycle consists of six steps. In the Feed step, the gas mixture is feed into the packed tubes to produce a N_2 stream at a pressure P_{high}. During this step, the exothermic high-pressure adsorption of VCM heats up the adsorbent material, and, therefore, must be continually cooled down by the shell side heat transfer fluid at T_{low}. In the Rinse step, part of the recovered VCM stream is refeed into the packed tubes. In the Blowdown step, the tubes are radially heated up by the shell side heat transfer fluid at T_{high}, and blown down counter currently to the low-pressure P_{low}, producing a VCM rich stream. In the Purge step, the packed tube is further regenerated by a counter current N_2 product purge. In the Cooldown step, the tubes are cooled down back to T_{low} and are repressurized to P_{high} using the N_2 product, in the Pressurization step.

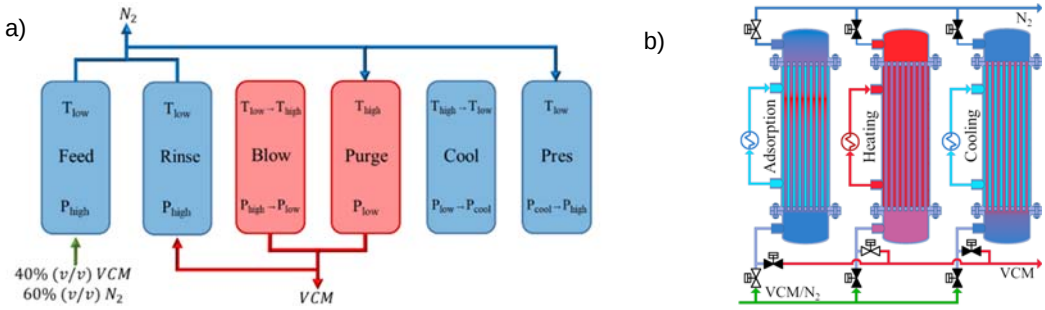

Figure 1. a) Outline of the TPSA cycle steps b) Schematic of the STHX-TPSA cyclic system.

It was set that each MTA should have 230 tubes with an outer diameter of 32 mm, thickness of 1.2 mm and 6 m length, for a total of 500 kg of adsorbent material. Following a square pitch design with a clearance of 8 mm, the shell diameter was estimated at 80 cm. The Feed step lasts 1800 s, the Rinse step 200 s, the Blowdown step 600 s, the Purge step 1400 s, the Cooling step 600 s and with a Pressurization step of 800 s the present model can be extended to a triple MTA system to guarantee a continuous feed consumption and purified stream production, as exemplified in Figure 1b. For this system, the high and low pressure, and temperature were, respectively, 100 kPa and 50 kPa, and 393 K and 293 K, which enables the use of pressurized water as the heat transfer fluid. In cyclic steady state, the purified N_2 stream contains 2.1 ppm (w/w) of VCM, and the VCM stream with a purity of 95.1% was obtained. This system reports a thermal energy consumption of 5.07 MJ/kg_{VCM}, which includes the thermal duties of the MTA and the electric energy consumption of the gas pressurization and vacuum, and liquid pumps.

4. Conclusions

A 2D multicomponent TPSA model following a MTA geometry was developed and successfully applied for the equilibrium adsorption separation of a VCM/N_2 mixture. The proposed equipment is successfully able to produce a VCM stream with a 95 % (v/v) purity, and a N_2 stream with a VCM content below the 8 ppm (w/w) emission level, with an energy consumption of 5.07 MJ/kg_{VCM}.

Modeling solid-state deracemization via temperature cycles

Brigitta Bodák*, Francesca Breveglieri, and Marco Mazzotti

Institute of Process Engineering, ETH Zurich, 8092 Zurich, Switzerland

**Corresponding author: bbodak@ethz.ch*

Highlights

- Mathematical model of solid-state deracemization via temperature cycles was developed.
- The effect of the model parameters was investigated.
- Favorable conditions were identified as a function of the model parameters.

1. Introduction

Although preferential crystallization is a standard industrial process to obtain enantiopure crystals of conglomerate forming compounds, its maximum theoretical yield is 50%, unless one adds to it recycle and racemization steps [1]. On the contrary, one can produce an enantiopure powder from an initially racemic one through solid-state deracemization by exploiting several techniques [1,2]. Among such techniques, that based on temperature cycles is a promising candidate for industrial applications due to the simplicity of the setup required [1, 3, 4]. Because of the complexity of the process, its optimal implementation requires an accurate and reliable mathematical model [3].

Extending our isothermal population balance based model of attrition-enhanced deracemisation [3], we have developed a non-isothermal model to provide a clear explanation of the phenomena involved in the process [5]. Moreover, this model aims at explaining the sensitivity to variations in the model parameters, such as the breakage rate, the agglomeration rate, etc. that is challenging to be experimentally investigated.

2. Methods

We describe the evolution of the crystals during temperature cycles using a population balance model. The model describes the interplay of several phenomena (size-dependent solubility, crystal growth and dissolution, agglomeration, attrition and racemization) accounting for the dependence of their thermodynamic and kinetic parameters on the crystal size and on the temperature.

3. Results and discussion

We have developed a non-isothermal model, assuming to operate with an ideal temperature controller, hence the specified time-dependent temperature profile can be used instead of modeling heat transfer and temperature evolution through an energy balance. By identifying the relevant variables and their corresponding characteristic values, we have also derived the non-dimensional equations associated to the non-isothermal model. The nondimensional model allows to study the deracemization process in a quasi-universal manner, without the knowledge of the physical and chemical parameters, which are dependent on the specific system considered.

Using the PBE-model that we have introduced, we have simulated temperature cycles in batch crystallizers. The model is characterized by several physicochemical parameters, additionally, the outcome of the process depends on the initial and on the operating conditions. The effect of the process parameters was shown to compare well qualitatively with the experimental results that were investigated in a systematic way previously by our group [1]. The focus of this contribution is to investigate the effect of the model parameters on the process, e.g. the rate of breakage, the parameters of the agglomeration kernel, the rate of racemization, etc.

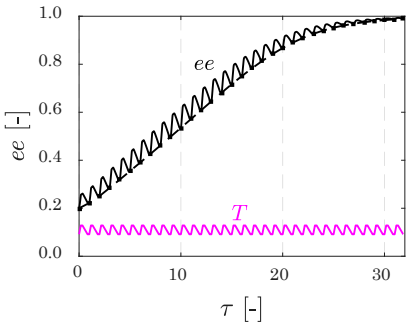

Figure 1. Evolution of the enantiomeric excess along the nondimensional time during deracemisation via temperature cycles. The magenta line indicates the generally utilized temperature profile (the line is not in scale with the values of the enantiomeric excess).

Various research groups studied experimentally how varying the operating temperature range or changing the cooling rate influence the process for different model compounds [1,4]. A thorough system parameter analysis can provide information on how to apply the role of initial asymmetry for different compounds to obtain the pure enantiomer. This analysis requires numerous simulations varying the model parameters that are associated with the chemicophysical properties of various model systems and their relative values that can vary for each substance. Therefore, we performed simulations to analyze the response of the system in a wide range of model parameters. With the help of the model these effects were evaluated and quantified based on the productivity.

4. Conclusions

We investigated the influence of several model parameters on deracemization via temperature cycles. Using the model the feasible and the optimal design spaces were identified.

The Role of Competitive Sorption in CO_2/CH_4 Separation with Membranes

Eleonora Ricci[1], Francesco Maria Benedetti[1], Maria Grazia De Angelis[1,*]

1 Department of Civil, Chemical, Environmental and Materials Engineering, University of Bologna, Via Terracini 28, 40131, Bologna, Italy

**Corresponding author: grazia.deangelis@unibo.it*

Highlights

- Sorption of CO_2/CH_4 mixtures in glassy polymers is characterized by strong competitive effects.
- Competition enhances the solubility-selectivity, improving membrane separation.
- Sorption has a greater influence on the separation than diffusion in multicomponent conditions.

1. Introduction

Gas separation with membranes is described by the solution-diffusion model, according to which the process is governed by a combination of solubility and diffusivity factors. When a moderately condensable gas, like CO_2, is involved in the separation, the solubility contribution plays a significant role in the process. Membrane materials characterization is often performed with pure gases. However, gas transport in mixed-gas conditions generally deviates from the pure-gas case. Competitive and synergistic effects are responsible for significant non-idealities, that cannot be properly evaluated with pure-gas measurements. Therefore, to uncover the relevant physical effects and assess the membrane performance closer to actual operating conditions, multicomponent tests are necessary.

In this work the sorption of CO_2/CH_4 mixtures in several high-performance glassy polymers was characterized experimentally, by means of a modified pressure-decay apparatus [1], and modelled using thermodynamic-based and empirical models, with the aim of identifying a reliable predictive tool, to reduce or complement the experimental effort. Finally, mixed-gas sorption measurements and literature multicomponent permeation data were coupled to evaluate gas diffusivity in multicomponent conditions and its effect on the separation.

2. Methods

Sorption of CO_2/CH_4 mixtures in several high free volume glassy polymers (PIM-1, TZ-PIM, PIM-EA-TB, PTMSP, Thermally Rearranged polymers) was evaluated at different compositions (10-50 mol.% CO_2) at 35 °C and up to 30 bar, using a dual-chamber pressure-decay apparatus coupled to a gas chromatograph [1]. Modelling of mixed-gas sorption data was performed with the NELF model (non-equilibrium extension of the Sanchez-Lacombe equation of state) [2] and with the Dual Mode Sorption model [3]. Both models require only pure-gas data in order to be parameterized and can be used to calculate multicomponent behavior predictively. Using the solution-diffusion model, diffusivity coefficients were calculated in the mixed-gas case, in order to evaluate the diffusivity contribution to the overall selectivity.

3. Results and discussion

The tests showed that the key feature of mixed-gas sorption in glassy polymers is the reduction of the solubility of both species with respect to the pure-gas case, due to competitive effects. However, the extent of this reduction is markedly different for the two gases, and is a function of mixture composition, temperature and pressure of the system, as it can be observed in **Figure 1** for the case of PIM-1. In particular, in the presence of a second component, the less condensable gas (CH_4) is excluded from the membrane to a much higher extent than CO_2.

This effect has a positive impact on the separation performance of the membrane materials, because it enhances the solubility-selectivity with respect to the ideal value, especially at high pressures, leading to increased ease of separation.

Both models used to calculate mixed-gas sorption were capable of capturing this reduction in solubility, however the NELF model showed a higher robustness and better quantitative agreement with the experimental data, also in the prediction of the solubility contribution to selectivity.

CH_4 diffusivity at multicomponent conditions was found to be systematically higher with respect to the pure-gas case, due to the simultaneous presence of a swelling agent (CO_2), which promotes a faster diffusion of CH_4. As a result, the diffusivity differences contribute only slightly to the selectivity of the membrane materials in real multicomponent operating conditions.

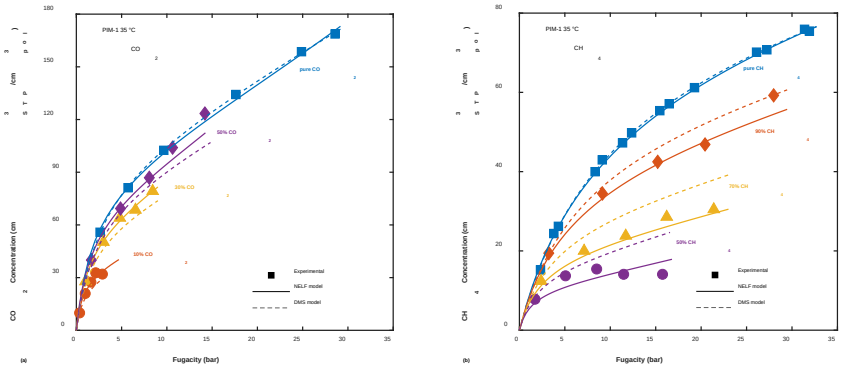

Figure 1. Sorption of CO_2/CH_4 mixtures in PIM-1 (symbols, [4]) at 35 °C and various mixture compositions, together with NELF model predictions (solid lines) and Dual Mode Sorption model predictions (dashed lines).

4. Conclusions

Sorption of CO_2 and CH_4 mixtures was measured in several glassy polymers suitable for CO_2 separation. The main effect in these systems is competitive sorption, which leads to a strong exclusion of the less condensable gas (CH_4) and results in an increased solubility-selectivity of the membrane. The NELF model successfully predicted this behavior, capturing also the effects of temperature and composition on the equilibrium, using only pure-gas parameters as input. Finally, a combined analysis of our measurements of mixed-gas sorption and multicomponent permeability data from the literature, allowed to establish that sorption is the most significant factor for CO_2/CH_4 separation with these membrane materials.

Highlights

- We succeeded in the preparation of silica membranes with hydrophobic functional groups.
- The prepared membrane showed higher durability than the previously reported polymeric membrane.

1. Introduction

Many nanofiltration membranes, which show the molecular weight cut-off (MWCO) of 200-2000, are used for the separation of water form aqueous solutions. Development of organic solvent nanofiltration (OSN) membranes, which can permeate organic solvents, is desired for recovery and recycling solvents in pharmaceuticals and petrochemical industries. This membrane technology can greatly reduce the waste solvents which need multiple separation steps and associated costs. However, polymeric membranes generally have a low durability for organic solvents. In this research, silica was used as a membrane material in order to improve the durability for organic solvents. We investigated the effect of the type of solute on the OSN performance of the silica membranes. In addition, short-time durability of the silica membrane was confirmed.

2. Methods

Membrane preparation

Propyl-functionaized silica membranes (PrFS membranes) were prepared on porous supports consisted of zirconia substrates (outer diameter: ϕ 2 mm, inner diameter: ϕ 1 mm) with γ-alumina interlayers[1]. A propyltrimethoxysilane (PrTMS) silica sol was prepared by hydrolysis and copolymerization of the PrTMS. The PrTMS (0.1 mol) was added to the solution consisted of cetyltrimethyl-ammoniumbromide (CTAB) (0.008 mol) and 25 mL of EtOH with gentle stirring. 7.5 mL of 1 mol $L^{-1}HNO_3$ was delivered by drops into the solution to promote the hydrolysis and condensation reactions of the PrTMS. Then, the solution was stirred continuously at room temperature for 6 h. The porous support was dipped into the PrTMS solution for 60 s and then pulled out at a speed of 1 cm min^{-1}. The support was dried at room temperature for 3 h and calcined at 453 K for 3 h. The membrane was then washed with ethanol to remove CTAB.

Nanofiltration test

Rose bengal(RB)/ethanol (EtOH), brilliant blue/EtOH, tartrazine(TZ)/EtOH and methyl orange/EtOH solution were used as the feed solution. Concentration of solutes in the feed solutions

was 35 µmol l^{-1}. The concentrations of the feed and permeate solutions were measured using an absorbance meter (ASUV 6300PC, ASONE corporation). Feed pressure was 5 bar.

3. Results and discussion

The MWCO of the PrFS membrane and average permeance in the solute are shown in Fig. 1. The MWCO of the PrFS membrane was 492. The permeance was highest in the case that TZ was used as the solute. It is considered that the affinity between the solute and the membrane surface may be related to this phenomenon. Fig. 2 shows the relationships between time and permeance in RB/EtOH system. The permeance reached 200 g m^{-2} h^{-1} bar^{-1} in about 60 min, and was nearly constant until end of the 420 min durability test. Since the PrFS membrane is based on the siloxane network, it is considered the durability against organic solvent is relatively high.

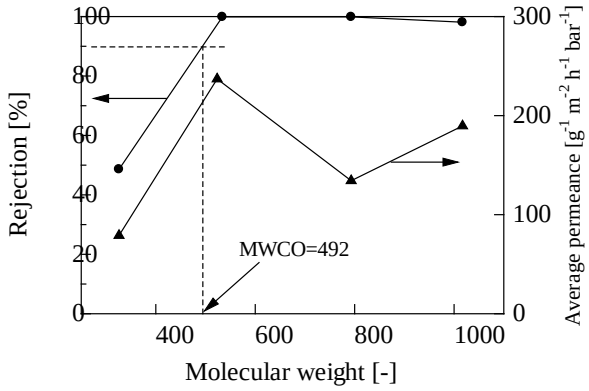

Fig. 1 The MWCO of the PrFS membrane and the relationships between molecular weight and permeance about PrFS membrane

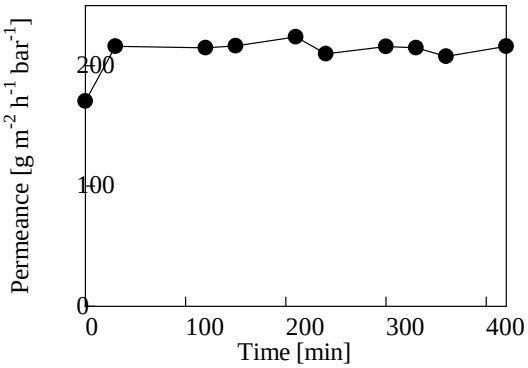

Fig. 2 The relationships between time and permeance in RB/EtOH system

4. Conclusions

The MWCO of the PrFS membrane was 492. The permeance was highest in the case that TZ was used as the solute. It is considered that the affinity between the solute and the membrane surface may be related to this phenomenon. The permeance was nearly constant form 60 min until end of the test in the RB/EtOH system.

Selective recovery of nickel and copper from spent acids by chelating resins

Laura Ulloa*, Eugenio Bringas, María Fresnedo San Román

Chemical and Biomolecular Engineering Department

ETySIIT, University of Cantabria, Avda. De los Castros, 39005, Santander, Spain

Highlights

- Chelating resins are able to separate and recover Ni and Cu from acid media
- Equilibrium is described by the Langmuir model
- pH allows to control the selectivity of Ni/Cu separation
- Selective recovery of both metals is achieved by using H_2SO_4 and NH_3

1. Introduction

The management of metal-containing acidic effluents is usually performed by conventional treatment methods which exhibit some limitations such as the lack of selectivity, limited efficiency to reach the required concentration limits, waste generation, etc.; therefore, novel technologies are needed not only to overcome the aforementioned limitations, but also to recover valuable metals for further use. Generally, spent acids are complex wastes that contain high concentrations of metals and mineral acids, usually sulfuric or hydrochloric acids. In this work, spent acids containing nickel, copper and iron in sulphate media were provided by a local waste management industry. The selective removal and recovery of nickel and copper was experimentally analyzed using the chelating resin MTS9600® (bis-picolylamine functionalization) (Purolite). After describing the adsorption equilibrium, the influence on the process kinetics of different operation variables namely pH and solid/liquid (S/L) ratio was analyzed. Finally, the regeneration of the loaded resins allowing the independent recovery of both metals was assessed using H_2SO_4 and NH_4OH as regeneration agents.

2. Methods

In the adsorption equilibrium experiments, a certain amount of resin was contacted during 24 hours and constant temperature (25ºC) with spent acids with the following average composition: $[Ni^{2+}]$=9 g/L, $[Cu^{2+}]$=3 g/L, $[Fe^{2+}]$=24 g/L and pH≈1). The equilibrium concentrations of nickel, copper and iron in the aqueous phase were analyzed by Plasma-Atomic Emission Spectrometer (4210 MP-AES, Agilent Technologies®) being the values fitted to theoretical equilibrium isotherms. Kinetic experiments were carried out at 25ºC in a flask with continuous stirring during 3 hours under uncontrolled and controlled pH conditions using NaOH 5M. The S/L to liquid ratio varied from 1/10 to 1/2.5 mg/mL and the pH set point was set to values in the range between 1.5 to 3. Samples were taken at different times during the process and metal concentrations were measured. Regeneration was performed by contacting during 1 hour loaded resins with H_2SO_4 and after NH_3 at different concentrations and S/L ratio.[1],[2]

3. Results and discussion

Equilibrium data for both metals, nickel and copper, followed the Langmuir equilibrium model with values of the maximum adsorption capacity (q_{max}) of 50761 mg Ni/Kg dry resin and 97087 mg Cu/kg dry resin. However, the equilibrium constant for copper (K_L=0.063 L/mg) is more than 40 times higher than the value for nickel (K_L=1.47 10^{-3} L/mg) thus confirming the preferential affinity of the resin towards copper ions. On the other hand, Figure 1 shows the influence of pH on nickel and copper kinetics. In the case of copper, it is observed that kinetics and removal percentages at equilibrium conditions, near 100%, do not depend on the pH. However, in the case of nickel, removal yields decreased from 90% at pH≥2 to values lower than 50% at pH<2. By varying the S/L ratio it is concluded that the lower the ratio, the slower the nickel kinetics and the smaller the extraction percentages (20% for S/L=1/2.5 and 90% for S/L=1/10). However, copper kinetics are only affected at low values of the S/L ratio. The results from the regeneration experiments proved the selectivity of the proposed methodology, since only nickel was found in the stripping solution after one step of regeneration with H_2SO_4 1 M (43% recovery, 957,81 mg/L solution) and only copper was detected after the second regeneration stage with NH_3 2 M (45% recovery, 614,06 mg/L solution).

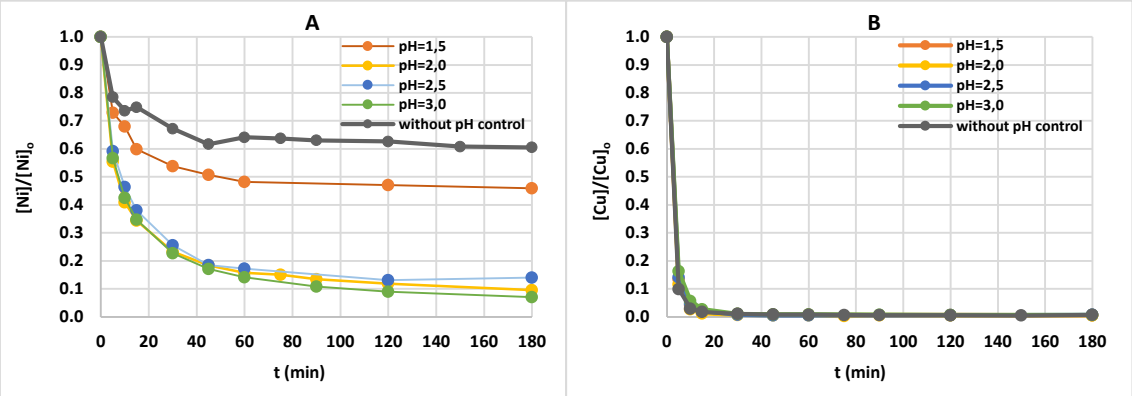

Figure 1. Time profiles for the removal of nickel (A) and copper (B) from spent acid wastes with MTS9600® resin.

4. Conclusions

From the experimental results it is concluded that the chelating resin MTS9600® is a suitable separation agent to recover transition metals from aqueous industrial wastewater at low pH values, since it reports removal percentages of nickel and copper of≈90% and ≈100% . It was also proved that the methodology proposed can lead to two high purity solutions of each metal after two in series regeneration stages with H_2SO_4 1 M and NH_3 2 M.

Analysis of gas-liquid mass transfer around ascending microbubbles

Audrey Devatine[1], Carine Julcour[1], Anne-Marie Billet[1]

[1]*Laboratoire de Génie Chimique, Université de Toulouse, CNRS, INPT, UPS, Toulouse, France*

Highlights

- Experimental device that generates a chain of individual sub-millimeter bubbles
- Coupled experimental techniques: ombroscopy and optical recording of dissolved oxygen concentration
- Mass transfer model accounting for the composition variation of the rising bubbles
- Evaluation and analysis of the liquid-side mass transfer coefficient associated to microbubbles

1. Introduction

Gas-liquid transfer using micro bubbles (i.e. smaller than 1 mm) is a specific operation which is encountered for instance in wine processing or for oxygenation of stress sensitive cell culture. However, mass transfer performance obtained with a swarm of microbubbles has been rarely studied (Chiciuc et al., 2010; Devatine et al., 2013) and available correlations for millimeter-sized bubbles are usually extrapolated to this case. In this work, we have designed a dedicated device allowing studying mass transfer around a single ascending microbubble. The liquid-side mass transfer coefficient is then obtained by interpreting the experimental results with a convenient model. The resulting values of the liquid-mass transfer coefficient are compared with conventional correlations for mass transfer around a rigid sphere.

2. Methods

The experimental device is illustrated in Figure 1. It consists in a square transparent column of 1cm wide by 5cm high. Pure nitrogen or air is injected at the bottom, via a capillary (50 µm inner diameter) with a beveled cut orifice to generate sub-millimeter bubbles. The size and generation frequency of the ascending microbubbles are determined from image analysis of video records using a fast camera (Micron M20 – frame rate = 200 Hz). Oxygen absorption or desorption experiments are performed and the time evolution of the dissolved oxygen concentration is determined using a non-intrusive optical sensor located at the top of the column (Presens – Pst3: 0-45 mg.L^{-1}).

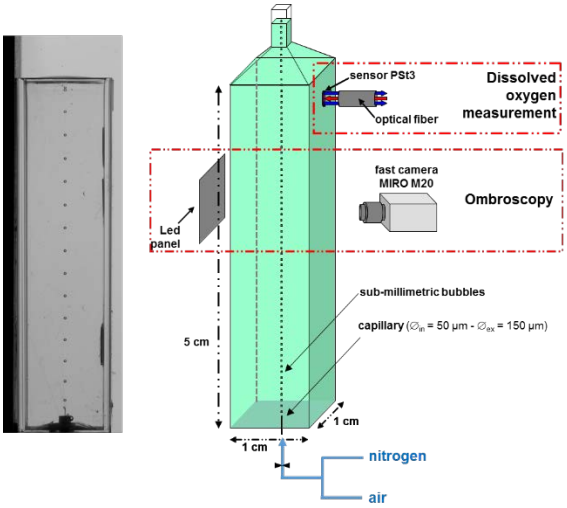

Figure 1. Experimental device.

3. Results and discussion

A quasi-steady state one-dimensional model evaluates the evolution of the bubble composition during its rise, thus the axial variation of the interfacial concentration. The average value is then accounted for in the mass balance describing the time-evolution of dissolved oxygen (DO) in the liquid bulk, which is considered perfectly mixed.

This approach gives access to the liquid-side mass transfer coefficient k_L according to the following equation:

$$k_L = -\frac{H_c V_b}{A_b H_L / \nu_b} \ln\left(1 + m \frac{V_L}{r_b H_c V_b}\right)$$

with k_L liquid-side mass transfer coefficient ($m.s^{-1}$)
H_c Henry's constant (referring to concentrations)
V_L liquid volume in the cell (m^3)
A_b bubble area (m^2)
H_L liquid height (m)
ν_b bubble velocity ($m.s^{-1}$)
V_b bubble volume (m^3)
r_b bubble frequency (s^{-1})
m slope of the regression line of $\ln(C_i/C) = f(t)$ for desorption experiment

where C_i DO concentration at initial time ($kg.m^{-3}$)
C DO concentration ($kg.m^{-3}$) during desorption

An example of time evolution of DO concentration is given in Figure 2 in the case of desorption by nitrogen bubbles. Figure 3 shows the linear regression of the DO data that gives the slope m for use in the above equation.

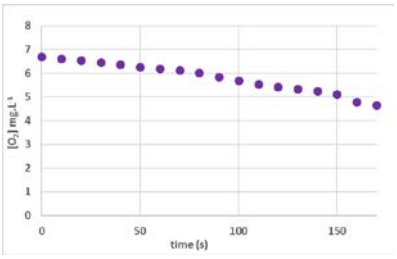

Figure 2. Oxygen desorption by nitrogen bubbles.

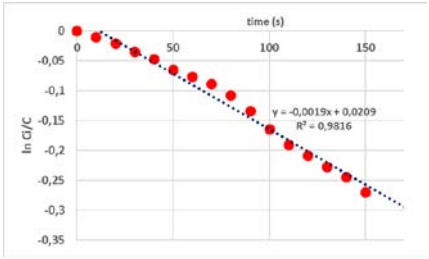

Figure 3. Mathematical processing of desorption data.

4. Conclusion and perspectives

The liquid-side mass transfer coefficient of individual ascending bubbles has been determined, showing a good agreement with that measured for a swarm of bubbles in our previous works (Devatine et al., 2013). Moreover, these values are well fitted by conventional mass transfer correlations established for rigid spheres.

Chiral Symmetry Breaking and Deracemization of Sodium Chlorate in Taylor Vortex Flow

Jaekyu Ahn[1], Bowen Zhang[1], Gerard Coquerel[2], Woosik Kim[1]

1 Department of Chemical Engineering, Kyung Hee University, Yongin-si Kiheung-ku Soechun-dong 1, Kyungki-do, Korea, 2 SMS Laboratory EA3233, University of Rouen Normandy, F-76821 Mont Saint Aignan CEDEX, France

**Woosik Kim: wskim@khu.ac.kr*

Highlights

- Taylor vortex flow promoted the chiral symmetry breaking and deracemization.
- Initial chiral symmetry breaking was enhanced by increasing the rotation speed.

1. Introduction

Due to the significant difference in pharmacological and biological effect of enantiomers of a chiral compound, the synthesis of chiral substance with a single chirality is of great value. A pioneer study for chiral symmetry breaking was reported by Kondepudi et al.[1] Enantiomerically pure crystals of sodium chlorate was obtained in evaporation crystallization with stirring, whereas symmetric chiral crystals were produced without stirring. Meanwhile, abrasive grinding using glass beads and temperature swing were demonstrated as highly effective techniques for promoting deracemization. [2] [3] According to Ahn et al study on the cooling crystallization of sodium chlorate, it was shown that the initial chiral symmetry breaking strongly depended on the turbulent fluid motion, because the turbulent eddy flow directly dictated the secondary nucleation during the induction period.[4] Thus, the initial chiral symmetry breaking was enhanced by increasing the agitation speed. Also, the final deracemization was determined by initial chiral symmetry breaking. So, the complete deracemization was achieved when the high initial chiral symmetry breaking occurred. It was already known that the periodic Taylor vortex flow was highly effective for the induction of nucleation and phase transformation in polymorphic crystallizations [5]. So, in the present study, Taylor vortex flow was applied to promote the chiral symmetry breaking and deracemization in cooling crystallization of sodium chlorate.

2. Methods

The cooling crystallization of sodium chlorate was carried out in a Couette-Taylor (CT) crystallizer. The feed solution of 96 g-$NaClO_3$/100 ml was prepared at a saturated temperature of 26 ºC, and then filtered with micro-filter paper. The feed solution in CT crystallizer was cooled from 26 ºC to 13 ºC at a constant cooling rate for cooling crystallization. After the feed solution reached at 13 ºC, the CT crystallizer was further run for the deracemization. Suspension samples were taken intermittently and quickly filtered using a vacuum pump, then dried in a convection oven. The chirality of crystals was analysed using polarized microscope (Olympus, BX53M, Japan). The

crystal enantiomeric excess (CEE) was defined as (CEE = ($N_{major} - N_{minor}$) / ($N_{major} + N_{minor}$)), where N_{major} and N_{minor} meant crystal numbers of major and minor forms, respectively.

3. Results and discussion

The effect of the Taylor vortex flow on the chiral symmetry breaking and deracemization of sodium chlorate was investigated. As shown in Figure 1(a), initial chiral symmetry breaking (initial CEE) at low rotation speed of 100 rpm occurred at around 50%, and then, increased finally up to 80% (final CEE) by deracemization of chiral crystals. As increasing the rotation speed over 300 rpm, initial chiral symmetry breaking was enhanced over 80% and the complete deracemization was achieved within 7 hours. When considering the results in random turbulent flow, Taylor vortex flow was much effective for initial chiral symmetry breaking and deracemization of chiral crystal due to its unique periodic fluid motion. That is, Taylor vortex was much effective for the secondary nucleation during the induction period, resulting in high initial chiral symmetry breaking. Also, it promoted the deracemization of chiral crystals, bringing about the enantiomeric pure crystals within several hours. The cooling rate was also an influential factor in chiral symmetry breaking and deracemization, as shown Fig. 1(b). Initial chiral symmetry breaking was about 60% at high cooling rate of 0.295 °C/min, and it increased by decreasing the cooling rate. So, 91% of initial chiral symmetry breaking occurred at 0.0738 °C/min of cooling rate due to long induction period for the secondary nucleation. The deracemization also depended on cooling rate. Due to low initial chiral symmetry breaking at high cooling rate (0.295 °C/min), it took about 11 hours for complete of deracemization. However, it was reduced to 6 hours by decreasing the cooling rate to 0.0738 °C/min.

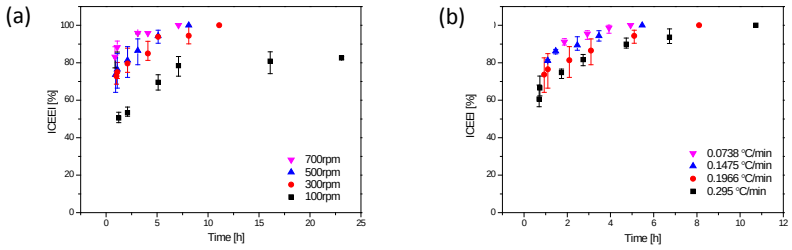

Figure 1. (a) Deracemization of sodium chlorate when varying rotation speed in cooling crystallization, The cooling rate was fixed at 0.197 °C/min; (b) Deracemization of sodium chlorate when varying cooling rate in cooling crystallization, The rotation speed was fixed at 500rpm [Calibri 9].

4. Conclusions

The Taylor vortex flow was highly effective for the secondary nucleation, resulting in high initial chiral symmetry breaking in the cooling crystallization of sodium chlorate. So, initial CEE was enhanced by increasing the rotation speed. As initial CEE increased, the deracemization was also facilitated. So, complete deracemization was achieved with initial CEE over 60%

Recovery of lignin from deep eutectic solvents by liquid-liquid extraction

Dion Smink[1], Sascha R.A. Kersten[1], Boelo Schuur[1]*

1 Department of Science and Technology (TNW), Sustainable Process Technology group, University of Twente, 7500 AE Enschede, The Netherlands

**Corresponding author: b.schuur@utwente.nl*

Highlights

- Lignin was recovered from DES by liquid-liquid extraction
- 2-MTHF is a suitable, bio-based extractant for lignin
- Addition of water greatly enhances lignin extraction by 2-MTHF

1. Introduction

Deep eutectic solvents (DES) are composite solvents that exhibit deep eutectic behavior upon mixing, and are often biocompatible, biodegradable and have a low toxicity.[1] Regeneration of deep eutectic solvents is most often performed by precipitation of either the solute or solvent in an anti-solvent. Especially in biomass fractionation, large amounts of water are required as anti-solvent for the precipitation of lignin.[2] We propose liquid-liquid extraction as an alternative method for the recovery of lignin from DES.

2. Methods

DES, solvent and any lignin were equilibrated in a shaking bath at overnight. The phases were separated and the concentrations of the DES constituents and solvent analyzed by high pressure liquid chromatography (HPLC). The lignin concentrations were analyzed as function of the molar weight by gel permeation chromatography (GPC). The lignin distribution coefficient was calculated as follows:

$$D = \frac{[lignin]_{Solvent}}{[lignin]_{DES}}$$

3. Results and discussion

The equilibria between the lactic acid - choline chloride DES and 2-MTHF were determined at three different temperatures. The phase equilibria are shown in figure 1. From this figure it can be seen that the temperature dependence of the equilibria is very small. Also, high amounts of choline chloride are required to create a phase split. All DES phases contained more than 27 wt.% choline chloride, but no choline chloride was found in the DES phases.

The lignin distributions between the 1.7:1 lactic acid - choline chloride DES and 2-MTHF were determined at 50 °C. Since water has a great influence on the lignin solubility in both DES[3] and low-hydrogen bond accepting solvents -such as 2-MTHF-, its influence on the lignin distribution was studied. It was found that the distribution coefficient increases with increasing amounts of water. Also, the effect of water is greater on the extraction of the higher molar weight fractions of the lignin. The results are shown in figure 2.

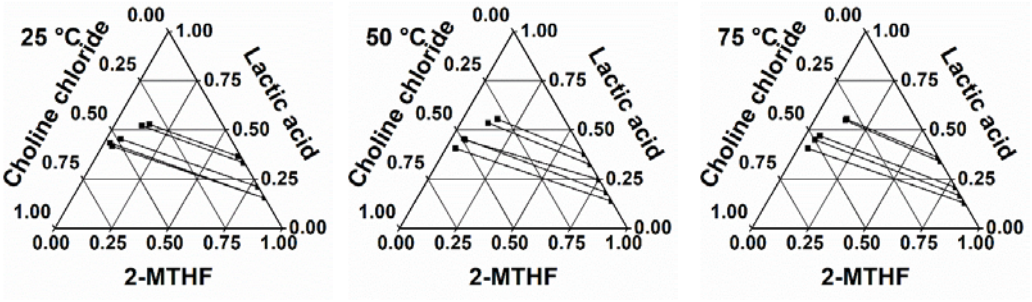

Figure 1. Phase diagram with liquid-liquid equilibrium data between choline chloride, lactic acid and 2-MTHF at 25, 50 and 75 °C. The axis show the mass fractions of the constituents.

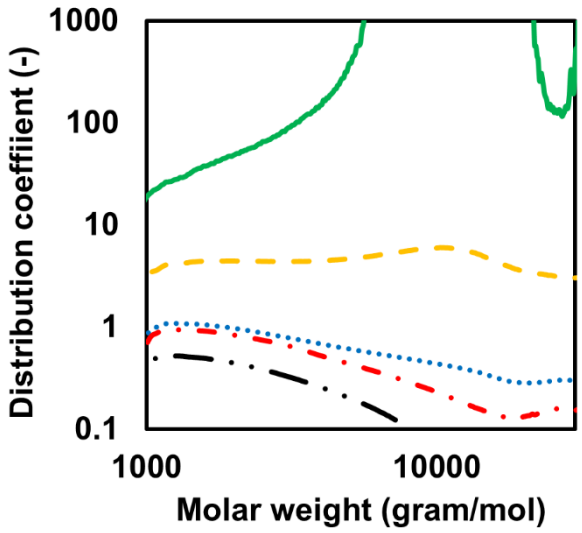

Figure 1. Distribution of lignin between DES and 2-MTHF at 50 °C. Various amounts of water were added to the DES: 50% (green-solid), 25% (yellow-dashed), 10% (blue-dotted), 5% (red-dash-dotted) and dry (black-dot-dot-dashed). For the parts of the green line that are out of the graph, no lignin fractions were found in the DES phase, and thus the distribution coefficient is infinite.

4. Conclusions

2-MHTF is a suitable extractant for lignin from DES. Addition of choline chloride to the DES is required to form two liquid phases and addition of more choline chloride decreased leaching of lactic acid to the 2-MTHF phase. The extraction lignin was studied and increases with increasing amounts of water.

Influence of Temperature and Pressure on Isooctane Permeability in Polydimethylsiloxane Membrane

Lenka Moravkova, Karolina Machanova, Petr Stanovsky, Zuzana Petrusova

Institute of Chemical Process Fundamentals of the Czech Academy of Sciences, Rozvojova 135, 165 02, Prague 6, Czech Republic

**Corresponding author: moravkova@icpf.cas.cz*

Highlights

- Separation ability of flexible PDMS is influenced on operation conditions
- Isooctane permeability depends significantly on trans-membrane pressure
- Isooctane permeability is negligible influenced by process temperature
- Reproducibility of isooctane permeability is within 5 %
- Membrane flux does not show any hysteresis for the change of feed concentration

1. Introduction

Generally, sorption and diffusion are the key parameters for gas and vapor permeation in the polymeric dense membrane. The diffusivity is higher for smaller molecules, while sorption is stronger for larger condensable molecules. The permeability mainly depends on the VOC concentration in the feed stream as well as the condensability of the relevant VOC. One of the main applications is the separation of volatile organic vapors from a permanent gas [1].

2. Isooctane and nitrogen permeability in PDMS membrane

The membrane was prepared by a casting knife from Elastosil polydimethylsiloxane (PDMS, Silicones and more) as a dense film with the thickness of 100 microns. Nitrogen and (isooctane + nitrogen) permeation experiments were carried out at three temperatures: 25°C, 30°C and 35°C and at four trans-membrane pressures: 100/50 kPa, 150/50 kPa, 200/50 kPa and 250/50 kPa. The membrane flux was determined from the increase of permeate pressure in time. The basic test apparatus was described previously in a detail [2].

3. Results and discussion

The representative figures of membrane flux are shown at various experimental conditions in Figure 1. PDMs polymer is a flexible material and it can be expected that operation conditions will influence the membrane flux. The temperature and trans-membrane pressure were changed within 25–35°C and 50–200 kPa. It was found that the flux increases with the isooctane feed concentration as expected because of a high solubility of organic vapors in polymeric membranes. The temperature influence was found to be small (Figure 1A) while the trans-membrane pressure influenced the membrane flux significantly (Figure 1B).

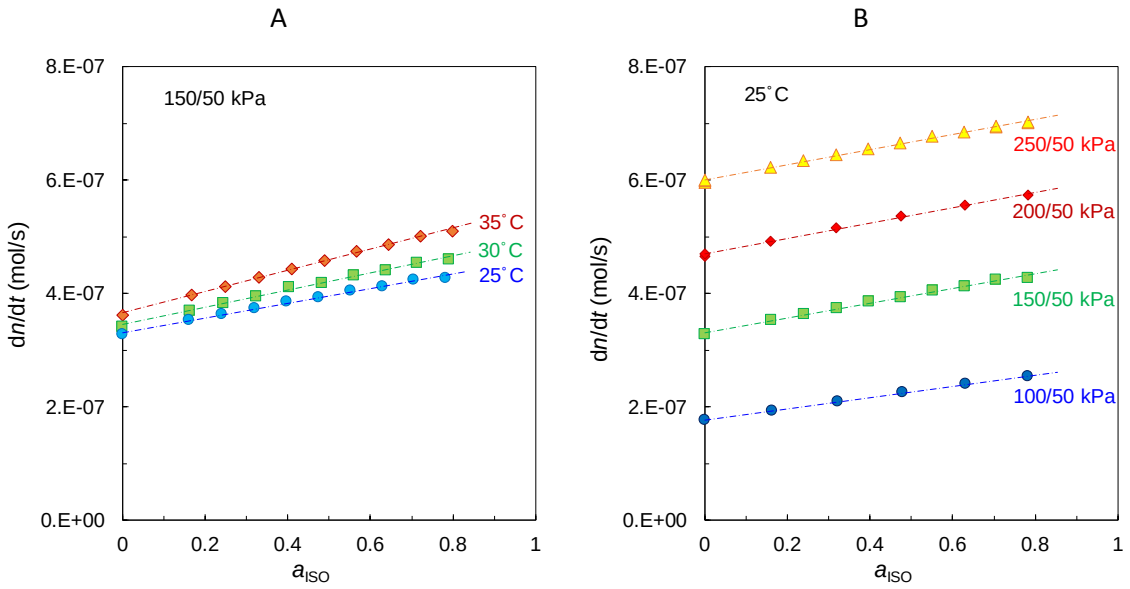

Figure 1. Influence of temperature (A) and trans-membrane pressure (B) on (isooctane + nitrogen) flux in PDMS.

4. Conclusions

It was found that the trans-membrane pressure has a significantly bigger influence on the flux in flexible PDMS polymeric membrane than temperature. None hysteresis was observed when the isooctane feed concentration increased and then decreased.

The increase of transmembrane-pressure from 50 kPa to 200 kPa caused almost three times higher membrane flux. While the membrane flux increased only negligible when the temperature increased from 25 °C to 35 °C. Interestingly, the increase of membrane flux was 40 % with the increasing isooctane feed concentration at the highest temperature while the membrane flux increased less at the highest trans-membrane pressure (by 17 %).

Highlights

- LCD measurements in real ED stacks are presented.
- Different profiled membranes are tested.
- LCD performance of profiled and flat membranes are compared.

1. Introduction

Limiting Current Density (LCD) is a crucial parameter in electrodialysis (ED), and depends mainly on membrane surface properties [1] and on concentration polarization phenomena [2]. The latter are influenced by fluid dynamic aspects related, above all, to the characteristics of the spacers used in the channels. When profiled membranes [3] are used to create the channel thickness in stacks without spacers, the modification of the membrane surface and the presence of active membrane areas in directions not orthogonal to the current affect the LCD. Also the profile type is expected to have an effect on the LCD. In the present work, we experimentally investigated the effect of different membrane profiles on the LCD, testing also different operating conditions. The performance of profiled membranes and flat membranes (with spacers in the channels) were compared. The results were also used to validate our ED process model.

2. Methods

A crossflow ED stack, consisting of 10 cell pairs, with an active area of 10×10 cm^2 was used. Fujifilm membranes profiled with pillars or with overlapped cross filaments were tested. Inlet concentrations of NaCl ranging from 0.5 to 60 g/l and inlet velocities in the range 0.25 – 2 cm/s were examined. Current-voltage curves were built by chronopotentiometric measurements, thus identifying the LCD. Results obtained with profiled membranes were compared with data previously obtained with flat membranes and spacers [4]. Moreover, the experimental results were compared with the predictions of a one-dimensional process model [4], in which all the non-ideal transport phenomena through the membranes (osmosis, electro-osmosis, salt diffusion) are considered. The model predicts also concentration polarization by correlations for the Sherwood number obtained from computational fluid dynamics (CFD) simulations.

3. Results and discussion

We observed that the current-voltage curves show different trends depending on the membrane profile type present in the diluate compartment. In particular, when the profiles of the anion exchange membrane (AEM) are in the diluate compartment (blue symbols in Figure 1), the *i-V* curve changes slope at higher currents, thus leading to higher LCD values. However, this configuration exhibits lower LCD values compared to a stack equipped with flat membranes and net spacers (empty symbols in Figure 1), which can be attributed, at least in part, to a poorer mixing promotion.

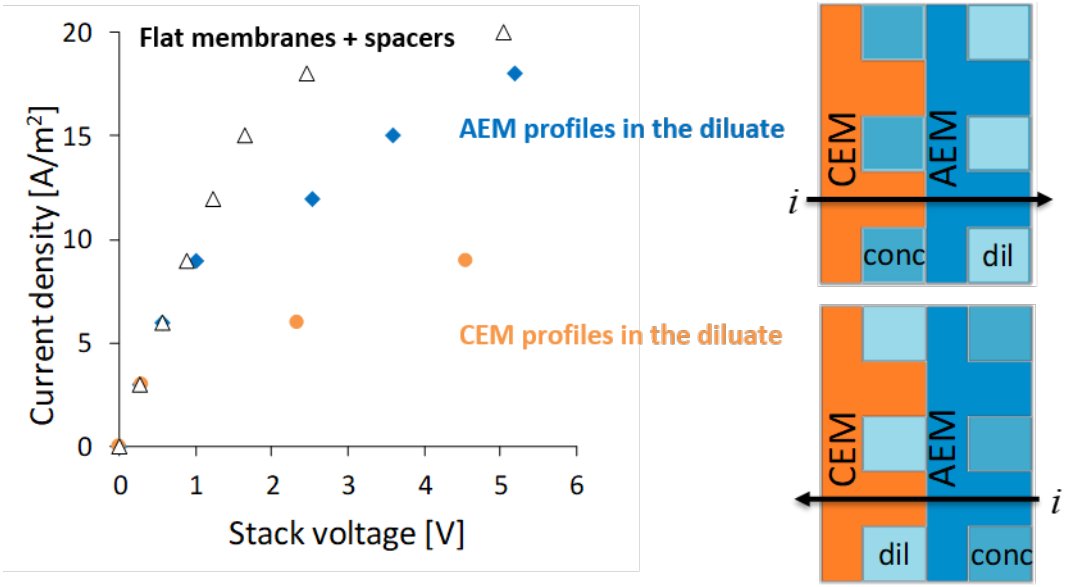

Figure 1. Current-voltage curves obtained with AEM profiles in diluate (blue symbols), with CEM profiles in the diluate (orange symbols) and with flat membranes and spacers (empty symbols). NaCl inlet concentration was equal to 0.5 g/l in both the concentrate and the diluate. Velocity was equal to 2 cm/s in both compartments.

4. Conclusions

In this work, we studied the influence of the membrane profiles on the LCD in ED units. We observed that the configuration with AEM profiles in the dilute channel is preferable, as provides higher LCD values. However, improved geometries have to be designed in order to enhance the performance with respect to conventional net spacers.

Highlights

- A mathematical model of heat transfer with specific heat and thermal conductivity coefficients dependence on temperature for a 3-layer environment is offered.
- Modeling of heat transfer process for 3-layer sandwich wall, made of gypsum materials with different densities, in case of fire is done.
- Theoretical model shown good connection with experimental burning results.

1. Introduction

The use of gypsum materials in construction is well known. The requirements for lighter materials with good thermal insulation are increasing. This material is foam gypsum, the technology of which makes it possible to obtain a product with a density of less than 200 kgm^{-3} [1]. Nowadays not only energy efficiency but also demands of better living comfort highly increase sound and fire safety requirements of building components. Lot of construction materials for acoustic and fire safety characteristics are gypsum based which can improved changing properties of the material. Sandwich type gypsum materials with different densities are widely used in construction. The objective of this study is to develop a mathematical model of heat transfer through sandwich type gypsum materials (gypsum board and foam gypsum layer) in fire conditions.

2. Methods

The 3-layer sandwich type wall in which the foam gypsum layer is bounded by gypsum boards is considered. It is assumed that the specific heat c_p and thermal conductivity *K* coefficients depends on temperature *T* similarly in [2]. The cubic spline interpolation for $c_p(T)$ and *K(T)* is used. In the case of three layers (N=3) we obtain the system of three PDEs

$$\begin{cases} D_1(T)\dfrac{\partial^2 T_1(x,t)}{\partial x^2} = \dfrac{\partial T_1(x,t)}{\partial t} \\ D_2(T)\dfrac{\partial^2 T_2(x,t)}{\partial x^2} = \dfrac{\partial T_2(x,t)}{\partial t} \\ D_3(T)\dfrac{\partial^2 T_3(x,t)}{\partial x^2} = \dfrac{\partial T_3(x,t)}{\partial t} \end{cases} \quad (1)$$

where $D_i(T) = \dfrac{K_i(T)}{\rho_i c_{pi}(T)}$, $i = 1,2,3$ are thermal diffusion coefficients depending on *T*. For the initial condition for *t=0* are given $T_1(x,0) = T_2(x,0) = T_3(x,0) = T_0$, where $T_0 = 20\ ^0C$. Following boundary and continuous conditions are used :

$$\begin{cases} D_1(T)\frac{\partial T_1(0,t)}{\partial x} - \alpha(T_1(0,t) - T_a) = 0\,,\ T_3(L,t) = T_b + T_l(t), \\ T_1(x_1,t) = T_2(x_1,t)\,,\quad D_1(T)\frac{\partial T_1(x_1,t)}{\partial x} = D_2(T)\frac{\partial T_2(x_1,t)}{\partial x} \\ T_2(x_2,t) = T_3(x_2,t)\,,\quad D_2(T)\frac{\partial T_2(x_2,t)}{\partial x} = D_3(T)\frac{\partial T_3(x_2,t)}{\partial x} \end{cases} \quad (2)$$

where α are the constant mass transfer coefficients, $T_l(t) = 345 \cdot lg(8t + 1)$ in minutes, $T_a = T_b = 20\ ^0C$.

Conservative averaging method for reduce problem (1)-(2) to an initial problem for system of ODEs [3] is used. The problem (1)-(2) is solved by using MathLab.

3. Results and discussion

Experiments were done with a wall of foam gypsum ($\rho = 450kgm^3$) inside separated by 6.5 mm gypsum boards ($\rho = 900kgm^3$). The thickness of the foam gypsum layer was 23 and 30 mm. Experimental and theoretical temperature distribution on both sides of wall and inside are shown at fig.1a and fig.2a. ,where the number means the distance to the fire in millimeters. Theoretical temperature distribution in the wall depending on the burning time at one of the edges is shown in the pictures 1b and 2b.

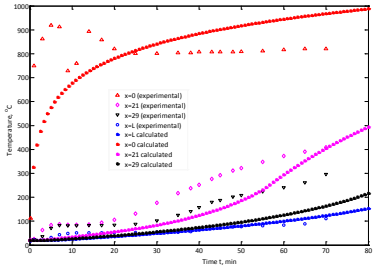

Figure 1a Temperature distribution in wall with thickness 36 mm.

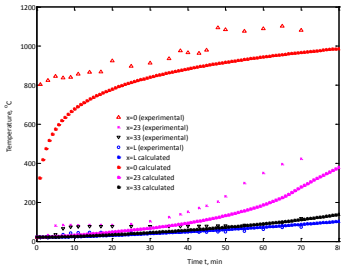

Figure 2a Temperature distribution in wall with thickness 43 mm.

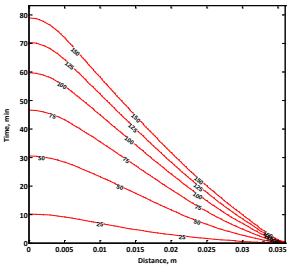

Figure 1b Theoretical calculated temperature distribution inside wall with thickness 36 mm.

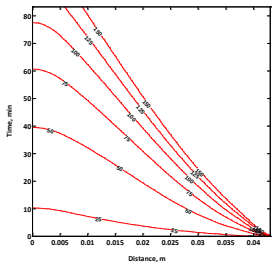

Figure 2b Theoretical calculated temperature distribution inside wall with thickness 43 mm.

4. Conclusions

Proposed mathematical model (1)-(2) can be used for more in-depth research of different material layer heat transfer problem. Theoretical model shown good connection with practical experimental burning results.

1. Introduction

During copper extraction processes from oxidized minerals to produce cathodic copper the cobalt is accumulated in the refine and in leaching piles by means of mechanical drag and electrolytic purges, reaching concentrations of 60 to 110 mg/L. However, during the electrodeposition process, cobalt salts are added to the electrolyte to stabilize the surface of lead anode with a layer of $PbO_2 - \beta$, improving its quality and, consequently, reducing the formation of ladder slats that provide an increase in the cathodic quality. This article presents the results of study of cobalt recovery through electrodialysis using ionic exchange membrane cationic.

2. Methods

The electrodialysis circuit consists of a cubic cell of two chambers with a cation exchange membrane were placed between the electrodes, at a distance de 10 cm, to form a separate anolyte and catholyte chambers (see Figure 1). Catholyte of volume 1 dm^{-3} containing 1 to 1,6 mol dm^{-3} H_2SO_4 and two anolytes 3 dm^{-3} in volume containing, the first: cobalt ions at a concentration of 100 mg dm^{-3} and 0,1 mol dm^{-3} HCl and the second: cobalt ions at a concentration of 100 to 1,000 mg dm^{-3} and 0.1 to 0.5 mol dm^{-3} H_2SO_4. Catholyte and anolyte were circulated to each chamber using separate pumps. The flow rate of both electrolytes was kept constant at 1 dm^{-3} min^{-1}. A stainless-steel cathode was used. The electrolytes are fed from the lower and the outlet is from top by gravity.

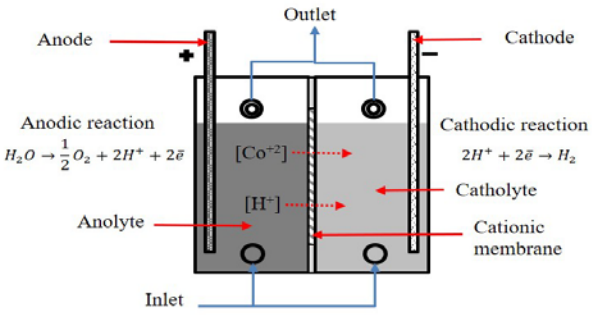

Figure 1. Scheme Electrodialysis cell

Anodic overpotential curves (SPA) to determine the material of anodic electrode were realized (graphite or titanium) in order to avoid the formation of chlorine gas. To determine the current intensity of work potential-current curves (CVC) were realized to the cationic membrane.

Finally, electrodialysis test was carried out for 8 h at 25 and 40°C and different current intensity depending on the results of the SPA and CVC curves, the parameters are show in Table 1.

Table 1 Parameters of electrodialysis test

Test	Current intensity (A)	T (°C)	Acid in anolyte (M)	H_2SO_4 in Catholyte (M)	Cobalt (mg dm^{-3})
1	0.02	25	0.1 HCl	1	100
2	0.02	25	0.1 H_2SO_4	1.6	100
3	0.02	25	0.1 H_2SO_4	1.6	1,000
4	1.5	40	0.5 H_2SO_4	1.6	1,000
5	3	40	0.5 H_2SO_4	1.6	1,000

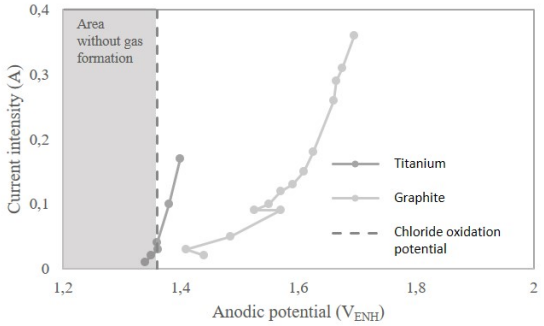

Figure 2. Anodic overpotential for titanium and graphite anode, and the area without gas formation.

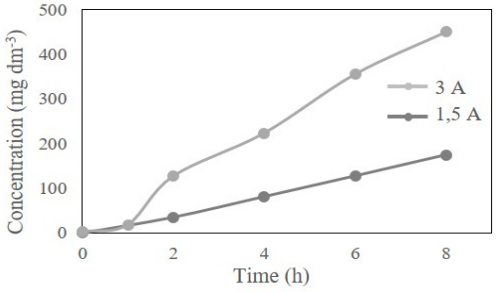

Figure 3. Profile concentration of cobalt in catholyte, mol dm^{-3}.

3. Discussion and Conclusions

The results of SPA curves (Figure 2) indicate that there is no gas formation to 0.03 A, using titanium anode while if using graphite anode there is gas formation according to the equation $2Cl^- \rightarrow Cl_2 + 2\bar{e}$ $(E° = -1.36V_{ENH})$. On the other hand, the CVC curves indicate that there was not limit current in the 0 to 3 A section for all solutions (Figure 3). Then, a test was performed at 0.02 A in chloride medium (test 1), however, no cobalt traces were found in the catholyte. The test 2 and 3 was performed at 0.02 A in sulphate medium to different cobalt concentrations, but no cobalt traces were found in the catholyte.

The test 4 and 5 were developed using a cationic membrane with less electrical resistance, it can see from in figure 3 that it was found cobalt in the catholyte in concentrations of 173.3 and 449.2 mg dm^{-3}, respectively. In conclusion, is possible recovery cobalt from acid solutions through ionic exchange with recovery rate of 21.7 and 55.85 mg dm^{-3} h^{-1} to 1.5 and 3 A, respectively with 0.45 and 0.48 Wh mg^{-1} specific energy consumption. These results give foot to continue the study of this processes and achieve recoveries on 1,000 mg dm^{-3}, optimizing the process with the use of electrodes and membranes of less electrical resistance.

In situ monitoring of the formation of mixed CO_2/CH_4 gas hydrates via Raman spectroscopy

Andreas S. Braeuer[1]

1 Institut für Thermische Verfahrenstechnik, Umwelt- und Naturstoffverfahrenstechnik, Technische Universität Bergakademie Freiberg, Freiberg, 09599, Germany

**Andreas.Braeuer@tu-freiberg.de*

Highlights

- *In situ* analysis of gas hydrate formation.
- Gas separation

1. Introduction

Gas hydrates are crystalline ice-like solids that consist of a three dimensional network of hydrogen bonded water molecules stabilized by the incorporation of small guest molecules, such as carbon dioxide (CO2) or methane (CH4).

Hydrate formation is a promising technology for gas separation processes, due to the gas specific thermodynamics of incorporation. For example, at certain pressure and temperature, the incorporation of CO2 molecules is preferred compared to CH4 molecules, which can be utilized for the separation of shale gas, biogas or the capture of CO2 from flue gas. In order to improve the separation process, fundamental understanding of the formation kinetics of the mixed gas hydrates on a molecular level is crucial.

2. Setup and Measurements

Here we present an experimental study on the formation kinetics of the formation of mixed CO2/CH4 gas hydrates. The experimental setup allows for the in situ monitoring of the composition of the gas phase as well as the hydrate phase during hydrate formation. The influence of initial gas composition, temperature and pressure on the evolution of the composition in the gas and in the hydrate phase is analyzed.

3. Conclusions

With our study, we aim to contribute further inside into the formation kinetics of mixed gas hydrates.

Separation of methycyclohexane – toluene mixture in the presence of ionic liquids

Elena Graczová*, Dávid Molnár, Pavol Steltenpohl

Institute of Chemical and Environmental Engineering, Faculty of Chemical and Food Technology, Slovak University of Technology in Bratislava, Radlinského 9, 812 37 Bratislava, Slovakia
elena.graczova@stuba.sk

1. Introduction

Modern chemical research is focused on the use of alternative, green, solvents as the traditional ones show numerous adverse properties including human health risk, volatility and flammability. Moreover, stringent legal requirements adopted recently oblige chemical and pharmaceutical companies to re-evaluate and adapt existing processes.

Since the 90th, there is an enormous increase in the number of studies regarding application of ionic liquids (ILs). ILs are a new type of solvents, often denoted as green solvents. They possess outstanding physical-chemical properties; they are liquid in a large region of temperatures, non-flammable, chemically and thermally stable. They act as liquid salts and due to their negligible vapor pressure, ILs are environment friendly and relatively easy to be regenerated [1].

Elevated polarity of ILs influences the properties of mixtures to be separated; in homogeneous systems it affects relative volatility of components of the original mixture, in case of heterogeneous systems, ILs polarity influences the components solubility and selectivity towards the extracted component. Hence, there is potential of ILs use in the separation of azeotropic and close boiling point mixtures, e.g. in extraction distillation and liquid phase extraction [2].

ILs are considered substitutes for traditional organic solvents in extraction of aromatics from their mixtures with aliphatic hydrocarbons. Thanks to their high selectivity, ILs can be used to separate aromatics by liquid extraction from mixtures containing less than 20 mass % of aromatics [1].

2. Methods

Aim of this work was to propose the process of **separation for methylcyclohexane–toluene model mixture in the presence of ionic liquid** (IL). Production line was composed of a counter-current liquid-phase extraction column coupled with single effect evaporator for extraction solvent regeneration and distillation column used to purify toluene. Mathematical models of individual devices were based on material and enthalpy balances taking into account phase equilibrium, too. Organic part of the equipment model simulation was energetic analysis of this complex systems including heat integration. Calculations were carried out partly in ASPEN+ simulation software and partly employing proprietary programs elaborated in Matlab.

3. Results and discussion

In the work, three ionic liquids (1-ethyl-3-methylimidazolium bis trifluoromethylsulfonyl imide ([Emim][NTf_2]); 1-hexyl-3-methylimidazolium tetracyanoborate ([Hmim][TCB]) and 1-butyl-3-methylimidazolium tetracyanoborate ([Bmim][TCB])) were used.

Based on experimental and calculated LLE data [3, and our experiment], capacities and selectivities of individual solvents were evaluated. Selectivities of [Bmim][TCB] and [Hmim][TCB] ILs were comparable, both ILs reached high capacity value (k_B > 1,2). [Emim][NTf_2] exhibited the lowest selectivity and capacity values amongst the ILs studied.

The input parameters of the extractor design calculations were the composition of the feed (methylcyclohexane–toluene mixture containing 10 mole % of toluene) and the extraction solvent composition (containing 99 % of IL). The required purity of the raffinate was maximum 0,5 mole % of toluene in the raffinate. The desired purity of toluene in the bottom product of the distillation column was 99,8 %.

The yield of methylcyclohexane in raffinate (99,98 %) was reached regardless the IL used. Assuming yield of toluene in the bottom product of distillation column, the values ranged from 95,50 % (for [Emim][NTf_2]) to 95,92 % (in case of [Hmim][TCB].

Solvent-to-produced methylcyclohexane mass ratio values were as follows: the lowest value (2,54 kg/kg) was obtained when [Hmim][TCB] was used as extraction solvent. In case of [Bmim][TCB] the value was somehow higher (2.69 kg/kg) and the highest value (9,38 kg/kg), i.e. the largest amount of solvent necessary for the model mixture separation was obtained in case of [Emim][NTf_2].

The energetic analysis of the process has shown that the largest heat demand was associated with evaporator operation, where almost 10 times more heat was consumed compared to that in the distillation column reboiler. The highest cooling demand was observed in cooler of the recirculated ionic liquid.

Total energy consumption for heating and cooling of the individual devices was comparable for simulations assuming [Bmim][TCB] and [Hmim][TCB] as extraction solvents (1,01 MJ and 1,05 MJ per kg of methylcyclohexane produced). Use of [Emim][NTf_2] ionic liquid for this purpose was connected with more than two-times higher heat and cooling demand.

The last part of the design was the thermal integration of the process. It was found that proper heat integration allows up to 72 % reduction of the overall energy demand.

4. Conclusions

Energetic analysis has clearly shown suitability of both [Bmim][TCB] and [Hmim][TCB] ionic liquids for their use in methylcyclohexane–toluene mixture separation.

Crystallization fundamentals and industrial processes

Intensified stereoselective secondary nucleation in solid state deracemization via microwave-assisted temperature cycles

Fabio Cameli[1], Christos Xiouras[1,2], Georgios D. Stefanidis[1]

1 Process Engineering for Sustainable Systems (ProcESS), Department of Chemical Engineering KU Leuven, Celestijnenlaan 200F, 3001 Leuven, Belgium

Highlights

- The high supersaturation ratios attained through the sharp thermal cycles performed in a microwave set-up favor the occurrence of secondary nucleation.
- Enantioselective secondary nucleation greatly affects deracemization rate in temperature cycling-induced deracemization.

1. Introduction

The need for single enantiomers is becoming central in the pharmaceutical and fine chemical industry. To this direction, various methods have been designed to produce single handed compounds, either by asymmetric synthesis or by downstream separation of a racemic mixture [1]. The latter approach has proved more efficient in terms of industrial feasibility, as cost effective and established separation techniques, such as crystallization processes (in the framework of deracemization methods) allow for high productivity of the target compound.

Among the most promising solid-state deracemization techniques, substantial attention has been lately given to temperature cycling-induced deracemization. This technique is based on thermal fluctuations, which induce partial dissolution and subsequent crystallization of a racemic suspension, whose liquid phase is maintained in a chemical equilibrium by a catalyzed racemization reaction [2].

As the process time of this kind of techniques is intrinsically long, cycle duration can be significantly reduced by efficient heating and fast cooling which can be easily performed, for example, in a microwave apparatus [3]. On the other hand, the high supersaturation levels achieved upon cooling are likely to result in the generation of secondary nuclei. Up to date, the occurrence of secondary nucleation as main pathway for the depletion of the solute supersaturation has been regarded as detrimental for deracemization due to the expected racemic nature of the produced crystals. However, a thorough evaluation of the handedness of the generated particles has not been performed yet, therefore this study aims at establishing the role of secondary nucleation in the framework of temperature cycling-induced deracemization and the connection between the magnitude of secondary nucleation and deracemization rate.

2. Methods

A chiral suspension of conglomerate crystals of 2-isopropyl-3-hydroxy-3-phenylisoindolin-1-one in toluene with catalytic amount of 1,8-diazabicyclo[5.4.0]undec-7-ene (DBU) was subjected to temperature cycles in a monomode microwave reactor capable of attaining rapid thermal cycles in which dissolution and crystallization phases can be run isothermally at the two temperature limits of the sweeps. Thus, the extreme operating windows employed in this study allow for investigation into the main factors affecting the occurrence of secondary nucleation which are namely:

- Solute supersaturation ratio
- Suspension density
- Stirring rate

3. Results and discussion

The sharp temperature cycles performed in the microwave apparatus induce high solute supersaturation ratios that are responsible for the generation of secondary nuclei during the low temperature period. The deracemization rate is positively affected by the increase in supersaturation up to a certain threshold, beyond which competition between stereoselective and non-stereoselective secondary nucleation hinders the rate of the process. On the other hand, increasing suspension density intensifies the stereoselective production of new particles leading to higher deracemization rate per unit mass. Lastly, vigorous stirring can deliver extensive generation of secondary nuclei that contribute to higher specific surface area of the overall crystals population (Figure 1a). The chirality of the new particles is seemingly influenced by the parent crystals in an autocatalytic manner resulting in enhanced deracemization as displayed in Figure 1b.

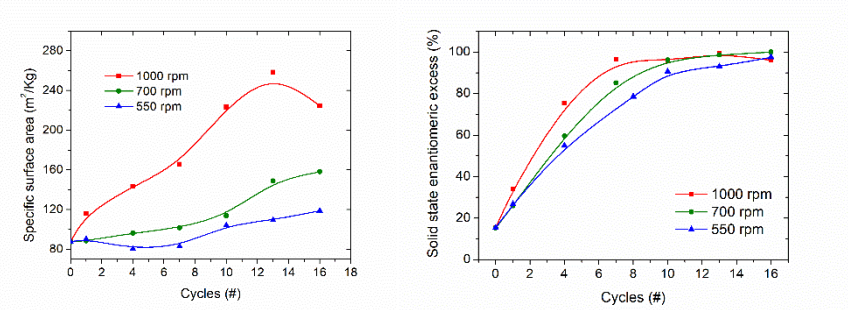

Figure 1. (a) Specific surface area and (b) enantiomeric excess trends of the particles obtained from experiments run under the same thermal profile but with different agitation conditions (in legend).

4. Conclusions

Enantioselective secondary nucleation plays a crucial role in solid-state deracemization via temperature cycles under intensified running conditions attainable within a microwave set-up. This physical phenomenon is greatly affected by operating parameters such as solute supersaturation, suspension density and agitation rate. Therefore, by optimizing these factors the total process time can be significantly enhanced.

Highlights

- Adsorption experiments using HBEA-25 as adsorbent and $ScCO_2$ as eluent.
- k_{ads}, Q_{sat}, k_L estimated using acetone, solketal and water pulse perturbations data.
- Water and solketal separation using a four zones SF-TMB.
- Solketal productivity of 8 kg/L·day at 150 bar, 353 K and 99% purity outlet streams.

1. Introduction

Increasing world's biodiesel production is leading to the accumulation of crude glycerol, a reaction byproduct with almost no economic value. A glycerol valorization route is reacting it with acetone over an acid catalyst, yielding water and 2,2-dimethyl-1,3-dioxolane-4-methanol (solketal) with almost full selectivity. Solketal is a high added value product and is considered a green fuel additive[1]. Solketal industrial production is not yet economic viable, and despite the scientific community efforts, almost no work was found concerning solketal separation process. In this work, supercritical CO_2 ($ScCO_2$) is proposed as an efficient and environmental friendly separation eluent for solketal separation process from water and unreacted acetone, to overcome equilibrium and mass transfer problems. $ScCO_2$ is cheap, safe, nontoxic, nonflammable, its critical point is readily attainable, has well-established industrial use and it is easily separated and recycled by depressurizing the system below CO_2 critical point[2-4]. The aim of this work is to design a supercritical fluid simulated moving bed (SF-SMB) to separate solketal from water, using a high water affinity HBEA-25 zeolite as adsorbent. For that, a supercritical fluid true moving bed supercritical (SF-TMB) was simulated using data obtained by single solute pulse experiments with $ScCO_2$ as eluent in a supercritical chromatographic fixed bed column (SF-FBC), under different operating conditions.

2. Methods

Mono component pulse perturbations at the inlet concentration were performed using $ScCO_2$ as eluent and zeolite HBEA-25 (from Süd-chemie, SiO_2/Al_2O_3 molar ratio of 25:75, particle diameters between 600 and 1180 nm) as adsorbent in a SF-FBC with dimensions 4 x 125 mm, bulk porosity of 0.438, particle porosity of 0.326 and total volumetric flow of 2 mL min^{-1}. A SF-FBC model was developed in gPROMS software assuming: plug flow model with axial dispersion and isothermal process and the adsorption is described by Langmuir competitive equilibrium isotherm model. The model was used to adjust the experimental pulse data, allowing the estimation of the Langmuir adsorption isotherm parameters, k_{ads} and Q_{sat}, and overall mass transfer coefficients, k_L. SF-TMB process was designed and optimized through numerical simulations using the data obtained and estimated for SF-FBC.

3. Results and discussion

Water solketal and acetone mass transfer coefficients and the adsorption isotherm parameters were estimated three different conditions: 150 bar and 313 K; 150 bar and 353 K; and 200 bar and 313 K (Figure 1 a) to c)). As expected, water presented the highest retention times, independently of the conditions tested. The SF-FBC model was able to accurately describe the experimental results obtained for the water, solketal and acetone pulse experiments.

A four zone SF-TMB was optimized through a simulation study for the three operating conditions, using columns similar to SF-FBC (except for the length, which was set to 37.5 cm) and considering the following parameters: safety factor of 0.4, solid flow velocity of 3.75 cm min^{-1}, raffinate and extract purity above 99 %. The best separation performance was achieved operating at 150 bar and 353 K (Figure 1 d)). A solketal productivity of 8.4 $kg/L_{Ads}{\cdot}d$ and an eluent consumption of 99.9 L_{Des}/kg_{solk} were estimated.

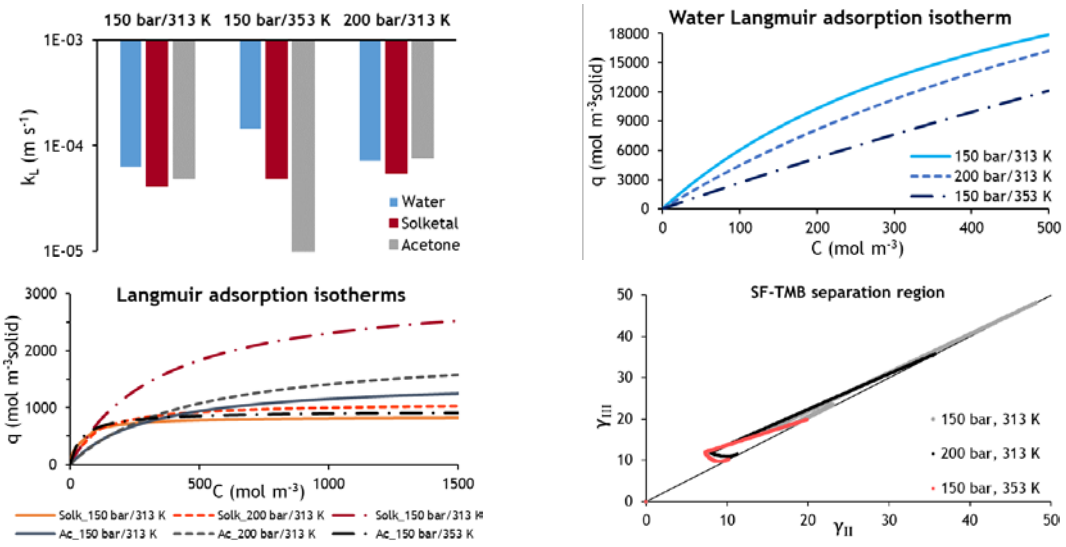

Figure 1 – a) Water, solketal and acetone estimated k_L. **b)** Water, **c)** solketal and acetone Langmuir equilibrium adsorption isotherms using the estimated K_{ads}, Q_{sat} at the three operating conditions, **d)** SF-TMB separation regions.

4. Conclusions

Through the present work it was possible to estimate k_L, K_{ads} and Q_{sat} for water solketal and acetone using SF-FBC pulse experiments. A four-zone SF-TMB unit was simulated, and the optimum operating conditions were found at 150 bar and 353 K. The zeolite HBEA-25 is also a strong acid catalyst for glycerol ketalization into solketal and its dehydration properties may overcome reaction equilibrium limitations by adsorbing water from the reaction media, allowing a possible future process intensification with reaction and separation in the same unit, such as a reactive SF-SMB.

A comparison of different amino acid solutions for CO_2 capture using a membrane contactor

Vida Sang Sefidi[1], Inès Winand[1], Patricia Luis[1]

[1] *Materials & Process Engineering (IMMC-IMAP), UCLouvain, Place Sainte Barbe 2, 1348 Louvain-la-Neuve, Belgium*

**Corresponding author: vida.sangsefidi@uclouvain.be*

Highlights

- Comparison of performance of five different amino acids with membrane contactor.
- Similar performance between arginine and NaOH solvents.
- Better performance of amino acid salts than amino acids alone.

1. Introduction

The growing concern about the global warming has triggered the public attention to the main greenhouse gas contributor namely carbon dioxide (CO_2) [1]. The most extended post combustion CO_2 capture technologies rely on absorption columns. Alkanolamines are typical solvents due to low cost and high absorption rates [2]. However, amine-based systems have high energy requirements for solvent regeneration and large solvent losses due to amine vaporization [3]. Lower energy consumption would be achievable using a different kind of technology: membrane contactors, which also allow an ease control of operating conditions, large contact area and scale-up flexibility [4]. In addition, the use of novel absorption solvents have been proposed in membrane contactors. For example, solvents with similar functionality as amines, such as amino acid salts (AAS) [5,6]. AAS are positively characterized by their high surface tension, non-volatility , etc., and their kinetics is defined by zwitterion reaction [7]. While an amino acid is initially inactive in the solution, it can be activated by addition of sodium hydroxide (NaOH), potassium hydroxide (KOH) and sodium carbonate (Na_2CO_3) [8,9].

In this work, five different amino acids have been studied for CO_2 capture. The CO_2 capture feasibility is studied in the membrane contactor using the amino acid salts solutions as the solvent, activated with NaOH. The process performance using the amino acids was compared to that using only NaOH in solution.

2. Methods

Serine (Alfa Aesar, >95%), methionine (Sigma Aldrich,>98%), Arginine(Sigma Aldrich,99%), 6-aminohexanoic acid (Alfa Aesar,99%) and Valine (Acros Organics, 99%) and sodium hydroxide (VWR,>98 %) were acquired and used without further purification. All amino acids were neutralized with an equilibrium molar amount of sodium hydroxide.

A hollow fiber membrane contactor (MiniModule 1x5.5 G543, liquid-Cel, Membrane GmbH, Germany) was used for the chemical absorption process. The inlet and outlet volume percentage

of CO_2 was measured via the CO_2 gas analyzer (Rosemount™ X-stream enhanced XEGK countinuous gas analyzer, Emerson, Germany).

3. Results and discussion

The overall mass transfer coefficient (K_{ov}) and process performance using amino acids and amino acid salts were studied. All amino acids saturated shortly after the start of experiments except arginine. The results could be explained since acid dissociation constant (pKa) for some amino acids is low. However, similar performance of arginine to NaOH is related to their comparable high pKa values.

The amino acid absorption improves after the activation with a base. As all amino acid have a primary amine group for the CO_2 capture, it is expected to observe a similar performance when they are activated. However, not all amino acids show same absorption rate for CO_2 capture, which is related to the difference in structure of amino acids. In addition, the absorption rate is higher when an amino acid is activated with a base that has higher pKa. A stronger base has higher capability of activation of amino acids.

4. Conclusions

This work uses a membrane contactor with amino acid salts for chemical absorption. The performance of different amino acids was compared to NaOH solution based on the mass transfer coefficient. Arginine performed similar to NaOH in the non-active form suggesting its direct application for CO_2 capture.

Synthesis and Gas Adsorption Properties of Hypercrosslinked Styrene-based Polymer for CO_2 capture

Kateřina Setničková[1]*, Karel Jeřábek[1], Tomáš Strašák[1], Petr Uchytil[1]

1 Institute of Chemical Process Fundamentals of the CAS, v. v. i., Department of Bioorganic Compounds and Nanocomposites, Rozvojová 2/135, CZ-165 02 Prague 6 – Suchdol, Czech Republic

**Corresponding author: setnickova@icpf.cas.cz*

Highlights

- Hypercrosslinked styrene-divinylbenzene porous material have been prepared.
- The resulting porous network exhibited the high surface area around 800 m^2/g.
- The CO_2/H_2, CO_2/N_2 selectivity of the polymer were 22 and 5 at 298 K, respectively.
- Promising material for mixed matrix membranes preparation usable to gas separation.

1. Introduction

The continuous and increasing release of carbon dioxide to the atmosphere due to human activities, being damaging to the environment and the earth, has initiated considerable interest in the development of new materials and technologies for CO_2 capture. To date, a cheap alternative solution to effective CO_2 capture has been developed by design and synthesis of microporous organic polymers (MOPs) categorized into four classes according to the types of organic reactions and the chemical structures [1]: polymers of intrinsic microporosity (PIMs), hypercrosslinked polymers (HCPs), conjugated microporous polymers (CMPs), and covalent organic frameworks (COFs). These organic porous materials generally possess low skeletal density, in which the precise control over the material's chemical composition and textural properties can lead to a significant enhancement in gas storage. In this study, we report on the synthesis of hypercrosslinked styrene-divinylbenzene microporous material and its application for CO_2 capture, gas separation.

2. Methods

The gas adsorption ability in new materials was determined using an apparatus based on the volumetric method. Simplified, the weighted amount of sample was placed in the adsorption chamber and evacuated. Then the chamber is filled with a gas at a certain pressure, the pressure value inside apparatus was monitored by computer. The pressure decrease corresponded to the adsorption of gas in the studied material.

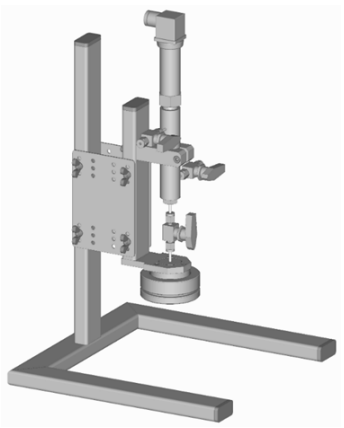

Figure 1. Design of the experimental apparatus for gas adsorption capacity measurement in materials.

After reaching the equilibrium the pressure is subtracted and used to determination of absorbed amount of gas in material. The constant temperature of the whole system during the absorption experiment was provided by a heated box.

3. Results and discussion

The results of adsorption capacities measurement of synthetized hypercrosslinked styrene-divinylbenzene microporous polymer for four tested gases is depicted in Fig.2.

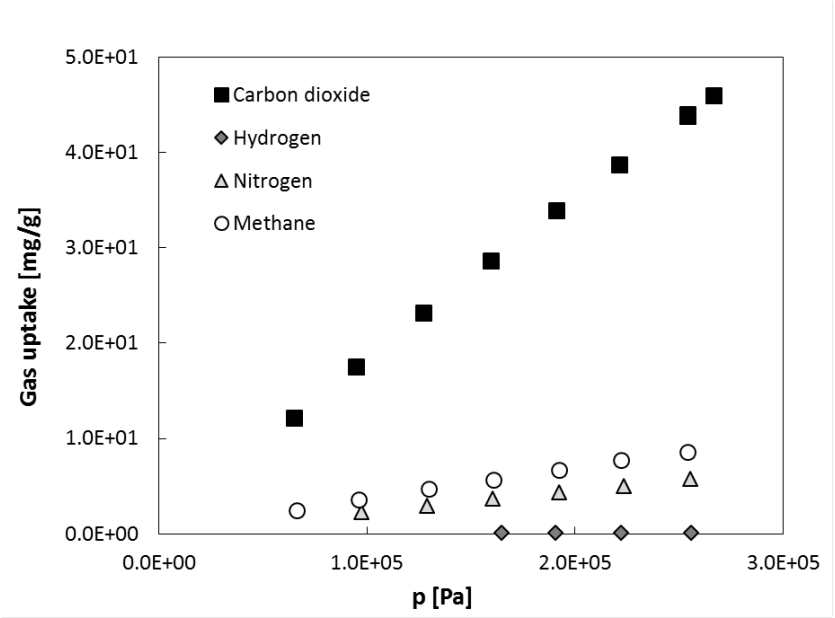

Figure 2. Gas adsorption isotherms in tested material.

4. Conclusions

The synthesis, characterization, and the CO_2 adsorption performance of new hypercrosslinked styrene-divinylbenzene based polymer exhibiting a high apparent surface area and very good sorption properties is reported in this study.

Process Intensification of the Hydrolysis of Cellulosic Fiber Wastes Using Membrane Bioreactors for Catalyst and Enhancer Recycle

Surya N. Jampana[1], Bandaru V. Ramarao*,[2]

1, 2 Department of Bioprocess Engineering, State University of New York ESF, SYRACUSE NY 13210

**Corresponding author: bvramara@esf.edu*

Highlights

- Recycled paper fibers are enzymatically hydrolyzed using cellulases.
- Surfactants are necessary to combat inhibition activity of mineral particulates.
- Better kinetics and yields are achieved using membrane separation in an MBR.
- Process modeling enables optimization of the operation of the MBR.

1. Introduction

Mixed office waste paper (MOW) and other grades of fine and packaging paper are widely reused to produce recycled tissue and packaging paper. Recycled pulp is made by dispersing the wastepaper in water and removing the ink and mineral particles by air flotation. However, fiber fragments also float and are rejected in the waste streams and up to 60% of such wastes can be such cellulosic particles. Furthermore, as fibers are recycled multiple times, they become brittle and fragment during pulp preparation. The fragments are a hindrance to paper manufacture. They clog the paper mats and wires during dewatering and drying, significantly slowing down the paper machine reducing the production rate. Modern paper machines are operated at very high speeds (in excess of 60 mph) and any hindrance can have significant impact on profitability. Recycled pulp fines also reduce bonding within the paper sheets and reduce the strength and quality of the final product. However, the rejection of such pulp fines into the waste stream increases the waste volume and its organic load imposing large disposal costs to the paper mills, negatively impacting the environment and the sustainability footprint of the paper products. Reduction of this waste stream through its utilization presents a great opportunity.

In recycled paper mills, these waste fines are usually rejected into the rejects stream which is eventually dewatered and the solids landfilled. However, there is increasing pressure on landfilling due to environmental degradation and increasing costs of transportation. Therefore, any effort to reduce the volume of these solid wastes can be economically attractive with a positive impact on the environment. Waste fibers (WF) represents an attractive biomass due to its cellulosic fibers content and the fact that its structure is feasible for bioconversion without pretreatment. Waste Fiber composition is diverse depending on the substrate and pulping and paper making processes but is mostly composed with 40-65% of sugars, 10-40% of ash and low portion of other materials such as lignin, plastics, or synthetic fibers [1-3]. These waste fibers are advantageous because the biomass particle size has already been reduced to the micrometer range (in fiber diameters) and the fact that the bulk of the lignin has been removed in the wood pulping process itself. However, high ash content in the WF inhibits the ability to convert its carbohydrates and reduces the productivity of processes. The heterogeneity of paper sludge results in low product concentration by limitation of solid loading]. Among the fillers, calcium carbonate ($CaCO_3$) is reported as the strongest inhibitor reducing enzymatic activity effecting on hydrolysis yield by pH drift. The inhibitory effect of $CaCO_3$ could also be potentially related to non-productive enzyme binding. The affinity of $CaCO_3$ is much higher towards enzyme more than the affinity of clay, and precipitated calcium carbonate (PCC) shows much higher binding affinity than ground calcium carbonate (GCC)].

2. Methods

Samples of waste fibers were procured from a recycled linerboard-manufacturing mill (RF). A synthetic model of this waste rejects was also prepared in the laboratory by grinding a sample of unbleached softwood kraft pulp (UKP) fibers. This was mixed with different quantities of clay and precipitated calcium carbonate. The hydrolysis was carried out in hydrolysis flasks placed in a shaking incubator (Reciprocal Shaking Bath 51221080, Precision Scientific Co., Denver CO) and hydrolyzed at 50°C up to 72 h at 130 rpm. The cellulase enzyme used was commercially available Cellic CTec2 (Novozymes USA) in 5% consistency using 0.05M sodium acetate buffer (pH 5). The hydrolyzate was removed after fixed time and samples withdrawn and analyzed with HPLC or NMR. For the calcium ion solution test, the PCC was dissolved in the prepared sodium acetate buffer and acetic acid was added to bring the pH to 5 (SU). The solid residue was filtered on Whatman filter paper #1 and the filtered solution was supplied for UKP hydrolysis to measure the effect of dissolved calcium ions. Tween 80 (Amresco®) was selected for non-ionic surfactant test for this study.

A continuous membrane bioreactor configuration was set up and used for experiments.

3. Results and discussion

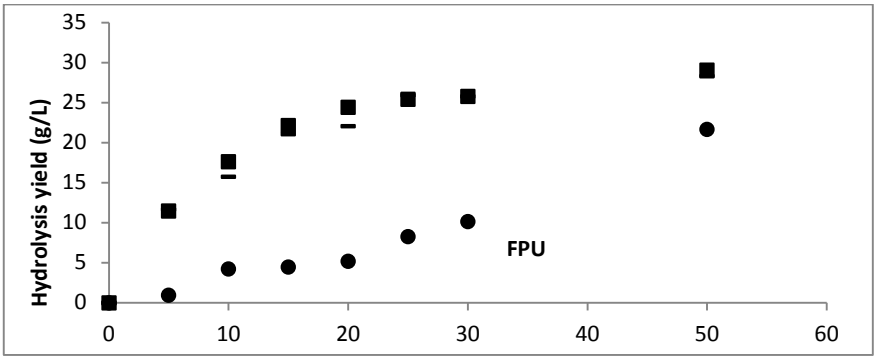

Figure 1. Hydrolysis of fibers as a function of enzyme concentration in FPU. Effect of surfactant.

The continuous separation of sugars as hydrolysis products from the reaction vessel allows faster kinetics and a reduction in the size of the reactors. Optimization of the reaction conditions by kinetic modeling is currently underway.

4. Conclusions

A membrane bioreactor is able to improve yields and kinetics of the enzymatic hydrolysis and also enable enzyme and promoter recycling, contributing to effectiveness and economical production costs of the process.

Improving the simulated moving bed separation of oleanolic and ursolic acids with a C30 stationary phase

I.S. Azenha[1], J.P.S. Aniceto[1,*], A. Mendes[2], C.M. Silva[1]

1 CICECO, Department of Chemistry, University of Aveiro, 3810-193 Aveiro, Portugal; 2 LEPABE-Faculdade de Engenharia, Universidade do Porto, 4200-465 Porto, Portugal

**joseaniceto@ua.pt*

Highlights

- C30 column and methanol/water were best phases to separate oleanolic and ursolic acids.
- Equil. & mass transfer constants of pure compounds were validated for binary mixture.
- An SMB using C30 columns is capable of separating the two acids with purities of 99.9 %.
- This is a significant improvement over previous results obtained with C18 columns.

1. Introduction

Eucalyptus globulus is a predominant species in the Portuguese forest [1] and a vital resource for the pulp and paper industry. The bark residues are usually burned for energy production without any further valorization. Recently, the bark has been identified as a source of triterpenic acids (TTAs) such as oleanolic and ursolic acids [2]. These compounds are known to possess a wide spectrum of bioactivities, including anti-oxidative, antitumoral, anti-inflammatory, anti-hyperlipidemic, and anti-microbial effects [3]. Thus, under the scope of the biorefinery concept, *E. globulus* bark is a potential candidate to extract high-value compounds such as TTAs. However, their separation after extraction is challenging as oleanolic and ursolic acids are two structurally related isomers and occur simultaneously in the same natural matrix. Simulated moving bed (SMB) chromatography is a continuous adsorption technique, which appears as an efficient alternative to batch elution chromatography. The SMB continuous countercurrent mode of operation maximizes the mass transfer driving force, providing improved productivity and reduced solvent consumption [4]. Thus, an SMB process may be a potential candidate for TTAs separation.

2. Methods

A series of impulse experiments were conducted to select appropriate mobile phases for the separation of oleanolic and ursolic acids. Experimental breakthrough curves were measured in a custom laboratorial installation. Breakthrough of pure components were conducted to determine equilibrium and mass transport parameters, by fitting a chromatographic model to the experimental data. Parameters were validated through the successful prediction of breakthrough assays of binary mixtures.

3. Results and discussion

From a series of several impulse tests methanol/water 95/5 (%, v/v) emerged as the most favorable mobile phase to conduct their continuous separation by SMB providing a value of selectivity of 1.08. The C30 column demonstrated a remarkable separation capacity for the triterpenic acids, enabling

simultaneously higher selectivities and faster analysis times, when compared with previous results using a C18 packing material and the same mobile phase [5]. Equilibrium and mass transport parameters obtained from breakthrough experiments of pure acids (and validated for a binary mixture) were used to design the SMB separation of a representative mixture of oleanolic and ursolic acids from a natural extract of *E. globulus*. A classical SMB scheme was simulated and optimized using a Design of Experiments – Response Surface Methodology. Purity requirements were defined while the productivity was maximized. Rigorous phenomenological simulation results, of which the concentration profile in the SMB at cyclic steady state is presented in Figure 1, demonstrated that the SMB is able to attain purities levels of 99.9 %, for both extract and raffinate outlets, and productivities of 1.705 kg/($m^3_{adsorbent}$ day) with 2-2-2-2 configuration. This is a significant achievement as previous results with a C18 stationary phase showed that purities of 99.4 % and 99.1 % for ursolic and oleanolic acids, respectively, were achievable at the expense of using three columns per section (3-3-3-3), and consequently at the expense of extremely low productivities [5]. The work presented here with the C30 column represents important improvements towards the successful chromatographic separation of these triterpenic acids.

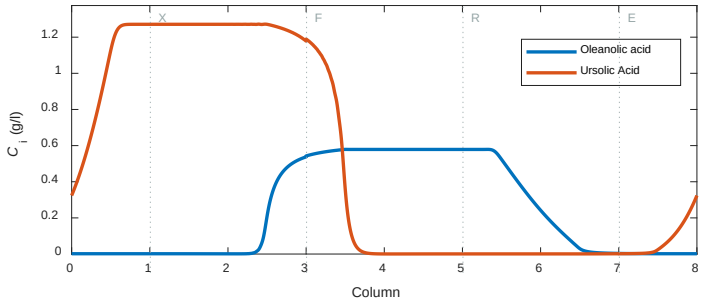

Figure 1. Simulation results of SMB operation at cyclic steady state for the isolation of oleanolic (blue line) from ursolic acid (orange line). E – eluent; F – feed; X – extract; R – raffinate.

4. Conclusions

The separation of oleanolic and ursolic acids by SMB was enhanced by applying C30 columns and a methanol/water 95/5 (%, v/v) mobile phase. The SMB unit with two columns per section, which was optimized combining the design of experiments and response surface methodologies with phenomenological computer simulations, attained purities of 99.9 %. This represents a significant improvement in terms of purity and productivity when compared with previous results obtained with C18 columns, which required a 3-3-3-3 configuration to attain purities of 99.4 %.

CO_2 solubility on ionic liquid + tetraglyme mixtures.

D. Hospital-Benito*, J. Lemus, R. Santiago, J. Palomar

Chemical Engineering Department. Universidad Autónoma de Madrid. 28049, Madrid, Spain

**Corresponding author: daniel.hospital@uam.es*

Highlights

- Ionic liquids (ILs) with chemical absorption show outstanding results for CO_2 capture application.
- Tetraglyme (TGM) is an effective additive in reducing ILs viscosity that also has a high CO_2 solubility.
- TGM/IL mixtures were found to be suitable for CO_2 capture application.

1. Introduction

The study of carbon dioxide (CO_2) solubility in different composition mixtures of ionic liquid (IL) and tetraglyme solvent (TGM) is interesting for the development of carbon capture and storage technologies [1]. In the present work, it was used four kind of ionic liquids, with different chemical and physical properties, implying different kinetic and thermodynamic results [2]. The ILs used in this study were two with chemical absorption by CO_2, such as [Bmim][Acetate] and [P66614][CNPyr], and two others with physical CO2 absorption, [Bmim][TCM] and [Bmim][$MeSO_4$].

2. Methods

The experiments were carried out using a high pressure termobalance that let us obtain high-pressure solubility of CO_2 in a wide range of TGM/IL mixtures (from 0 to 90 wt% TGM), measured at 303 K and at different pressures, from 1 up to 20 bar. The CO_2 capture performance of all composition mixtures of IL and TGM was evaluated using Aspen Plus commercial process simulator. To model the absorption operation in Aspen Plus using the ILs with chemical absorption by CO_2, a multiscale COSMO-based methodology developed in our group was used to include them into the simulator database. [Bmim][TCM] and [Bmim][$MeSO_4$] are contained in ILAUM database [4] and TGM and its COSMOSAC parameters are already included in Aspen Plus by default. The absorption column was simulated as a packed column using the RAD-FRAC rigorous model in Rate-Based mode. The solvent mass flow needed to achieve a capture rate of 90% was calculated.

3. Results and discussion

Tetraglyme as co-solvent improves the mass transfer kinetics by reducing viscosity and enhances CO_2 physical absorption. Promising TGM/IL mixtures were found using ILs with chemical absorption because of their high CO_2 solubility compared with TGM, so minimum solvent needs can be achieved as can be seen in Figure 1. Otherwise, ILs with physical CO_2 absorption due to their lower CO_2 solubility are useful at high operating pressures so do not seem a good alternative to TGM.

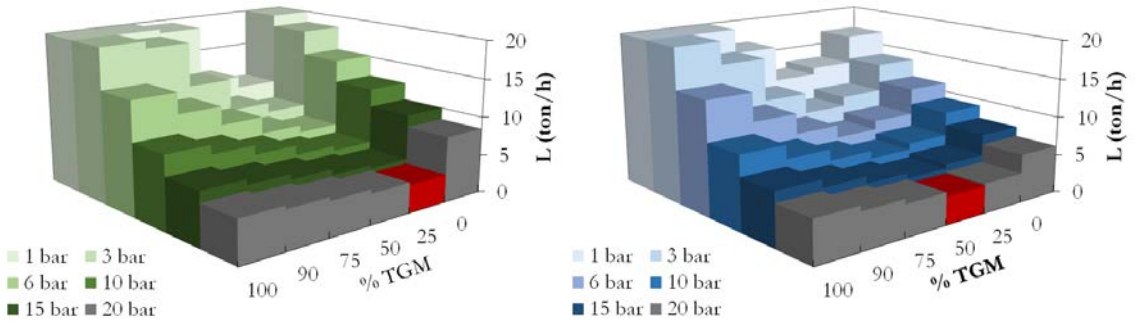

Figure 1. Solvent flow needed to reach a 90% CO2 captured rate by the solvent as a function of the CO2 partial pressure and compositions mixtures IL/TGM calculated by Rate-based RADFRAC model using [P66614][CNPyr] (left) and [Bmim][Acetate] (right).

4. Conclusions

It can be concluded that although ILs with chemical absorption show outstanding results for CO_2 capture application, their relatively high viscosity presents a challenge for the mass transfer properties [3]. In this sense, this work shows that TGM, which has a relatively low vapor pressure at temperatures of interest for these applications, is an effective additive in reducing viscosity of the IL tested, improving drastically the kinetic of the process, without high weakening of the absorption capacity. In the case of ionic liquids with physical absorption, they present low solubility compared with TGM and they have to be used at high operating pressures.

Absorption of Natural Aromas in a Rotating Packed Bed.

Ilya Lukin[1], Gerhard Schembecker[1]*

1Laboratory of Plant and Process Design TU Dortmund University, Emil-Figge-Strasse 70, D-44227 Dortmund/Germany

**Corresponding author: gerhard.schembecker@tu-dortmund.de*

Highlights

- The faster rotation speed of an RPB increases the absorption efficiency
- Variation of the rotation speed allows flexible throughput at equal efficiency
- RPB can be operated with highly viscous absorbents at a low pressure drop

1. Introduction

An increasing demand for natural aromas enhances the role of a biochemical production as an alternative to the natural feedstock extraction [1]. A combination of in-situ product stripping and absorption in a Rotating Packed Bed (RPB) is a novel potent technique to overcome downstream challenges during the recovery of natural aromas from crude biochemical mixtures (Figure 1).

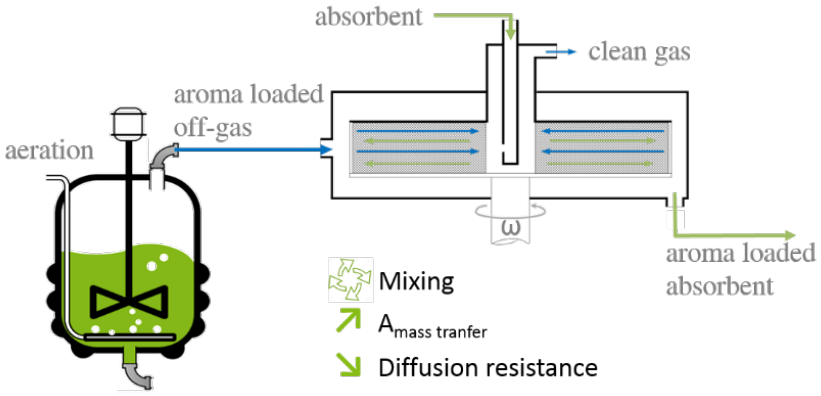

Figure 1: Schematic process of the recovery of natural aromas using Rotating Packed Bed technology

Inside a rotating circular packing of an RPB, the centrifugal force leads to an intensified gas-liquid mixing increasing the mass transfer of a target compound[2-4]. In order to investigate the influence of process parameters on the recovery of aromas, a newly designed small-scale RPB was integrated into a laboratory aroma stripping and absorption plant.

2. Methods

A stripping column was used in order to mimic a bioreactor. Inside the stripping column, the air was loaded with the desired aroma and then brought into contact with the absorbent in the rotating packing of the RPB. The results of gas and liquid phase analytics were used for the calculation of absorption efficiency, pressure drop and mass transfer resistances.

3. Results and discussion

The results show that the absorption efficiency of an aroma compound decreases with the increased gas throughput implicating some mass transfer limitations (Figure 2). Due to the intensified mixing at higher rotation speed the later could be overcome leading to an increased efficiency. Altogether, the variation of the rotation speed enables larger gas loadings at constant absorption efficiencies leading to higher space-time productivity of the recovery process.

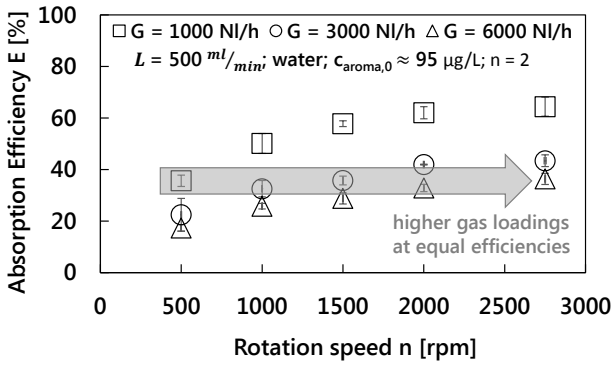

Figure 2: Effect of the rotation speed of an RPB on the absorption efficiency of benzaldehyde in water at varying gas throughputs.

A further efficiency increase is expected when stronger hydrophobic absorbents, e.g. plant oils, are used. The often challenging distribution of highly viscous oils in conventional absorption columns can be assisted by the generated centrifugal field allowing the operation of the RPB at moderate pressure drops (Figure 3) decreasing the process costs.

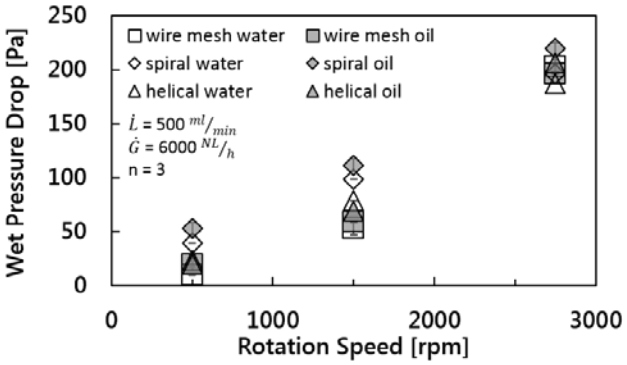

Figure 3: Wet pressure drop of different packings inside an RPB for water and rapeseed oil at varying rotation speed.

4. Conclusions

The use of the centrifugal field inside the packing of a Rotating Packed Bed helps to overcome mass transfer limitations leading to the improvement of the recovery process. Rotation assisted liquid distribution expands the selection of absorbents towards highly viscous plant oils.

An investigation of the controllability of optimal reactive distillation processes

A. Tsatse[1)], S.R.G. Oudenhoven[2)], A. J. B. ten Kate[2)], E. Sorensen[1)*]

1) Department of Chemical Engineering, University College London, Torrington Place, WC1E 7JE London, United Kingdom; 2) Nouryon, Zutphenseweg 10, 7418 AJ Deventer, the Netherlands

** Corresponding author: e.sorensen@ucl.ac.uk*

Highlights

- The reactive distillation column superstructure is solved based on an economic objective function
- The impact of the reaction kinetics on the final process design and associated cost is investigated
- The controllability of the design alternatives is evaluated in the frequency domain
- This work provides a methodology on how to synthesize a reactive distillation process, including its control system

1. Introduction

Over the last few decades, there has been an increasing focus on process intensification in an effort to reduce environmental impact and to improve the economic performance of chemical processing plants. Reactive distillation combines reaction and separation into one single unit, offering significant energy and capital savings as well as improvements in reaction selectivity and yield[1-2]. The combination of the two different phenomena in a single unit, however, makes the design, operation and control of the process more demanding due to the interactions between the reaction and the separation[3]. Although research has shed light on many aspects of reactive distillation, the extension of conventional distillation design techniques to reactive systems is still a challenge and thus, a rigorous method of reactive distillation systems design, which also includes consideration of the controllability of the system, has not yet been fully established[4].

2. Methods

The concept of distillation column superstructures has been successfully applied in the past for the design of distillation columns[5]. In this work, this approach will be extended to consider reactive distillation column superstructures[6] in order to determine structural and operational decisions, including but not limited to, total number of stages, feed stages location, reactive zones, existence of additional units (pre/side/post reactors) etc. Case studies are considered with different kinetic characteristics. The Mixed-Integer Non-Linear Optimization Problem (MINLP) formed aims to minimize the total (capital and operational) cost of the process, subject to constraints such as

maximum number of stages, product purity etc. gPROMS ProcessBuilder is used for the simulation and the optimization due to its rigorous optimization capabilities. The optimal design is then considered in dynamic mode and the controllability indices of the dynamic system are finally generated within the frequency domain in MATLAB in order to investigate the controllability and stability of the optimal design alternatives.

3. Results and discussion

It will be shown how the existence of fast or slow reaction kinetics inside the distillation column impacts on the optimal process design and control. In addition, the difference in the optimal total cost found for the various systems will be evaluated in order to explore how reaction kinetics impact on the total cost of the process and whether this can be a reason to render reactive distillation less economically attractive for systems with certain reaction characteristics. Moreover, the controllability analysis in the frequency domain will demonstrate how fast or slow kinetics impact on the stability and controllability of a process, and how controllability can determine whether a process alternative is selected for further investigation or not.

4. Conclusions

In this work, a Mixed-Integer Non-Linear Optimization Problem (MINLP) is solved, based on the superstructure method, for the synthesis of an economically optimal design of a reactive distillation column given a specific separation duty (target product purity). Different case studies are considered (slow/fast kinetics) and the impact of reaction kinetics on the optimal process design and cost is evaluated. The controllability and stability of the design alternatives are also evaluated. This work provides a methodology for how to select the most suitable reactive distillation process design, based on the minimum total cost as well as on the controllability of the process, especially in cases when more than one process design configuration exists.

Ultrafiltration System Optimisation for Nuclear Decommissioning

Kyriacos Hadjidemetriou[1,2], Jay J. Dunsford[2], Genevieve Boshoff[2], Claudio P. Fonte[1], Thomas L. Rodgers[1].

1 School of Chemical Engineering and Analytical Science, The University of Manchester, UK.

2 National Nuclear Laboratory, Workington, UK.

Corresponding author: kyriacos.hadjidemetriou@postgrad.manchester.ac.uk

Highlights

- Ultrafiltration optimisation using modelling and experimental work.
- Ferric floc filtration properties in the ultrafiltration process.
- Effluent treatment in nuclear decommissioning.
- Fouling control and cleaning methods for UF tubular membranes.

1. Introduction

The decontamination process of waste radioactive effluent in the Enhanced Actinide Removal Plant (EARP) at the Sellafield Site (UK) has been operating for more than 20 years. The plant has successfully generated and separated ferric flocs with incorporated radioactive components produced from acidic feeds arising from upstream spent nuclear fuel reprocessing plants. The EARP treatment process focuses on the chemical precipitation (CP) of ferric floc and an ultrafiltration (UF) process, in which separation of ferric floc is achieved in a two dewatering stage process [1].

UF technology performance and longevity are affected by the fouling deposition on the surface and inside the pores of the membrane. The development of a UF rig will be used for experimental work on the separation of flocs and the validation of the computational models [2].

2. Methods

Computational modelling work to build the 1D and CFD models has been utilised to predict the UF rig system performance under various operating conditions. The Darcy's law and the Poiseuille model for calculating the permeability coefficient were incorporated in the equations to build the 1D model across a tubular metallic membrane, as well as the friction factor for the loss of pressure through the membrane [3].

$$J_M = \frac{K\Delta P_{TM}}{\mu\delta} \quad (1) \qquad K = \frac{d_0^2\varepsilon}{32} \quad (2)$$

The laminar interface for the laminar flow and the k-epsilon model for the turbulent flow were used on building the 2D CFD model of the membrane. The experimental data from the developed UF system will be used to validate and improve the 1D and CFD model and the fouling resistance effects. The average pore diameter, d_0, and the porosity of the membrane, ε, were measured by using ESEM and porosimetry analysis- Porolux 1000.

3. Results and Discussions

The CFD results show the fluid behaviour inside the membrane and the fluid pulsations happening at the inlet of the membrane due to the pipe - membrane different diameter and the extra shear stresses being caused at the inlet of the membrane and the high fluid velocity, Figure 1.

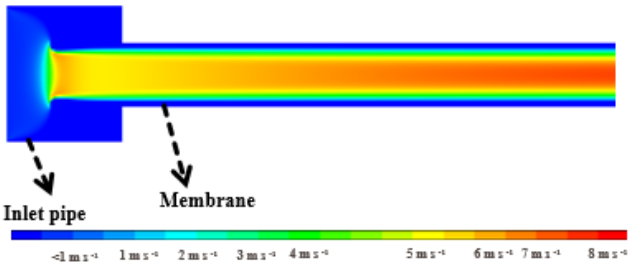

Figure 1: Velocity results of the fluid behaviour in the UF membrane.

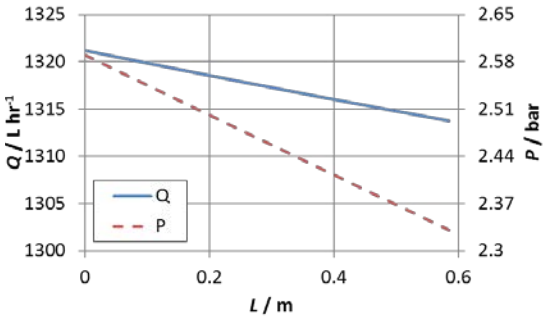

Figure 2: Volumetric flowrate and pressure across the membrane.

A 1D model is generated based on equation 1 and 2 using the experimental measurements of pore size and porosity and checked with the CFD model. Figure 2 shows the volumetric flowrate reduction along the membrane as permeate is generated and the pressure drop along the membrane. Table 1 compares the predictions of this 1D model with the obtained experimental data for the pressure drop and the total percentage of the inlet flow as permeate generation across the membrane.

Table 1: Pressure loss through membrane and permeate generation comparison of the 1D model and experimental data.

	1D Model	**Experiment**
Pressure Loss:	0.26 bar	0.26 bar
Total % as permeate generation:	0.56%	0.50%

4. Conclusions

Initial 1D and CFD models share similar results with the experimental data obtained from the UF system. The two models can predict the flux generation across the membrane, the volumetric flowrate and the pressure differences in the presence of membrane resistances. Further experimental work on the UF rig can potentially prepare fouling control and cleaning methods to reduce the fouling build-up in the system and improve the membrane longevity.

Preparation of graphene oxide/silica composite membranes and their application for nanofiltration

Kojiro Ueda[1], Masanobu Nakata[1], Hideki Yamamoto[1], Sadao Araki[1*]

1: Kansai University, Department of Chemical, Energy and Environmental Engineering, 3-3-35 Yamate-cho, Suita-shi, Osaka 564-8680 Japan

Highlights

- Graphene oxide/Silica composite (GO/SiO_2) membrane was prepared by using hydrolysis and polycondensation reaction of tetraethoxysilane.
- GO and GO/SiO_2 membranes showed high rejection of rose bengal.
- GO/SiO_2 membrane showed high adhesion properties compared to GO membrane.

1. Introduction

Graphene oxide (GO) multi-layered membranes have high permeability and good separation properties. However, since it is formed just by laminating GO on a support, GO layers easily peel off in plug flow type modules and the performance is remarkably decreased. In this study, to solve this issue of GO membranes, graphene oxide/Silica composite (GO/SiO_2) membranes were focused. It is expected that silanol groups react with hydroxyl groups of GO. Therefore, it is thought that GO/SiO_2 membranes have high durability compared with GO and polymer composite membranes. We prepared the GO/SiO_2 membranes and their nanofiltration properties was confirmed. In addition, the effect of composite of GO and silica on their adhesion was evaluated.

2. Methods

2.1 Preparation of GO membrane

GO suspension was synthesized using a modified Hummerś method and its concentration was 0.05 g/L [1]. Yttrium stabilised zirconia (YSZ) hollow fiber support with dead-end structure was soaked in the suspension. GO layers were deposited on the support by vacuuming inside of the support for 30 minutes. Then, the membrane was dried in air for 2 days.

2.2 Preparation of GO/SiO_2 membrane

0.1 mol of tetraethoxysilane (TEOS) as a silica source was added to 50 ml of ethanol. As an acid catalyst, 15 ml of 1 mol/ml nitric acid was added at a dropping rate of 1 ml/min. By stirring for 3 h, silica sol was prepared. GO was dispersed in the silica sol at a concentration of 0.05 g/L, and GO/SiO_2 membrane was prepared by the same procedure as the GO membrane.

2.3 Nanofiltration test

GO and GO/SiO_2 membranes were tested by connecting them in a pressure vessel filled with 35 µM rose bengal aqueous solution. The filtration tests were conducted at 5 bar. The permeation flux was calculated from the weight of the permeate. The dye concentration of the permeate was determined by using a UV-spectrometer (ASUV-6300PC, Shimadzu). The rejection rate calculated from the concentration ratio of permeate to feed solution. In addition, to confirm the adhesion of GO and GO/SiO_2 membranes, the pressure of 2 bar was added from inside of the fiber. Then, their nanofiltration properties were confirmed by 35 µM rose bengal solution.

3. Results and discussion

Table 1 shows nanofiltration results of GO and GO/SiO_2 membranes. The permeance of GO/SiO_2 membrane was reduced to one-third of the GO membrane. It is thought that SiO_2 inhibited permeation of water molecules. The rejections of both GO and GO/SiO_2 membranes was almost 100%. Table 2 shows nanofiltration results of GO and GO/SiO_2 membranes after the applying counter pressure. The rejection of GO membrane was reduced to 0% because GO layers were peeled off. On the other hand, GO/SiO_2 membrane kept a high rejection rate. From the above results, compared to the GO membrane, the adhesion properties of the GO/SiO_2 membrane were improved by the siloxane network.

Table 1. NF results of GO and GO/Si membranes.

Membrane	Permeance[L m^{-2} $h^{-1}$$bar^{-1}$]	Rejection[%]
GO	0.686	99.9
GO/Si	0.23	99.9

Table 2. NF results of GO and GO/Si membranes conducted durability test.

Membrane	Permeance[L m^{-2} $h^{-1}$$bar^{-1}$]	Rejection[%]
GO	11.3	0
GO/Si	0.32	97.2

4. Conclusions

GO/SiO_2 membrane was prepared to improve the adhesion properties of GO membranes. GO/SiO_2 membrane showed a high rejection of rose bengal, which is similar with the GO membrane. After the addition of counter pressure, the rejection of rose bengal for GO membrane was dramatically reduced. On the other hand, GO/SiO_2 membrane kept the rejection after the applying counter pressure.

Preparation and formation mechanism of AFX zeolite

Koki Maekawa[1], Satoshi Imasaka[2], Koji Kida[2], Hideki Yamamoto[1], Sadao Araki[1*]

1 Kansai University, Department of Chemical, Energy and Environmental Engineering, 3-3-35 Yamate-cho, Suita-shi, Osaka 564-8680 Japan

2 Hitachi Zosen Corporation, 2-11, Funamachi 2-Chome, Taisho-ku, Osaka 551-0022, Japan

**Corresponding author: araki_sa@kansai-u.ac.jp*

Highlights

- Effect of hydrothermal synthesis time on the preparation of thee AFX zeolite was confirmed.
- The FAU zeolite could be completely converted to the AFX zeolite for 7 h.
- The shape of AFX zeolite is hexagonal cylinder with bipyramidal tips at each ends.

1. Introduction

Zeolite is a crystalline oxide composed of silicon and aluminum. Zeolite generally shows high chemical and mechanical stabilities. Moreover, since zeolite has regularly arrayed pores of 1 nm or less, they can selectively separate certain materials by the difference of their molecular diameters. Among them, AFX zeolite can be expected for N_2 (0.36 nm)/ CH_4(0.38 nm) separation because the AFX zeolite has the pore structure of 0.36 × 0.34 nm. However, the formation mechanism of the AFX zeolite has not been clarified and optimized the synthesis conditions. In this study, AFX zeolite was prepared by using 1,1'-(1,4-butanediyl)bis(1-azonia-4-azabicyclo[2,2,2]octane)dication (Dab-4^{2+}), and synthesis time for obtaining AFX zeolite was examined in detail.

2. Methods

A synthesis gel was prepared by mixing sodium silicate, deionized water, 40 wt % Dab-4Br_2, 48 wt % sodium hydroxide, and FAU zeolite particles to be predicted molar composition. The obtained mixture was sealed in an autoclave and heated at 150 °C for 0 h, 3 h, 6 h, 7 h, 9 h, and 12 h. After the hydrothermal synthesis, the obtained solid product was filtered, washed, and dried at 80 ℃ overnight. These products were evaluated using X-ray diffraction and Field Emission Scanning Electron Microscopy（FE-SEM）.

3. Results and discussion

The FE-SEM images and XRD patterns of the products synthesized at each time (0 h, 3 h, 6 h, 7 h, 9 h, 1 2 h) are shown in Fig. 1 and Fig.2, respectively. As shown in Fig.2, XRD patterns of the products prepared for 0 h and 3 h were only FAU phase. In addition, no change for the shape and particle size of FAU zeolite was observed for the samples of hydrothermal synthesis of 0 h and 3 h, as shown in Fig. 1. For the XRD pattern of the product prepared for 6 h, the peak intensity of the FAU zeolite decreased and the peaks of the AFX zeolite were confirmed. Moreover, the crystals of hexagonal

cylinder with bipyramidal tips of AFX zeolite with crystal sizes ranging from 2 to 3 µm were observed with FAU zeolite particles, as shown in Fig. 2. At first, the agglomeration of FAU zeolite particles was occurred and then it turned to AFX zeolites, as shown yellow circle in Fig.1. The products of 7 h hydrothermal synthesis, the peaks of AFX zeolite were only confirmed. In addition, crystal size and shape of these products were similar. This result suggests that the FAU zeolite could be completely converted to the AFX zeolite for 7 h in this condition.

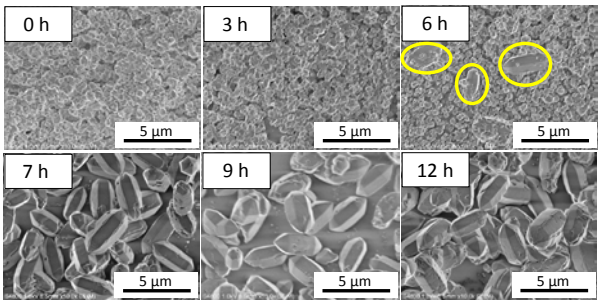

Figure. 1 FE-SEM images of zeolite synthesized at different hydrothermal times(0 h, 3 h, 6 h, 7 h, 9 h and 12 h).

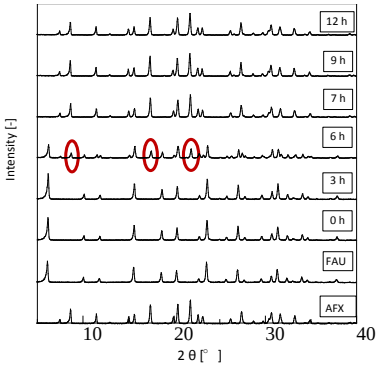

Figure. 2 XRD patterns of zeolite synthesized at different hydrothermal times (0 h, 3 h, 6 h, 7 h, 9 h and 12 h).

4. Conclusions

Conversion of FAU zeolite as a starting material to AFX zeolite was confirmed at 6 h hydrothermal synthesis. In addition, after 7h hydrothermal synthesis, FAU zeolite completely converted to AFX zeolite.

Highlights

- Thermodynamic server;
- Complex mixtures;
- Modeling and simulation;
- Batch distillation.

Batch distillation is an important unit operation in the batch processing industry and is used in a wide range of applications: fine chemical industries, pharmaceuticals, specialty chemicals, biochemical, essential oils, alcohols… The great flexibility of batch distillation allows for the separation of complex mixtures with a single column. This flexibility, combined with the inherent unsteady state nature of the process, poses challenging design and operation problems [1]. There is no 'rule of thumb' to achieve the optimal solution (reduced operating time, good product separation, minimum energy consumption…) and dedicated tools are required.

BatchColumn software [2] allows for the detailed representation almost any kind of distillation column, e.g. azeotropic and close boiling separation using heterogeneous or homogeneous entrainers [3, 4, 5, 6], batch distillation with a middle vessel column [7], etc. The software takes into account the associated equipment technology (middle vessels, boiler, condenser…) and column hydrodynamics. It provides the evolution through time of all parameters of interest such as compositions, temperature, pressure, reflux ratio… Through the creation and analysis of operating scenarios, it enables the identification of the best resources management policies, recipes for product quality optimization and cost reduction. BatchColumn allows modeling of complex systems by taking advantage of the power of Simulis Thermodynamics (thermodynamic properties server) which offers an extensive set of thermodynamic models with a pure components database of more than 2,300 pure components (AIChE's DIPPR® database [8]). The main features and strengths of BatchColumn are highlighted on various application examples.

Dynamics and process parameters evaluation of citric essential oils vapor distillation extraction

Esperanza Medina[1], Luis Miranda[2], Yaimi Cordova[3], Jhoan Velazquez[4]

1 San Agustín National University of Arequipa. emedinale@unsa.edu.pe; 2 San Agustín National University of Arequipa. lmirandaz@unsa.edu.pe

**Esperanza Medina: emedinale@unsa.edu.pe*

Highlights

- The study was carried out at a pilot plant level.
- The extraction dynamics differed significantly from one citrus to another
- Steam pressure/packing factor of the bed, determined the extraction dynamics

1. Introduction

This work evaluates at a pilot plant level, the dynamics of the process of extraction by steam distillation of essential oils in citrus (*citrus sinensis*, *citrus limetta*, *citrus latifolia* and *citrus reticulata*) from different Peruvian regions. The processing conditions have been determined in the extraction and phase separation units, ensuring efficiency while maintaining a high oil quality. The steam distillation method of extraction has been selected, because it is the only one that is normalized and that is widely used in industry [1]. New technologies for extracting essential oils are being tested, but they do not necessarily provide better results than the steam distillation method[2,3], if oil quality and process yield are main guidelines.

The dynamics of extraction, may be represented by the model developed by Ho & Oumarou [4]:

$$\frac{dCt}{dt} = k(Cs - Ct)^2$$

Where:

k second order constant of velocity of extraction ($Lg{-}1 - min{-}1$);
Cs concentration of oil in saturation ($gL{-}1$);
Ct concentration of oil in the solution at any time instant ($gL{-}1$) t (min)

2. Methods

The steam distillation process of extraction took place in a 15 L pilot plant provided with pressure and temperature sensors. Oil production was monitored with a precision of 0.2mL. The following variables have been manipulated: the packing factor of the citrus peel in the extractor, the inlet pressure of the steam and its flow, as well as the extraction time. Also, in order to understand the mass transfer mechanism of the essential oil located in the citrus peels to the vapor phase, microscopic analysis have been performed to the skin of the citrus materials.

3. Results and discussion

The process of extraction presents a dead time (θ) that depends on the citrus species, vapor pressure (u) and packing factor (ϕ). We have formulated a model including these variables, based

on the approach of transfer functions for process control. The model we obtained is characterized by the equation $y(t) = \{1\text{-exp}\,[-(t-\theta)/\tau]\}$ K Δu(t).

Both the gain *K* and the time constant τ depend fundamentally on the type of citrus material. Our results showed a substantial difference (up to 80%) in the dynamics of orange with respect to other citrus species. The optimal time for extraction for all four citrus materials is very much alike, in the range of 10 to 15 minutes, where 80% of the essential oil has been already extracted.
The relation between vapor pressure and packing factor as a function of oil yield is exponential for the orange, hence an optimal point for maximal efficiency can be obtained. However, for the other citrus species it has a linear inverse relation, therefore the best results are obtained with a minimal relation between steam inlet pressure versus packing factor.

In the oil extraction process the dead time could indicate the time required to meet the conditions for the oil to flow out of the glandular trichomes where it is contained, in order to be dragged by the vapor flowing across de bed. These conditions refer to the pressure for breaking the walls of the trichomes, and the temperature to vaporize the essential oil. The measured dead time is in the range of 1.5 to 3 minutes.
Along the extraction, a convective process takes place since there is a continuous vapor flow through the extraction bed; and a diffusive process as well, with the oil flowing across the solid phase due to a concentration gradient. Therefore the gain *K* might represent a mixed transfer coefficient that accounts for both, the convective and diffusive phenomena pointed out, that will be helpful in determining a global efficiency of the extraction process. On the other hand, the time constant is referred to the velocity of the extraction, and indicates the time needed to extract most of the oil. This parameter allows estimation of extraction process ending.

4. Conclusions

The dynamics of the extraction of essential oils from citrus is best explained considering a first-order model with dead time, process gain and time constant. These parameters account for bed resistance, convective/diffusive coefficient, and extraction velocity, respectively. A critical zone was achieved where maximum efficiency is obtained, which lies in the range of 10 to 15 minutes of extraction time. The relation between steam inlet pressure and packing factor is a good indicator of the extraction process dynamics.

Multidimensional fractionation of finely dispersed particles using the cross-flow filtration with superimposed electric field

Philipp Lösch, Kai Nikolaus, Sergiy Antonyuk

Institute of Particle Process Engineering, Technische Universität Kaiserslautern, 67663 Kaiserslautern

**Corresponding author: Philipp.loesch@mv.uni-kl.de*

Highlights

- Fractionation of fine particles by hydrodynamic effects
- Affect the separation method by adding additives
- CFD simulation of a crossflow filtration with electric field

1. Introduction

The separation of particle fractions with highly specific physical properties from suspensions has great importance for process success in various engineering processes. The physical properties of a particle collective are directly related to the particle size, particle shape, surface properties and chemical composition of the individual particles. Frequently, suspensions form highly complex particle collectives, which contain all of these features in different distributions. Since the characteristic dimensions of the technical structures in the raw materials are continuously decreasing, ever finer, more highly specific particle systems will be produced, processed and recycled. In known separation processes, such as e.g. Sedimentation, filtration or centrifugation, the particles are either classified according to a certain grain size or sorted by a physical characteristic. However, in many applications in which finely dispersed multicomponent mixtures of particles with sizes < 10 µm with different properties are to be separated in industrially relevant quantities, the use of a single separating feature is often no longer sufficient. Therefore this present study focusses on the utilization of multiple separating features to amplify the separation process.

2. Methods

In this research project, a novel cross-sectional superficial electric field filtration technique is being developed, which is a promising method for the highly specific separation of micro- and sub-micron suspensions. The particles are thus subject both to an electric field and to the lift and drag force. The method not only allows fractionation with regard to the particle size, but also the particle shape, the chemical composition and the physical properties of the individual particles. In most theoretical and experimental studies, individual separation features were only studied separately, but the development of a multidimensional fractionation method requires knowledge of the relationships between the superimposed effects. The construction and operation of suitable facilities should be made possible by the knowledge gained in the research project.

3. Results and discussion

First studies on the hydrodynamic effects of different particle distributions and concentrations showed, that a classification is possible. To achieve a multidimensional fractionating, an electric field across the filter media add an electrophorese force. The multidimensional fractionation of a suspension according to the separation characteristics grain size, particle shape and zeta potential can be achieved by the combination of lift force, drag force and electrophoretic force. Therefore, the isoelectric point and the charge of the particles of the used stable suspensions were investigated.

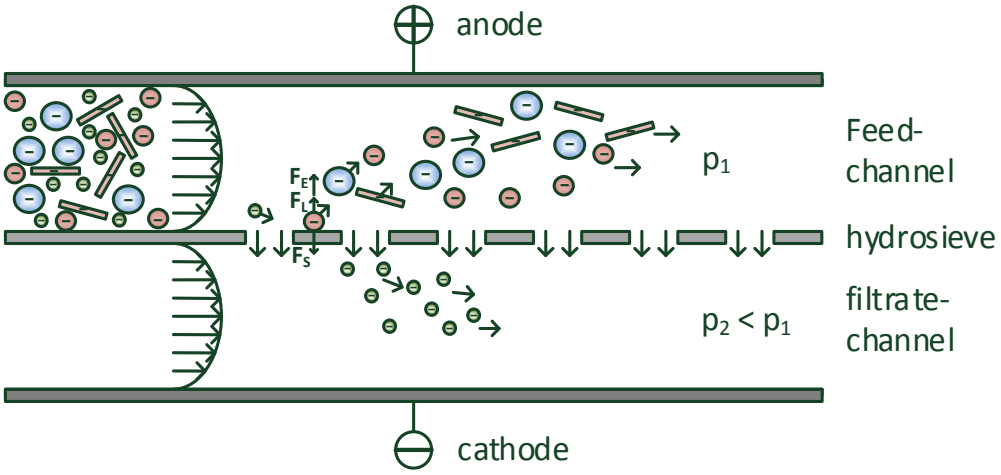

Figure 1. scheme of the fractionation process

Beside the experiments, the adjustment of the macroscale particle transport process is supplemented by CFD simulations with the Euler-Lagrange approach. This will help to find the operation point for the experimental investigations.

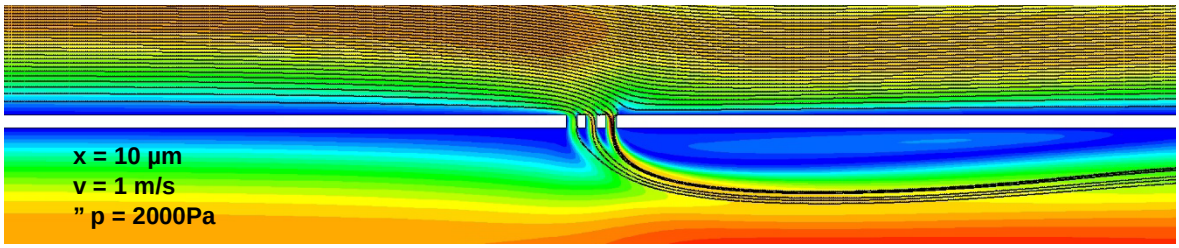

Figure 2. CFD simulation of the flow channel with particle tracking

Here, with the flow velocity and the electric field strength the hydrodynamic and electrophoretic forces can be adjusted, to achieve a classification.

4. Conclusions

A new method of fractionation finest particles using the crossfow-filtration is investigated. The effect of a hydrodynamic classification is shown. By using CFD-methods, the operating parameters are figured out. Due to the scalability of the process, which is based on membrane technology, the large-scale feasibility of the process is guaranteed. The individual effects used in the process and plant components needed for the process are known from filtration and membrane technology, but are still not used today for fractionation.

Simulation of a two-stage membrane system for the recovery of hydrogen from a flue gas stream

Fernando Pardo*, Gabriel Zarca, Ane Urtiaga

Department of Chemical and Biomolecular Engineering, University of Cantabria,

Av. de Los Castros s/n. Santander 39005, Spain

**Corresponding author: pardof@unican.es*

Highlights

- Efficiency of the overall process was evaluated in terms of H_2 purity and recovery.
- Operation conditions can be optimized towards H_2 purity or H_2 recovery.
- Maximum H_2 purity of 95% could be achieved at feed gas pressure of 12 bar.
- Maximum recovery of 83% could be achieved at feed gas pressure of 12 bar.

1. Introduction

Given the current global context of progressive depletion of fossil fuels and increasing environmental concerns for global warming, research efforts towards shifting from a linear production model to a circular economy model are a priority. In this sense, industrial processes must look for a better efficiency of resource use and waste management, not only to minimize their environmental impact, but also to increase the competitiveness of the productive process. In particular, this study is focused on the valorization of the flue gas generated in carbon black manufacturing. Considerable amounts of hydrogen (up to 20% vol on dry basis) can be found in this type of gaseous stream [1], thus its recovery could provide a competitive advantage towards a more sustainable production. In this sense, membrane technology offers a cost-effective alternative over other separation technologies such as cryogenic distillation and pressure swing adsorption. There is extensive knowledge in the use of H_2 selective materials for hydrogen recovery from ammonia purge gas, syngas ratio adjustment or H_2 recovery in the steam methane reforming process. Nevertheless, available data for the material valorization of tail gas from the carbon black manufacturing process is scarce. Therefore, the novelty of this work focuses its attention on the simulation of a two-stage membrane process with recirculation (Figure 1) to improve both material and energy management of the carbon black manufacturing process. The effect of critical variables such as feed pressure, permeation area and type of polymeric material on the effectiveness of the overall process, evaluated in terms of H_2 purity in the permeate stream and H_2 recovery, is assessed.

2. Methods

The tail gas data composition considered in this work corresponds to reference values included in the Best Available Techniques for the manufacture of carbon black [1]: water vapor (30–50%), N_2 (30–50%), H_2 (7–14%), CO (6–12%), CO_2 (1–5%) and CH_4 (0.1-1 %), as well as traces of sulphur and nitrogen compounds. Membrane modules of polyphenylene oxide (PPO) and polyimide (PI) in

hollow fiber configuration were considered [2]. Permeability values for N_2, H_2, CO, CO_2 and CH_4 gas were obtained from literature [3,4]. A mathematical model describing gas permeation through the hollow fiber membrane module has been implemented in Aspen Custom Modeler. Permeation of gases though the polymeric material are described by the solution-diffusion model [5]. This model was then exported to Aspen Plus to simulate the gas separation processes with a two stage membrane system.

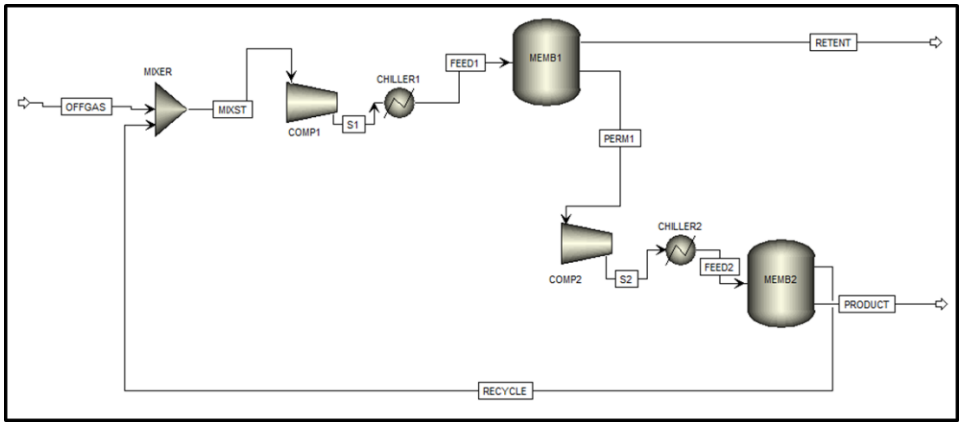

Figure 1. Configuration of the two-stage membrane process.

3. Results and discussion

According to the simulated results, 95% H_2 purity can be obtained in the product stream at a reachable feed pressure up to 12 bar using a 2-stages system consisting of two polyimide hollow fiber membrane modules. The highest hydrogen recovery (80%) was obtained when the PPO polymer was used as material for the first membranes module.

4. Conclusions

This work provides valuable data of the extent of the potential application of membrane technology for the recovery of hydrogen from a tail gas stream. Despite the limitations to deal with the trade-off between H_2 purity and recovery, the results show that polymer membrane technology can be successful for obtaining H_2 enriched streams with sufficient quality to be used in applications that do not require ultra-high purity H_2 as feedstock, such as hydrodesulphurization or hydrocracking.

Highlights

- Molecularly imprinted polymers (MIP) were synthesized for the purification of lincomycin (an antibiotic) in chloroform solution.
- Three monomers (methacrylic acid, trifluoromethyl acrylic acid, and acrylamide) were investigated, respectively, for their performance in related MIPs.
- Separation mechanisms, equilibrium, kinetics and operation parameters were studied. Industrial fermentation solution was used to examine the performance of the MIPs.

1. Introduction

With strong antibacterial effect against gram-positive bacterium and inhibitory effect to mycoplasma, lincomycin has attracted strong interest in global pharmaceutical industries [1, 2]. It possesses such advantages of: broad antimicrobial spectra, strong antibacterial ability, low toxicity and convenient administration, etc.. The industrial purification process of lincomycin involves mainly the extraction of fermentation products with butyl-alcohol or mixed alcohol[2, 3]. The crude product is obtained by crystallization process, following repeatedly extracting, concentrating and bleaching processes. A few companies utilized the hydrochloric acid stripping technique after extraction, thereafter the crystals are obtained by bleaching/crystallizing with acetone. These technologies suffered from such disadvantages as: high cost, low yield, high material and energy consumption, and environmental pollutions, etc. [3]. The fermentation solution of Lincomycin

contains mainly lincomycin A, as well as a few analogues such as lincomycin B, C and D, which are known for less antibacterial activity but toxic side effects. Therefore, new technology is needed for high purity and low-cost production of the antibiotics.

Molecular imprinting is a new technology to prepare adsorbents with highly specific affinity (selectivity). The molecularly imprinted polymers (or MIPs), whose spatial structure and binding sites were designated to match with the template molecules, shed new lights for the separation of large/biomolecules out of the complicated mixture solutions[4]. The spatial structure and physicochemical properties of the template molecules are created in the MIP which can identify the template molecules effectively from a complex mixture solution [5, 6]. This technology has found numerous application in chemical[7-9], biological [10], medicine[11-13] and other fields.

2. Methods

Lincomycin was used as the template molecule, ethylene glycol dimethacrylate as the cross-linker. Three MIPs were synthesized, respectively, with different functional monomers (namely, methacrylic acid, trifluoromethyl acrylic acid, and acrylamide) via a two-step swelling method, and grown on the polystyrene microspheres. The related non-imprinted polymers (NIP) were also synthesized using the same procedures as MIPs, nut without adding the template molecules. The 6 samples were denoted as: $MIP_{TF\text{-}MAA}$ and $NIP_{TF\text{-}MAA}$; MIP_{MAA} and NIP_{MAA}; MIP_{AM} and NIP_{AM}, respectively.

The MIP/NIP samples were structurally characterized using a number of instruments (SEM, FTIR, XRD, Particle size analyser, etc.), which suggested that the MIP was successfully grown on the substrates with homogeneous structure. Adsorption studies were performed in aqueous solution, chloroform solution and industrial extracts solutions, respectively. Fixed bed column breakthrough experiments were also performed to examine the kinetics and reusability of the MIPs.

3. Results and discussion

Figure1a shows the adsorption of lincomycin on MIPs prepared by different functional monomers. The initial concentration was fixed with a dosage of 50mg-adsorbents/20ml-chloroform solutions. We see that the adsorption capacity increases steadily with the lincomycin concentration, while the adsorption on NIPs gradually approaches to its saturation. Regardless of MIPs or NIPs, the

adsorption capacity is gradually decreasing in order of TF-MAA, MAA, and AM. This is mainly attributed to the molecular structure of lincomycin. Lincomycin shows alkaline because of an amino group in molecule, so the imprinted polymer prepared by acid functional monomer has better adsorption capacity, especially the TF-MAA with three fluorine atom substituents. To MIPs and NIPs prepared by the same functional monomer, the binding capacity of MIPs is obviously higher than NIPs; this gap increases with lincomycin concentration's increase. It indicated that the spatial structure and binding sites matched with lincomycin formed in the synthesis process, which made MIPs better adsorbents than NIPs, which are absent of the special recognition ability for lincomycin.

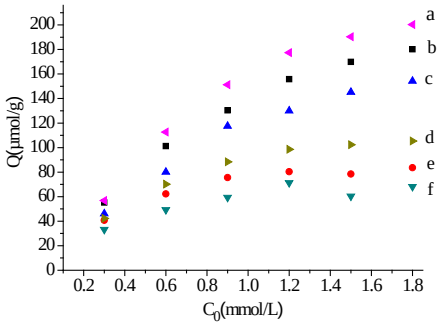

Figure 1. Adsorption isotherms of $MIP_{TF\text{-}MAA}$ (a,d) and $NIP_{TF\text{-}MAA}$, (b,e)--Adsorption isotherm of MIP_{MAA} and NIP_{MAA}, (c,f)--Adsorption isotherm of MIP_{AM} and NIP_{AM}

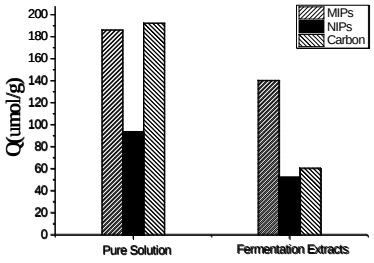

Figure 2 The adsorption capacities of lincomycin on MIP, NIP, and activated carbon in two solutions (left: pure lincomycin solution from Lab; right: raw fermentation extracts solution from industry)

Figure 1b shows the comparative studies for MIP with activated carbon and the NIPs. It was found that MIP presented a moderately higher capacity in pure solution of lincomycin, but a significantly higher capacity (more than doubled) in the practical lincomycin fermentation solution extracts, confirming the superior performance (specific affinity/selectivity) of the MIP over NIP and carbon for this application.

The adsorption/desorption kinetics were also studied on MIP_{MA} in a fixed bed column. The breakthrough curves were found to be well fitted by the Thomas model and the fixed bed has the good regeneration capability with the elution ratio > 93%.

4. Conclusions

With lincomycin as the template molecule, 3 different MIPs were prepared using TF-MAA, MAA and AM as functional monomers, respectively. Adsorption studies showed that MAA as the optimal functional monomer for this application. By comparing the lincomycin adsorption on MIP, NIP, as well as on activated carbon, it was found that MIPs gave better specific recognition and an adsorption capacity upto 180 μmol/g, which is higher than NIP and carbon in pure solution This

difference became much higher (~ 2.5 times) for the adsorption in the practical fermentation solution extracts. Column adsorption experiment indicated that MIP had good separation effect for lincomycin. The fitting results of the kinetic model indicated that Thomas model gave a good correlation to the breakthrough curves (R^2=0.98). Elution-regeneration experiments showed that the adsorption column had good desorption and regeneration capacities, with an elution ratio of 93.8 % while the breakthrough curves little changed in many cycles. These results proved that the MIP is a promising adsorbent for industrial separation and purification of lincomycin.

Thermodynamics of stereoisomer mixtures. Identification of ambiguously defined substances and interpretation of their properties.

Vladimir Diky[1], Andrei Kazakov[1]

1 Material Measurement Laboratory, National Institute of Standards and Technology,

325 Broadway, Boulder CO 80305, USA

**Corresponding author: diky@nist.gov*

Highlights

- Thermodynamic properties of stereoisomer mixtures have been analyzed.
- Magnitudes and nature of deviations from the component properties has been revealed.
- Principles of identification of ambiguously defined compounds have been developed.
- They can be adopted in chemical engineering.

1. Introduction

Accurate knowledge of thermophysical properties is critical for process simulation and other engineering applications. One of the sources contributing to data errors is incorrect identification of substances which are actually mixtures of components or species, and subsequent misinterpretation of their properties. Those substances can be mixtures of stereisomers (e.g., 2,3-butanol) or isomers (e.g., xylene) or undergo reversible chemical transformations (e.g., carbohydrates or nitrogen dioxide). While some properties of such substances (typically, fluid properties) are close to those of their components, the others (such as entropy, molecular, formation, solid-state properties, and phase equilibria involving solid phase) are not or are even not applicable to mixtures. Special care has to be taken when dealing with properties of mixtures containing similar substances as even correctly measured values can be assigned to inappropriate phenomena and cause apparent inconsistencies, misleading recommendations, and wrong expectations.

2. Methods

A thorough analysis of the available property data for ambiguously defined substances and their components has been performed at Thermodynamics Research Center (TRC) of the National Institute of Standards and Technology (NIST). The analysis involved about 1000 pairs of stereoisomers and 50 composition-explicit mixtures of stereoisomers. That analysis was possible because of the availability of a large thermodynamic data collection presently containing over 6.6 million distinct property values (SOURCE database [1, 2]), detailed molecular structures stored in that database, and structure comparison algorithms based on the molfile, InChI, and other representations.

3. Results and discussion

The available property data for composition-explicit mixtures of stereoisomers revealed the patterns of the composition-dependent properties and the magnitudes and of their deviations from the properties of the components. The nature of those deviations can only be interpreted if such substances are treated as mixtures. The presentation will include an overview and give typical examples. Numerous ambiguities and inconsistencies have been identified and explained, such as the spread of the available data on the melting temperature of 2,3-butanediol. Many of them can be avoided if the type of each substance (pure species, equilibrium or non-equilibrium mixture) is defined and the results of experimental measurements are correctly interpreted. That is done in the TRC databases, where the relations of the ambiguously defined compounds to their components or species are also maintained. The type of a substance not only controls interpretation of its experimentally measured properties, but also defines specific requirements to the substance characterization, as well as measurements and reporting of its properties. That is important, in particular, for reviewing experimental reports and for design of processes involving solid substances.

4. Conclusions

The principles and methods of identification of ambiguously defined substances have been developed at TRC on the basis of the analysis of molecular structures and available thermodynamic property data. They allow resolving apparent inconsistencies and obtaining a more accurate knowledge. Being adopted in chemical engineering, they can provide better understanding and higher fidelity of process simulation.

Experimental Influence of Thermodynamic Inhibitors on the Phase Equilibria of Carbon Dioxide Hydrates Above the Q_2 Point

Jose Carlos Cordeiro Jr.[1], Moisés A. Marcelino Neto[1]*, Rigoberto E. M. Morales[1], [2] Amadeu K. Sum

**Corresponding author: mneto@utfpr.edu.br*

Highlights

- Some oilfields can have very high concentrations of CO_2.
- Experimental data for condensed CO_2 hydrates are scarce in literature.
- New data for CO_2 hydrates above the Q_2 point with MEG and NaCl is presented.

1. Introduction

Due to high pressures and low temperatures achieved in oil and gas industries, the formation of hydrates can block pipelines, causing damage and preventing normal operations. Hydrates are a solid non-flowing phase that forms by the combination of water molecules that trap a molecule of a second type. A common practice in the industry is the use of thermodynamic inhibitors, such as Monoethylene Glycol (MEG), which can change the conditions at which hydrates form, preventing their appearance. In offshore oil and gas extraction, the water that accompanies the production is naturally inhibited by the presence of salts. These salts, such as sodium chloride (NaCl), acts similarly to MEG, lowering the activity of water and consequently causing the conditions for the formation of hydrates to be more severe [2]. Some oilfields, for instance in the Brazilian pre-salt region, can have very high concentrations of carbon dioxide (CO_2), changing the conditions at which hydrate formation occurs. Due to these high CO_2 concentrations, the condensation of the vapor phase becomes possible. This causes the appearance of an upper quadruple point (Q_2) in the phase equilibria, which is characterized by the presence of four phases: Liquid CO_2 / Vapor CO_2 / Liquid Water / Hydrate [3]. This work presents new experimental data for carbon dioxide hydrates above Q_2 formed with the presence of MEG, NaCl and their mixtures in the aqueous phase. For validating the experimental procedure, data for CO_2 hydrates with pure water was obtained and compared with data available in literature with good agreement.

2. Methods

To determine the hydrate equilibrium temperature for a given pressure, an isobaric experimental procedure was performed. A stainless steel equilibrium cell was connected to a syringe pump, which added or removed CO_2 in order to keep a constant pressure. The formation was induced by lowering the temperature of the cell; next, the temperature was increased, promoting hydrate

dissociation. Data for the change in volume of the pump and the temperature inside the cell were collected and the equilibrium temperature was determined graphically. The equilibrium conditions for a given pressure was determined as the temperature of which hydrates no longer exist.

3. Results and discussion

Experimental results obtained in this work are shown in Figure 1. For evaluating MEG (blue symbols), mass concentrations of 10%, 20% and 30% were used. For NaCl, mass concentrations of 5% and 10% were considered. The concentrations of 5% NaCl and 10% of MEG were found to be practically equivalent. In addition, the mixture of 5% of NaCl + 10% of MEG had an inhibition effect slightly higher when compared to the single inhibitors concentrations.

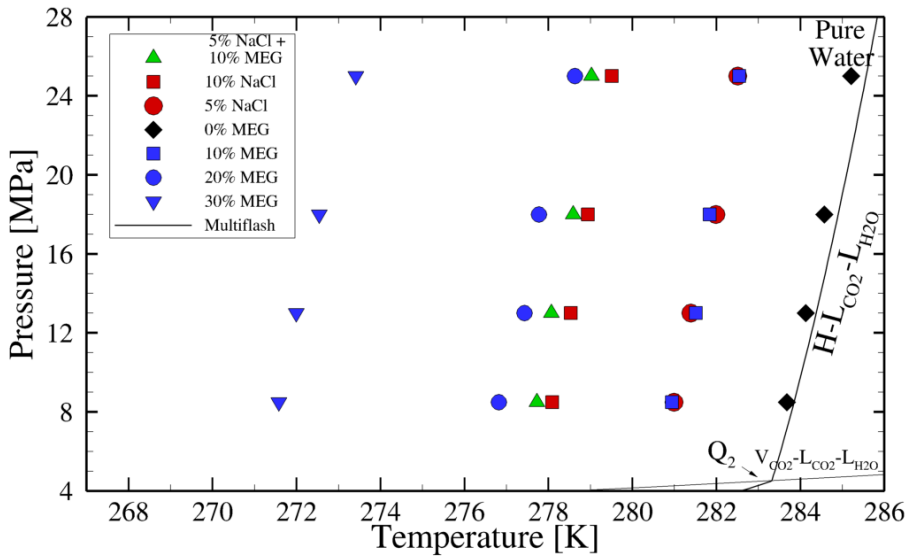

Figure 1. Liquid water-liquid carbon dioxide-hydrate equilibrium condition. The line is prediction done using Multiflash [3]. Blue symbols are data for MEG. Red symbols are for NaCl. Green symbols are for the 5% NaCl + 10% MEG mixture. All concentrations are in mass base.

4. Conclusions

In order to evaluate the influence of thermodynamic inhibitors, NaCl and MEG aqueous solutions were prepared and the equilibrium for carbon dioxide hydrates was experimentally determined above the upper quadruple point. As expected, higher concentrations of inhibitor caused a higher decrease in the equilibrium temperature. Lastly, the mixture of NaCl and MEG resulted in a higher inhibition effect than the simple sum of the temperature decrease caused by the aforementioned single inhibitors concentrations.

Thermodynamic prediction of the glass transition temperature in polymers and polymer blends

Margarete Roericht, Sabine Enders*

Karlsruhe Institute of Technology, Institute of Technical Thermodynamics and Refrigeration Engineering, Engler-Bunte-Ring 21, 76131 Karlsruhe, Germany.

**Corresponding author: sabine.enders@kit.edu*

Highlights

- Calculation of the glass transition temperature with an equation of state.
- Comparison of the results with experimental data from the literature.
- Application of the theory to various examples e.g. miscible/immiscible blends.

1. Introduction

The development of reliable approaches for the prediction of the thermodynamic properties of polymer systems is crucial for the reasonable design of polymer materials and polymer processing in a wide range of polymer applications (for example composites, electronics, food, controlled drug delivery systems, medical devices). Glasses are disordered materials that lack the periodicity of crystals but behave mechanically like solids.

The assumption that the glass transition is basically thermodynamic in nature was used to derive a theoretical framework for the calculation of the glass transition temperature (T_G) of polymers, copolymers and polymer blends [1,2,3]. The theory is a synthesis of a thermodynamic equation of state suitable for polymers, the generalized entropy theory for glass-formation in polymer materials, and the rigorous Kirkwood-Buff theory for concentration fluctuations in binary mixtures [2,3].

2. Methods

In the present contribution the above described framework is applied in order to compare the theoretical results with experimental data taken from the literature. Hereby the Sanchez-Lacombe equation of state (SL-EOS) [4] was used, because the pure-component parameters for several different polymers (polystyrene, (PS); poly(vinyl methyl ether), (PVME); poly(methyl methacrylate), (PMMA); poly(p-phenylene oxide), (PPO)) as well as for the statistical copolymer consisting of styrene and acrylonitrile (PSAN) are available. Unfortunately, the parameters for polyacrylonitrile (PAN) are not available, because no PVT (pressure, volume, temperature) data can be measured with high accuracy. The reason for this finding is the thermal instability of this polymer. Therefore, the pure-component parameter for PAN were estimated using PS and PSAN data simultaneously.

3. Results and discussion

Using the above mentioned theoretical framework [1,2,3] the T_G of pure polymers was calculated as function of the molecular weight, and compared to experimental data. The analysis shows, that

one adjustable parameter per pure polymer is required to match experimental T_G data. Regarding the molecular weight dependency, the theory predicts correctly that the T_G tends towards a limiting value for high molecular weight polymers. This concept can also be applied to statistical copolymers (i.e. PSAN), where the T_G is predicted as function of the chemical composition in good agreement with experimental data taken from the literature [5].

Furthermore the theoretical method can be applied for polymer blends, where the Kirkwood-Buff formalism serves for the determination of the concentration fluctuation. These calculations were performed for immiscible blends made of PS and PVME, where the T_G was investigated as function of blend composition. The results are compared with experimental data [6,7] in Figure 1. Blends made of PS and PPO serve as an additional example for miscible blends, where experimental data are taken from [8].

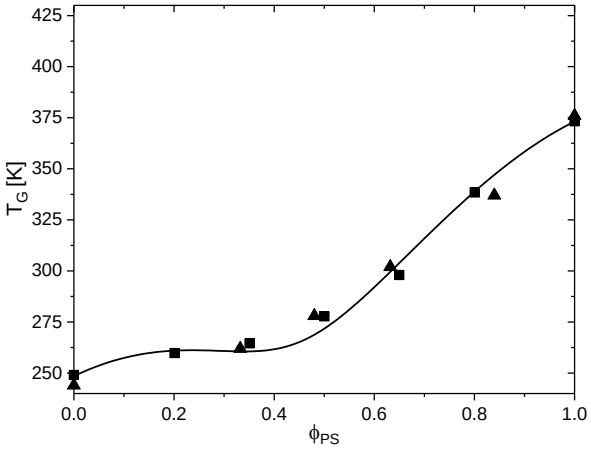

Figure 1. Calculated (solid line) and experimental data from the literature (squares [6], triangles [7]) for the glass transition temperature in a PS-PVME blend.

4. Conclusions

It is shown that the calculation of T_G in polymers and polymer blends can be done with an equation of state e.g. SL-EOS. Hereby the application of the Kirkwood-Buff formalism allows to combine thermal and concentration fluctuations in polymer blends. The results are in good accordance with experimental data and can be applied for different systems e.g. miscible/immiscible polymer blends.

Highlights

- Binary-mixture membrane adsorption isotherms are obtained by molecular dynamics
- The Reactive Vacancy Solution Theory is used to model the gas mixture adsorption
- Activity coefficients and selectivity are calculated up to 20 bar in non-ideal conditions
- Our approach allows a precise description of multi-adsorption at high pressure

1. Introduction

Polymeric membranes are nowadays the class of membranes mostly used in gas separation at moderate temperatures due to their relatively low cost compared to the ceramic ones. Thus, a considerable research work has been carried out to create polymeric films with high values of permeability and selectivity. In particular, the TR-PBO membranes have been extensively studied [1-4], reporting a detailed analysis on the free volume and its relation to solubility, diffusivity and permeability. These studies conclude that TR-PBO has high permeability mainly due to a high diffusivity owing to the higher amount of the free volume. However, the behaviour of these membranes in non-ideal conditions subject to multicomponent sorption at high pressure has not been considered yet in the literature, which is indeed the aim of our work.

2. Mathematical approach to adsorption model

The *Reactive Vacancy Solution Theory* (*RVST*) [5] is paired with the Wilson activity model for the adsorbate phase to predict the membrane behaviour at high pressure in non-ideal conditions. To do that, the single-gas isotherms of four light gases of interest (H_2, N_2, CH_4, CO_2) and their six binary-mixture isotherms were obtained by means of molecular dynamics at 35°C. Then, these data are used to calculate the parameters of the RVST by means of a robust in-house routine.

3. Results and discussion

Some results are shown in Figure 1 as adsorbate activity coefficients and adsorption selectivity. We can see that the activity coefficients are significantly different from the unity, this stating the strong system non-ideality, which thus cannot be modelled by an ideal adsorption model.

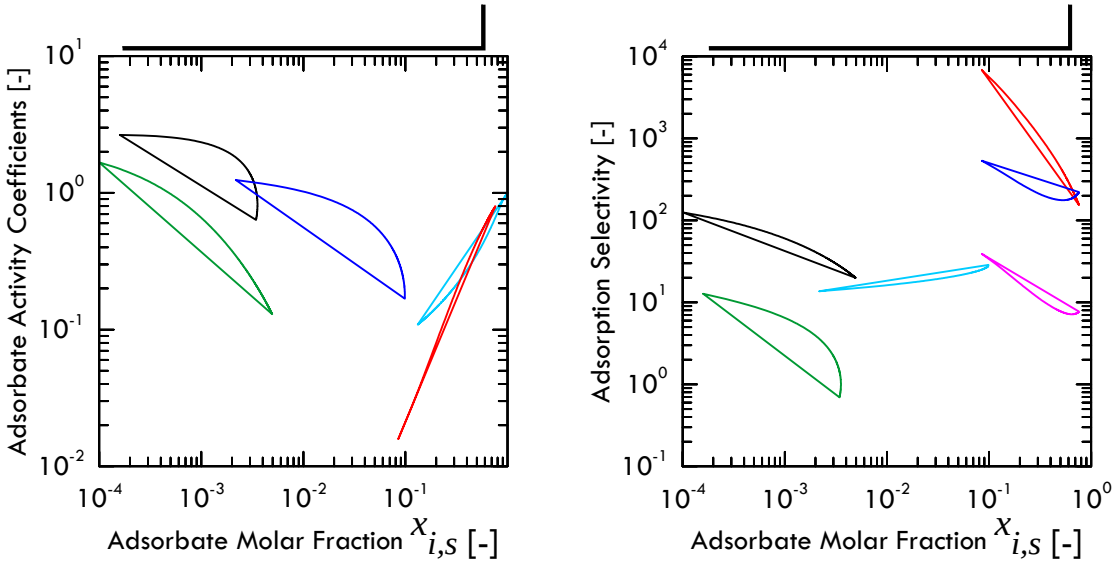

Figure 1. a) Adsorbate activity coefficients and b) Adsorption Selectivity as functions of the adsorbate molar fraction for an equimolar four-species gas mixture at 35°C. The adsorbate composition refers to the upper species in the selectivity definition and is let vary by changing the total pressure within [0.01, 20] bar.

Furthermore, interesting values of adsorption selectivity are found, with the CO_2/H_2 and CO_2/N_2 ones that are respectively estimated around 150 and 210 at a total pressure of 20 bar. These observations suggests possible applications of these materials to gas separation also as adsorbents rather than as membranes, since their perm-selectivity is expected to be lower than the adsorption selectivity due to their relatively high free volume.

4. Conclusions

In this work, the multicomponent adsorption of light gases – H_2, N_2, CH_4, CO_2 – in thermally-rearranged Polybenzoxazole (TR-PBO) membranes was described using the *Reactive Vacancy Solution Theory* (*RVST*) in order to deal with high-pressure and non-ideal conditions. For this purpose, both single-gas and binary-mixture isotherms were obtained by means of molecular dynamics techniques at 35°C. Afterwards, we interpreted these data by the reactive vacancy solution theory (RVST) paired with the Wilson activity model for the adsorbate phase, developing an in-house robust routine to calculated the model parameters.

Our approach, which can be generally applied to all membranes, allow us to predict the real adsorption behaviour of multicomponent mixtures at high pressure (at least up to 20 bar) and in non-ideal cases, where simple Langmuirian models used within the Ideal Adsorption Solution Theory (IAST) cannot satisfactorily describe the mutual adsorbate-adsorbate-adsorbent interactions present in conditions of interest for process industry.

1. Introduction

Carbon dioxide emissions represent one of the main environmental issue of our time. The greenhouse gases atmospheric loading, due to anthropogenic activities, are causing a continue rise of global temperature. In the field of CO_2 capture from gas streams, membrane technologies are promising alternative to the more common operations. Among these, Facilitated Transport Membranes show high performances in terms of CO_2 permeabilities and selectivities even at low pressures by coupling a simple solution diffusion transport mechanism and a reversible chemical reaction with a carrier agent. Polyvinyl amine (PVAm) binds one primary amino group for each monomer along the chain, showing high hydrophilicity and affinity to CO_2. In this work we use the PC-SAFT [1] Equation of State to model the H_2O uptake and the solubility of CO_2 in the ternary system of PVAm / H_2O / CO_2.

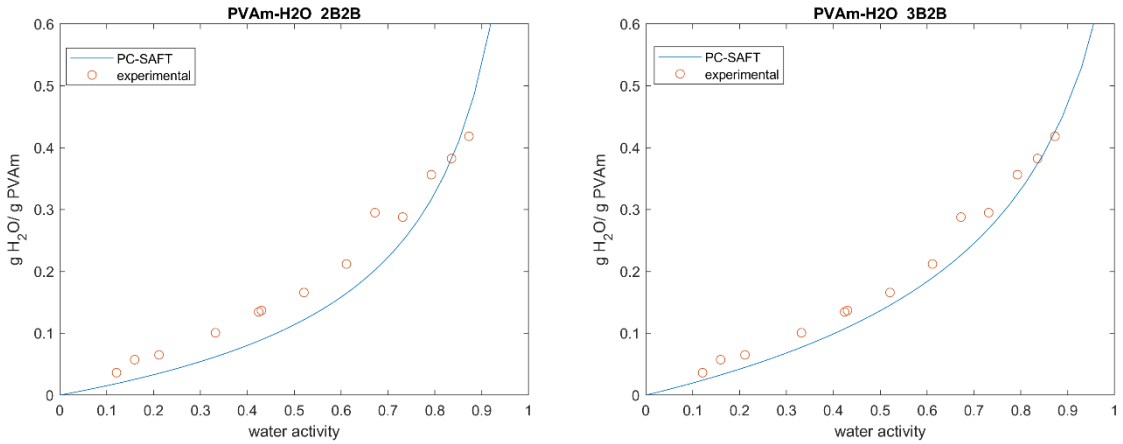

Figure 1. Water uptake in PVAm at 35°C. Circles are experimental data, lines are model calculations.

2. Methods

Within the PC-SAFT, each species is pictured as a series of chained spheres, interacting each other by dispersive, repulsive and associative forces. In the present work, the water has been treated as

a self associative species, with 2 association sites (2B). The same scheme, together with the 3B [2], has been tested also for the PVAm. Besides the non associative case, two sites have been hypothesized for carbon dioxide to better consider the physical interactions among CO_2 and H_2O.

3. Results and discussion

In the figure 1 above, the uptake of water at 35°C in purified PVAm is reported, experimental points are the red circles while the blue lines are the model calculation. Both the association scheme used can describe the actual behaviour of the system in quantitative agreement with the experimental data. The scheme 3B (right) agree better over all the water activity range in respect to the 2B one. The physical sorption prediction (without considering explicitly the chemical reaction(s)) of CO_2 in the ternary system is reported in figure 2 below.

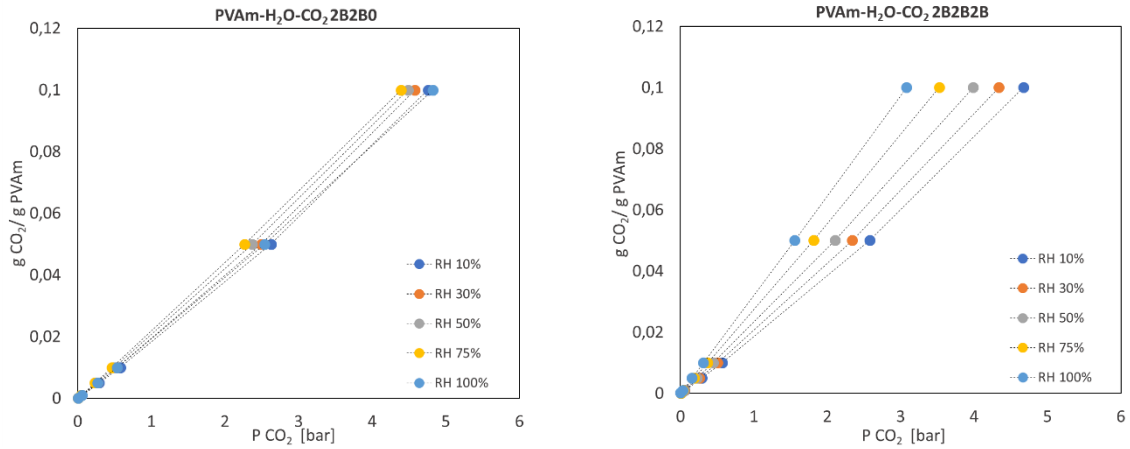

Figure 2. Prediction of CO_2 physical sorption in humidified PVAm.

In the non associative case (left figure) the relative humidity of water does not influence the uptake of CO_2 ; the presence of two sites, instead, elucidate the role of relative in humidity in the system . The higher the water activity, the higher the gas uptake, as we could expect for the system under study.

4. Conclusions

Both the two associative scheme used, 2B and 3B, are able to describe the behaviour of the membranes in terms of H_2O sorption. Moreover the physical solubility of the carbon dioxide in the ternary system of PVAm / H_2O / CO_2 is predicted and the role of relative humidity is elucidated by the presence of two possible associative sites on CO_2. A deeper investigation on the reacting ternary system is undergoing by the use of extended PC-SAFT [3] for polyelectrolyte.

Phase Equilibrium and Density of Highly Asymmetric Gas-Oil Mixtures at High Temperatures and High Pressures

Yiqun. Liu, Teresa Regueira, Erling H. Stenby, Wei Yan*

CERE, Department of Chemistry, Technical University of Denmark, DK-2800 Kgs. Lyngby, Denmark

**Corresponding author: weya@kemi.dtu.dk*

Highlights

- Density and phase equilibrium of CH_4, N_2 and CO_2-oil mixtures systematically measured up to 190 ℃ and 1400 bar.
- Measured data most valuable for modeling highly asymmetric reservoir fluids.
- The more theoretical PC-SAFT model evaluated using the data against the classical cubic models with and without volume translation.

1. Introduction

The global demand for oil is still increasing and expected to stay at a high level for the near future. This has driven many production activities to deep reservoirs at high pressures and high temperatures (HPHT). Accurate description of phase equilibrium and thermophysical properties is of paramount importance to reduce the technical and economic risks in developing HPHT reservoirs. This study is a continuation of our previous work on measuring and modeling asymmetric hydrocarbon systems relevant to reservoir fluids[1][2]. Although we measured binary, ternary and multiple component systems, it is found that the well-defined mixtures are not sufficiently representative for reservoir fluids. Hence, we here conducted a systematic measurement using the mixtures of a stock tank oil with various gases (CH_4, N_2 and CO_2). The measurement includes phase equilibrium and density data up to 190 ℃ and 1400 bar. Since the systems mimic reservoir fluids better, the obtained data provide a more relevant evaluation of various thermodynamic models in describing highly asymmetric reservoir fluids. We evaluated classical cubic models SRK and PR, and the more theoretical PC-SAFT EoS with a heptanes plus characterization method specially developed for it[3].

2. Methods

The density measurement was conducted in an Anton Paar DMA-512P high pressure oscillating tube densimeter following a modified Lagourette et al. method[4][5]. Densities of CH_4-oil, N_2-oil, and CO_2-oil mixtures with different compositions were measured at six temperatures from 25 to 190 ℃ and at six pressures from 400 to 1400 bar. A full visibility cell ST PVT 240/1500 was used to measure the saturation pressure and liquid fractions in the two-phase region for the same gas-oil mixtures. The cell has a motor-driven piston to vary the system pressure and a sapphire window at its bottom to allow full visual observation of phenomena inside the cell and determination of phase fractions. At six temperatures from 25 to 190 ℃, gas (CH_4, N_2, or CO_2) was added to the oil stage by stage to prepare mixtures with increasing gas mole fraction. The classical cubic models SRK and PR were compared with the more theoretical PC-SAFT EoS in modeling the measured data. For SRK and PR, calculation results with and without volume translation were presented.

3. Results and discussion

Our measurement has produced over 270 density points and over 70 saturation pressure points. Figure 1 shows the phase envelopes for three selected mixtures with a gas mole fraction of 0.2. All models predict the correct trend but SRK and PR show large deviations for N_2-oil. Overall, three models show comparable deviations for the C_1-oil and CO_2-oil but PC-SAFT is better for N_2-oil. Some typical density modelling results are shown in Figure 2 for mixtures with a gas mole fraction of 0.2. PC-SAFT is clearly more accurate than SRK and PR without volume translation, but the volume translated SRK and PR show comparable and sometimes even better results than PC-SAFT.

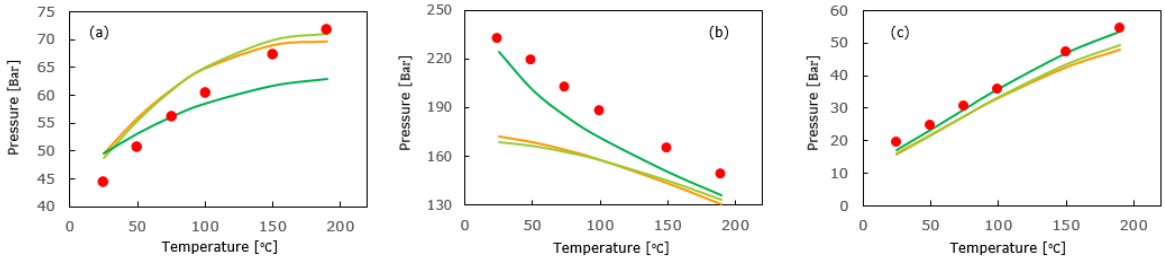

Figure 1. Phase envelope of C_1-oil (a), N_2-oil (b), CO_2-oil (c): data (●); prediction by SRK (—), PR (—) and PC-SAFT (—).

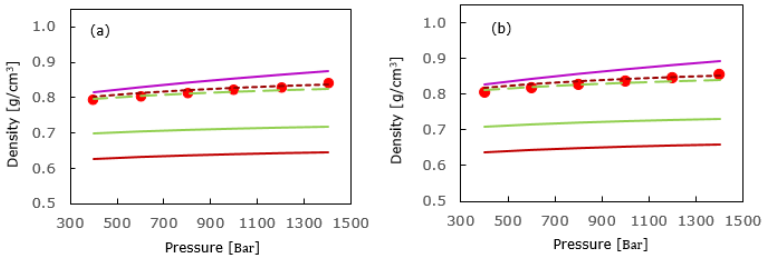

Figure 2. Density for C_1-oil (a) and N_2-oil (b) at 25 °C: data (●); prediction by SRK (—), PR (—), PC-SAFT (—), SRK-VT (- -), and PR-VT (– –).

4. Conclusions

This study has produced valuable HPHT density and phase equilibrium data of highly asymmetric C_1-oil, N_2-oil and CO_2-oil mixtures in a wide composition range. The data are particularly valuable for evaluating and further improving thermodynamic models for HPHT reservoir fluids since well-define mixtures turned out useful but not sufficiently representative in our previous study. The model comparison of PC-SAFT with classical models show that the more theoretical PC-SAFT has some advantages but may not be superior to PR (VT) and SRK (VT) in density modelling. For a more comprehensive evaluation, it is worthwhile to compare these models using other derived properties like excess volume and compressibility data.

Combination of different methods to characterize surface chemistry of activated carbons

Johanna Muthmann[1], Christian Bläker[1], Christoph Pasel[1], Michael Luckas[1], Dieter Bathen[1,2]

[1]Chair of Thermal Process Engineering, University of Duisburg-Essen, Lotharstr. 1, 47057 Duisburg, Germany, [2]Institute of Energy and Environmental Technology e. V. (IUTA), Bliersheimer Str. 60, 47229 Duisburg, Germany

Highlights

- New and improved methods for characterization of surface chemistry
- Chemical modification changes surface chemistry but not structural properties
- Increasing number of acidic oxidic surface groups increases polarity
- Change in surface chemistry shows hardly any effect on the heat of adsorption

1. Introduction

Carbonaceous adsorbents such as activated carbons are used in many technical adsorption processes. Depending on the raw material and the activation conditions, these materials may have different properties. Adsorption is significantly influenced by structural properties and surface chemistry. To characterize structural properties well established methods are available like mercury porosimetry and nitrogen adsorption. At the same time, the impact of surface chemistry on adsorption is not well understood for activated carbons. The aim of the project is to improve the characterization of the surface chemistry of activated carbons and to distinguish between the influence of surface chemistry and structural properties on adsorption.

2. Methods

In this project activated carbons are investigated, which differ systematically in surface chemistry due to chemical modification. To characterize surface chemistry, new and improved methods such as Boehm titration, the measurement of excess isotherms as well as the coupling of volumetric and calorimetric measurements are used. The structural properties are analyzed by nitrogen adsorption

Boehm titration enables quantitative determination of acidic oxidic surface groups of activated carbon using different bases. The ratio of polar, non-polar and aromatic surface groups can be described by excess isotherms [1]. These isotherms reflect the adsorption preference between two competing sample molecules as a function of mole fraction in the liquid phase and thus provide additional information about surface polarity. By coupled volumetric and calorimetric measurements the adsorption enthalpy can be determined, which is a parameter for the strength of interactions in adsorption and allows an energetic characterization of the adsorbent surface [2].

3. Results and discussion

The activated carbon surface was oxidized using nitric acid (HNO_3). The chemical modification changes the surface chemistry whereas structural properties largely remain the same. Boehm titration shows that the number of acidic oxidic surface groups increases with increasing concentration of HNO_3.

In excess isotherms the rising number of acidic oxidic surface groups leads to an increasing ratio of adsorbed polar component over adsorbed aromatic and non-polar components. The increased affinity for the polar adsorptive indicates an increasing polarity of the activated carbon.

In contrast, the heats of adsorption of acetone, toluene and n-heptane are almost identical for the original and for the chemically modified activated carbons . This suggests that the strength of the interactions between surface and adsorptive molecules are dominated by the energetically heterogeneous multimodal pore size distribution of the activated carbon. The surface chemistry plays only a minor role.

To investigate the influence of structural properties in detail, activated carbons manufactured under different activation conditions will be characterized.

4. Conclusions

The combination of different methods enables to distinguish between the influence of structural properties and surface chemistry on adsorptive properties. The investigations were carried out on activated carbons with the same structural properties but different surface chemistry. A rising number of acidic oxidic surface groups results in an improved adsorption of a polar component in a binary mixture and increases the polarity of the activated carbon. In contrast, an influence of surface chemistry on the strength of the interactions between surface and adsorptive molecules could not be detected.

Preferential Adsorption in Electrolyte Mixtures

Max F. Döpke[1], Remco Hartkamp[1]

1 Process & Energy Department, Delft University of Technology, Leeghwaterstraat 39, 2628 CB Delft, The Netherlands

**Corresponding author: r.m.hartkamp@tudelft.nl*

Highlights

- Preferential adsorption is driven by a balance between interactions
- Different surface sites show preference to different electrolytes

1. Introduction

Interfaces between aqueous solutions and oxide surfaces are critical to a plethora of industrial and biological systems. Solutions typically contain various monovalent and multivalent electrolytes. However, countless studies have considered solutions with only a single electrolyte to represent systems in which the concentration of one electrolyte is dominant, such as seawater.

Although such an approach may be appropriate for the study of bulk fluid properties, local properties at the solid-liquid interfaces can be highly ion specific. Consequently, even electrolytes that are present in small quantities can dominate the electric double layer (EDL) and thus play a key role in nanofluidic transport, sensing,[1] energy storage, sensing and electrochemical processes.

This study reveals the origin of preferential ion adsorption onto an amorphous oxide surface. Furthermore, we show how traditional electric double layer models fall short in predicting or fitting the ion distribution in the case of electrolyte mixtures.

2. Methods

Experimental techniques often rely on fitting measurement data to EDL models (such as variants of the Gouy-Chapman model) and macroscopic transport relations to infer quantities that cannot be directly measured.[2] Such simplified models disregard ion specificity and assume that the solid surface is flat and homogeneous and that fluid transport coefficients are constant in space. Alternatively, molecular dynamics (MD) simulations can provide detailed insight into the three-dimensional EDL structure and local transport properties, without the need for an assumed EDL model. As such, MD offers an appealing approach to gain detailed insight into interfacial properties and can aid in improving models and assumptions used for interpreting experimental measurements.

3. Results and discussion

Using all-atom MD simulations[3] of NaCl-$CaCl_2$ solutions in a charged oxide nanochannel (Figure 1), we found that Na^+ and Ca^{2+} ions were simultaneously adsorbed to the surface, with some surface

sites showing a distinct preference for Na^+ and others for Ca^{2+}. Although Ca^{2+} ions experience stronger electrostatic attraction to the negatively charged surface sites, their large and strong hydration shell forms a steric hindrance at some of the surface sites, whereas the hydration shell of the Na^+ ions does not suffer from the same hindrance. Using a metric to quantify the geometry of surface sites, ion-specific adsorption can be successfully predicted.

Turning to adsorption kinetics, Ca^{2+} ions were found to be adsorbed much longer than Na^+, with adsorption times depending on the specifics of the surface site. As such, the presence of even small quantities of preferentially adsorbed ions can dramatically alter interfacial dynamics, including fluid-wall slip, interfacial viscosity enhancement, and conductance.

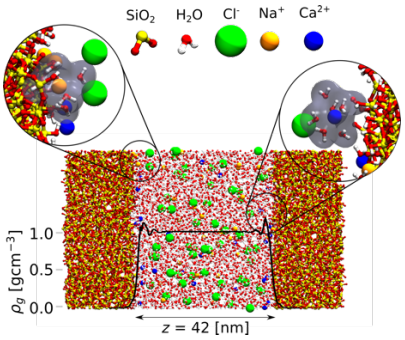

Figure 1. Channel configuration for simulations with fluid density overlaid on the channel. The left inset shows Na^+ adsorption, with the hydration shell penetrating the wall. Right inset shows Ca^{2+} adsorption, with the hydration shell remaining intact.

4. Conclusions

Surface roughness, as well as placement and orientation of surface sites, severely impacts preferential adsorption. Insight from MD simulations into the relation between surface structure and preferential adsorption can help to interpret experimental measurements and can also be used to microengineer surfaces with selectivities for specific ions.

Molecular-Thermodynamic Correlation of Solubility Data for 20 Amino Acids in Water, in Ethanol and in Water-Ethanol Mixtures.

Nathan Bowden[1], Marieke E. Bruins[2], Johan Sanders[3], John M. Prausnitz[4]

1 Institute for Sustainable Process Technology, Groen van Prinstererlaan 37 3818JN Amersfoort, the Netherlands; 2 Wageningen Food & Biobased Research, Bornse Weilanden 9, 6107WG Wageningen University and Research, The Netherlands; 3 Biobased Chemistry and Technology Group, AFSG, Bornse Weilanden 9, 6708WG Wageningen, Wageningen University and Research, The Netherlands; 4 Department of Chemical & Biomolecular Engineering, Gilman Hall, University of California, Berkeley, CA 94720-1462, USA

Highlights

- The solubilities of some amino acids show maxima in a water-ethanol mixed solution
- These calculated maxima, predicted by the model, are in agreement with experiments
- Solubility of amino acids depends its on $(f^s/f^L)_{pure}$ ratio and its solvent interaction
- Amino acids with the lowest interaction parameters are not necessarily the most soluble
-

1. Introduction

Models have been proposed for amino acid solubility in aqueous solution [1] and for the solubility of amino acids in salt solutions [2]. A few empirical models with regressed parameters have been proposed to describe the solubility of α-amino acids in ethanol/water systems [3,4]. In this work, we apply the van Laar equation for the molar excess Gibbs energy to all 20 proteinogenic amino acids in ethanol, in water and in ethanol-water mixtures.

2. Methods

For each amino acid, T_m and Δh_{T_m} are estimated using the method proposed by Marrero and Gani [4]. To predict the solubility of an amino acid in mixtures of water and ethanol, we must determine the interaction parameters, A_{ij}, of an amino acid (i) in water (j) or ethanol (j) and of water (i) and ethanol (j) in a solute free solution, where i and j are all possible binary combinations of solute (1), water (2) and ethanol (3). To obtain the A_{ij} parameters, we used the van Laar equation obtained from Wohl's expansion for the molar excess Gibbs energy of a binary solution.

We then obtain the saturated mole fraction of the amino-acid solute, x_1^S by simultaneously solving the model with the mass balance $x_1 + x_2 + x_3$= 1.00. The ratio $(f^s/f^L)_{pure}$ at 25 °C is obtained.

$$x_1^S = (f^s/f^L)_{pure}\left(exp\left[\frac{x_2{}^2 A_{12}\left(\frac{A_{21}}{A_{12}}\right)^2 + x_3{}^2 A_{13}\left(\frac{A_{31}}{A_{13}}\right)^2 + x_2 x_3 \frac{A_{21}A_{31}}{A_{12}A_{13}}(A_{12}+A_{13}-A_{32})\left(\frac{A_{13}}{A_{31}}\right)}{\left(x_1 + x_2\frac{A_{21}}{A_{12}} + x_3\frac{A_{31}}{A_{13}}\right)^2}\right]\right)^{-1} .$$

This calculation is not explicit in x_1^S. Solution of Equation is achieved by a simple iterative computer program.

3. Results and discussion

The Normalized Root Mean Square Variance for 16 of the 20 proteinogenic amino acids were lower than 0.100, indicating very good agreement with the solubility data. This group of amino acids includes L-tyrosine, whose maximum solubility occurs when the solute-free mixed solvent contains 91.1 mole% water and 8.90 mole% ethanol, higher than that at 100 mole% water. For L-isoleucine, L-tryptophan, L-phenylalanine and L-proline, NRMVs are lower than 0.220, indicating good agreement with the solubility data.

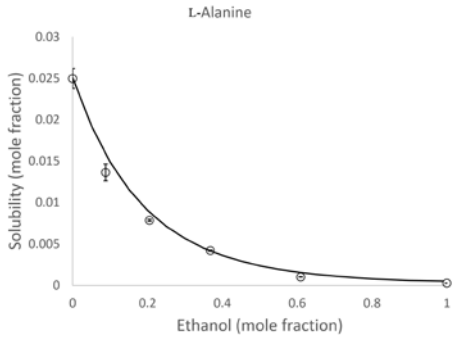

Figure 1: Predicted (solid line) and experimental (circles) solubilities of L-alanine in water-ethanol mixtures at 25 ˚C.

4. Conclusions

The ternary form of the van Laar equation for the molar excess Gibbs energy is useful for predicting the solubilities of amino acids in water-ethanol mixtures at 25 °C. The calculated solubilities of some amino acids show maxima in a water-ethanol mixed solution. These calculated maxima, predicted by the van Laar model, are in agreement with experiments.

The advantage of the thermodynamic technique used in this work is scale-up. A good solubility of a solute in a binary solvent (i.e. a ternary system) can be calculated based on only binary information.

Development of a new experimental method to determine inherent dissolution properties of active pharmaceutical ingredients

Highlights

- Drug release can be limited by diffusion or surface reaction kinetics.
- A flow channel was constructed to ensure well-defined fluid conditions.
- Intrinsic material data were derived by analyzing four different drugs.
- A model that accounts for diffusion- and surface reaction limited drug release was developed.

1. Introduction

The dissolution behavior is a crucial factor in novel drug substance formulation. The two main factors limiting the dissolution kinetics of active pharmaceutical ingredients are diffusion (Fick, 1855) and surface reaction kinetics (Paus et al., 2015).

2. Methods

Dissolution experiments such as the intrinsic dissolution test described in the pharmacopeia (European Pharmacopoeia Commission, 2017) have been performed for many years. To overcome the disadvantages of the intrinsic dissolution test, a flow channel was constructed and evaluated to ensure well defined flow conditions. The mass transfer rates from a flat, solid surface into the solvent flowing over the solid surface within the flow channel were used to derive a mathematical model that distinguishes between diffusion limited and surface reaction limited drug release.

3. Results and Discussion

A rectangular flow channel was designed (Shah and Nelson, 1975) (Figure 1, left) based on fluid dynamics calculations (Ansys CFX® 19.1, Ansys Inc., Canonsburg, USA). A rectangular surface with a width to height ratio of 5 was chosen (Ward-Smith, 1980). The characteristic velocities for a flow of Re 250 are color coaded. The powder sample was compress into a die resulting in a well-defined sample surface. The sample concentration in the dissolution media was measured by UV spectroscopy. The right-hand image in Figure 1 shows the weight flux from the sample as function of the Reynolds number. For particularly low Reynolds numbers, the weight flux is limited by diffusion (intercept with the ordinate (Re=0); J^{w}_{D}). For high Reynolds numbers (Re > 150) the

weight flux begins to level out indicating it is limited by the surface reaction. Between those stages the weight flux depends on the flow conditions and is a function of the Reynolds number.

$$J_{diss}^{w} = \left(0.5 \cdot sgn\left(\left(0.03 \cdot \sqrt{\lambda} \cdot Re \cdot Sc^{\frac{1}{3}} \cdot J_D^w + J_D^w\right) - \frac{k_{SR} \cdot \rho_{solid}}{\delta_{SR}}\right) + 0.5\right) \cdot \frac{k_{SR} \cdot \rho_{solid}}{\delta_{SR}}$$
$$+ \left(0.5 \cdot sgn\left(\frac{k_{SR} \cdot \rho_{solid}}{\delta_{SR}} - \left(0.03 \cdot \sqrt{\lambda} \cdot Re \cdot Sc^{\frac{1}{3}} \cdot J_D^w + J_D^w\right)\right) + 0.5\right) \cdot \left(0.03 \cdot \sqrt{\lambda} \cdot Re \cdot Sc^{\frac{1}{3}} \cdot J_D^w + J_D^w\right)$$

The weight flux from pure diffusion is quite similar for the two tested model substances. This is unsurprising based on their similar molecular size, which is used to predict diffusivity via the Stokes-Einstein correlation. Theophylline shows a much higher flux at high Reynolds number compared to benzocaine, which indicates a faster surface reaction for theophylline. The reason is not clear yet and needs to be investigated further. The linear correlation between flux and Reynolds number (0 < Re < 150) can be attributed to convection and is captured by an approach based on Prandlt's work (Brauer and Mewes, 1971).

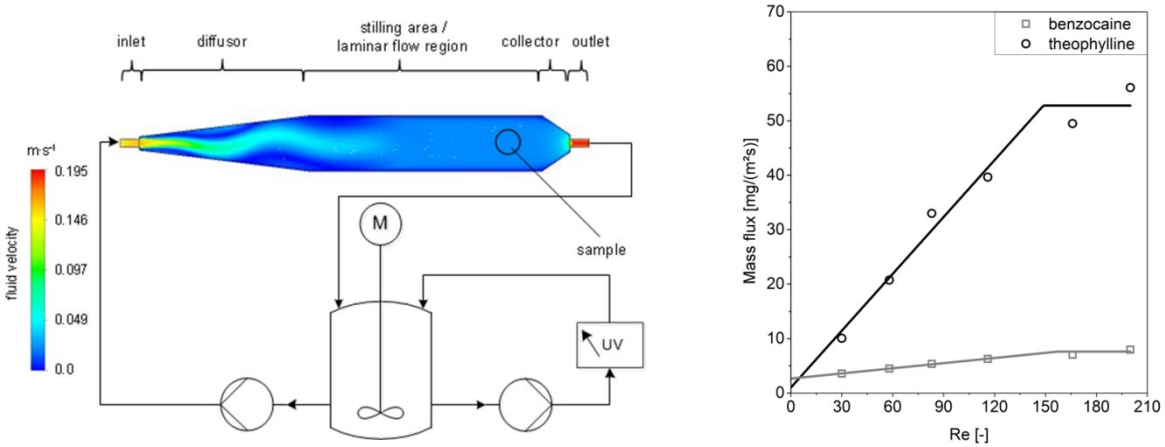

Figure 1. Set up of the flow channel dissolution experiment (left) and the resulting weight flux of benzocaine, theophylline as a function of the Reynolds numbers (av, n = 3).

4. Conclusions

A new intrinsic dissolution setup has been deigned in order to overcome the limitations of the pharmacopeia test. This enables diffusion- and surface reaction limited regimes for drug release to be determined experimentally. Two model drugs were tested and differences were observed.

Molecular Dynamics Simulations of Confined Water inside Stacked Graphene Oxide Membranes

One-Sun Lee
Qatar Environment and Energy Research Institute, Hamad Bin Khalifa University, Doha, Qatar

Stacked graphene oxide (GO) is an emerging membrane with the application of desalination. However, the structure and dynamics of water molecules and ions inside GO membrane is not known, and this has proven to be a hindrance in understanding how this system functions. Here, we investigate the dynamic behavior of water inside GO membrane using computational approach. We developed four different models of GO membrane with different interstice distance (*d*) between GO sheets (*d* = 7, 9, 11, and 13 Å in Figures 1 (A) and (B)), and performed molecular dynamics simulations of water (SPC/E model) inside each membrane. The measured diffusion coefficients (in unit of $\times 10^{-5}$ cm^2/sec) of water are 0.3 (*d* = 7 Å), 0.9 (*d* = 9 Å), 1.2 (*d* = 11 Å), and 1.5 (*d* = 13 Å). To understand the retarded diffusion of water with narrower interstice distance, we analyzed the hydrogen bond autocorrelation relaxation and the rotational relaxation. The molecular rotation is described by the first and second-rank Legendre polynomials,

$$P1_i(t) = \left\langle \vec{u}_i(0) \cdot \vec{u}_i(t) \right\rangle = \left\langle \cos\theta_i(t) \right\rangle \quad (1)$$

$$P2_i(t) = \left\langle \frac{3}{2}\left(\vec{u}_i(0) \cdot \vec{u}_i(t)\right)^2 - \frac{1}{2} \right\rangle \quad (2)$$

using the molecular body-fixed axes (See Figure 1(C)). We found that the hydrogen bond lifetime is longer in the GO membrane with the narrower interstice distance, and the rotation relaxation of water is also slower in the GO membrane with the narrower interstice distance (Table 1). Therefore, we concluded that the diffusion of water is retarded by the hydrogen bond with the hydroxyl or epoxy groups of GO membrane. Our simulation result would be a useful theoretical source for designing new carbon-based membranes for desalination.

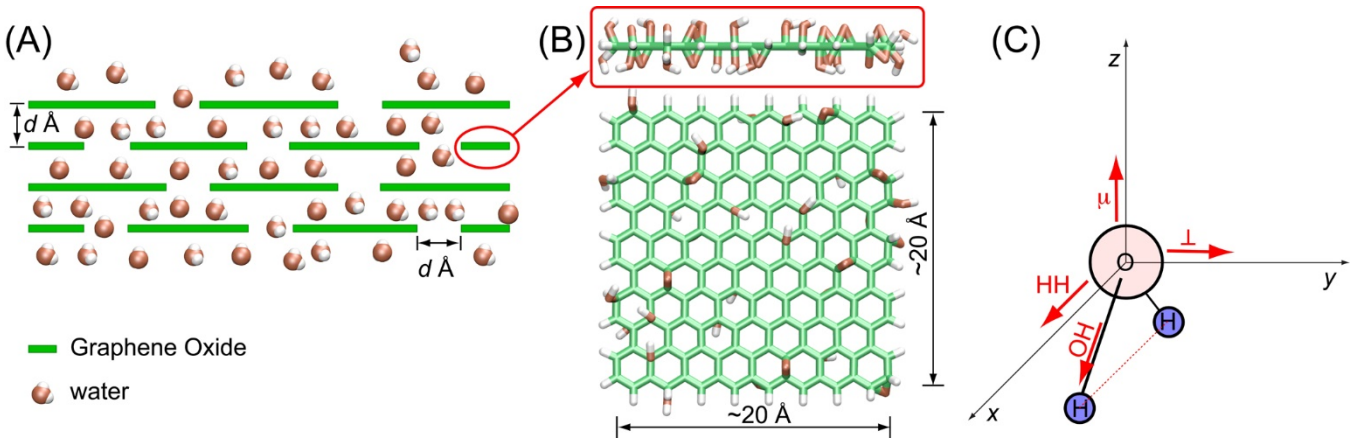

Figure 1. (A) Schematic representation of the penetration of water through the interstices of stacked GO membrane. (B) Snapshots of the side and top view of GO used in the simulations. (C) Coordinates of water molecule for the analysis of rotation dynamics.

Highlights

- Remarkable wide ILC temperature domain of systems containing bio-based ILs
- Mixing ILs and fatty acids improved their physical and thermal properties
- The investigated mixtures form solid solutions
- Mixtures presented high MP depression and high decrease in ILC temperature domain

1. Introduction

Bio-based ionic liquids (ILs) are promising compounds and their synthesis by using compounds obtained from natural sources has been considered as an alternative way to overcome the toxicity aspect and expand their applications in food and cosmetic industries [1]. This is the case of ILs based on fatty acids and choline. Fatty acids are considered GRAS substances and food additives with functional properties (e.g. omega fatty acids) [2], which makes them interesting precursors to produce low toxic and possible edible ILs. Choline cation belongs to the B-complex vitamins, that can be found in several foods and is considered as essential and nontoxic nutrient.

Mixing ILs have been considered an alternative way to improve their thermal and physical properties, but studies on such approaches using ILs obtained from natural compounds are still scarce [3]. The phase behavior of mixtures containing such ILs are far from be fully evaluated, especially those systems with liquid crystalline mesophases. In this context, new possibilities toward the design of bioproducts by using compounds of interest for food and cosmetic industries, such as lipidic based products, have been encouraged.

The aim of this work was to characterize the Solid-Liquid-crystal-Liquid thermodynamic Equilibrium (SSLcLE) of two binary mixtures of bio-based ILs and fatty acids.

2. Methods

The two systems comprises ILs with their fatty acid precursor: cholinium stearate + stearic acid ($[Ch][C_{18}OO] + C_{18}OOH$) and cholinium oleate + oleic acid ($[Ch][C_{18:1}OO] + C_{18:1}OOH$). The melting temperatures were determined using a DSC8500 calorimeter (PerkinElmer, USA) in a cooling-heating cycle at 1 K min^{-1}. The liquid crystalline mesophases (LCMs) were evaluated using a polarized optical thermomicroscope (Leica, Germany) in a 0.1 K min^{-1} heating run.

3. Results and discussion

Phase equilibrium data indicated two phase transition regions S-LC and one LC-L, presenting three solid phases with solid solutions SS, one mesophase LC and one isotropic liquid phase L. This behavior is commonly observed for ILs. Furthermore, the investigated mixtures form solid solutions. This work also revealed a remarkable wide ILC temperature domain of ILs derived from choline and fatty acid. The system [Ch][C_{18}OO] + C_{18}OOH presented lower decrease on their ILC temperature domain and lower depression of the melting points (MPs). This could be related to higher anion-cation interactions and layered structures, as well as mesophases-forming ability due to their long alkyl chain length and linearity. Otherwise, systems containing molecules with unsaturation in their structures presented a higher decrease on ILC temperature domain and a higher MP depression.

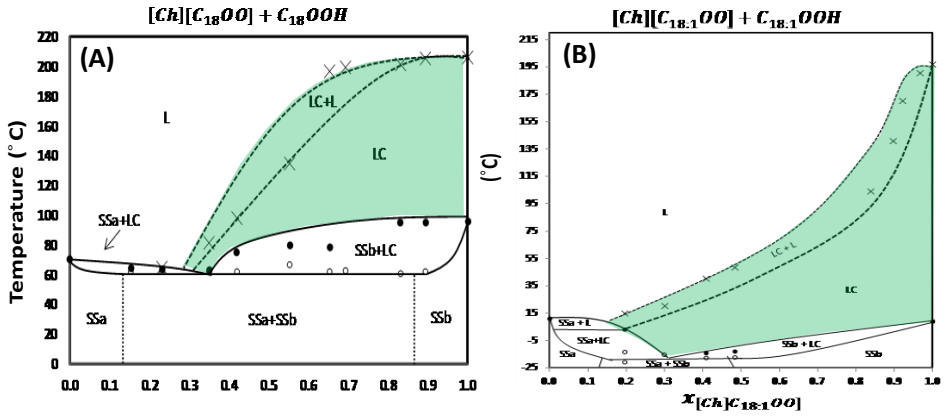

Figure 1. Phase equilibrium of the binary mixtures of ILs and fatty acids: cholinium stearate + stearic acid ([Ch][C_{18}OO] + C_{18}OOH) (A) and cholinium oleate + oleic acid ([Ch][$C_{18:1}$OO] + $C_{18:1}$OOH) (B).

4. Conclusions

The results reported in this work show a decrease on the ILC temperature domain and melting temperature by mixing bio-based ILs and fatty acids. The tunability on the thermal and physical properties of the mixtures are related to the concentration and presence of unsaturation in the molecular structure of their components. The melting profile exhibited the formation of very well define liquid crystalline mesophases in a wide temperature range. These results open perspectives on the applications of ILs for the design of lipid-based structuration agents or industrial applications in processes at high temperatures.

Highlights

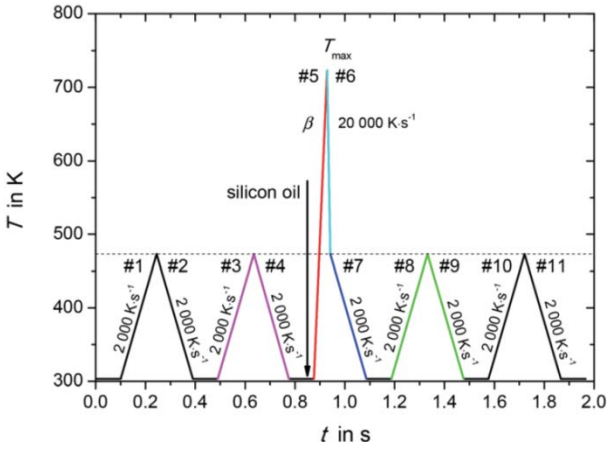
- **New experimental melting properties of amino acids**
- **Prediction of aqueous solubility of amino acids with PC-SAFT**
- **Transfer of the method to peptides**

1. Introduction

The solubility of amino acids plays an essential role for the production and purification of amino acids, especially for crystallization processes. The solubility affects product yield and purity as well as the choice of solvent for the process. Further, several (bio)chemical operations are processed at homogenous conditions, i.e. amino-acid precipitation has to be avoided; this also requires solubility data. The experimental measurement of solubility is time-consuming and expensive considering the nearly uncountable different conditions in biological solutions (pH-value, temperature, type and concentration of co-solutes and co-solvents). Therefore, the prediction of solubility using thermodynamic models is desired, which however requires activity coefficients and the melting properties of the considered solute. However, measuring the enthalpy of fusion and the melting temperature of biomolecules such as amino acids is usually not possible using conventional differential scanning calorimetry due to decomposition of the solid during the measurement.

2. Methods

Application of fast scanning calorimetry (FSC) overcomes the problem of decomposition, and FSC was used in this work to measure the melting properties. The measurements were performed under an inert atmosphere of nitrogen with a sample mass less than 100 ng. Figure 1 shows the temperature-time profile used in this study.
The profile is divided into three measurements stages. (i) Sample mass determination (#1-#4), (ii) sample melting and quenching (#5-#7) and (iii) reheating of supercooled sample (#8-#11). In this work the enthalpy of fusion and melting temperature were measured for a series of amino acids.



Fiure. 2: Temperature-time profile for determination of melting properties with fast scanning calorimetry.

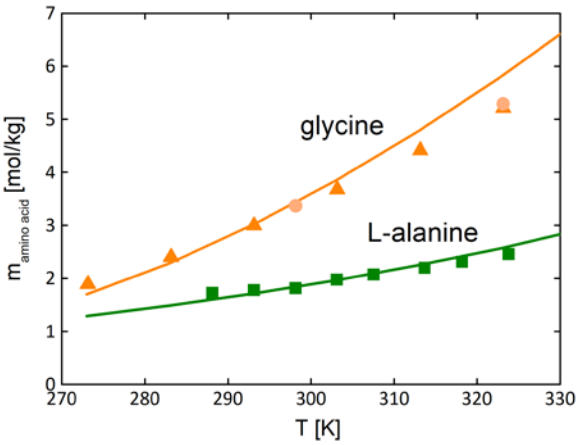


Figure 1 Glycine and L-alanine solubility in water as molality vs. temperature. Symbols represent experimental data (circles[3], triangle[4], squares[5]). Lines represent PC-SAFT predictions.

2. Results and discussions

The solubility measurements of amino acids were performed in aqueous solution. The PC-SAFT pure-component parameters for the amino acids as well as the water parameters were taken from literature [2]. Additionally, one binary interaction parameter k_{ij} was used between amino acid and water. The values for k_{ij} were fitted to experimental osmotic-coefficient data of aqueous amino-acid solutions at 298.15 K and atmospheric pressure. As shown in Figure 2 the temperature-dependent solubility of glycine and L-alanine in water were predicted with PC-SAFT using the melting properties measured from FSC in very good agreement to the experimental data. The method could be successfully transferred to peptide solutions as well as to solubility of amino acids in water-alcohol mixtures.

4. Conclusions

In this work it was the goal to predict solubility of components that decompose before melting, e.g. amino acids or peptides. The predictions require PC-SAFT parameters and melting data. All PC-SAFT parameters were taken from literature or fitted to new solubility-independent thermodynamic properties such as osmotic coefficients. Melting properties were measured using FSC. The results revealed that amino-acid solubilities can be accurately predicted over a broad temperature range. The combination between PC-SAFT and FSC generally allows the predicting solubility of molecules that decompose before melting.

A Discrete Modeling Approach for Excess Gibbs-Energy Models Coupled with Random Sampling of Molecules.

Christoph Mayer[1], Thomas Wallek[1]

1 Graz University of Technology, Institute of Chemical Engineering and Environmental Technology, Inffeldgasse 25/C, 8010 Graz, Austria

Highlights

- Condensed phase equilibrium calculations
- Ab initio distinction between isomers
- Intrinsic configurational information

1. Introduction

Thermodynamic models for fluid phase equilibria calculations, such as equations of state and activity coefficients, are being challenged by the need to describe complex and/or strongly oxygenated molecules. In this context, previous papers proposed 'discrete modeling' as a novel approach to incorporate a more detailed molecular picture into thermodynamics from scratch. The approach is characterized by the rigorous use of Shannon information as thermodynamic entropy. As a proof of concept, the thermal and caloric equations of state, heat capacity and Maxwell-Boltzmann distribution for ideal gas were derived on the basis of discrete states of individual molecules [1-2]. To further extend this approach to strongly interacting condensed-phase systems [3], a previous application of discrete Markov-chains to thermodynamic modeling [4] was modified and extended from a flat lattice towards a three-dimensional, Ising-type lattice model. The initial step of this model was the description of spherical molecules [5]. In this paper, it is extended and coupled with a force field-based random sampling algorithm to account for real substances, beyond spherical molecules.

2. Methods

From the whole lattice system, a small, three-dimensional subgroup resp. cluster of sites is picked out as a representative part of the system and the basis for thermodynamic modeling. Its stepwise formation is described by starting from one lattice site and successively adding further nearest-neighbor sites using conditional probabilities in terms of discrete Markov-chains. Such clusters can be treated as statistically independent subsystems, yet account sufficiently for cooperative effects due to molecular interactions inside the cluster. The according probability of occurrence of clusters can more vividly be rewritten in terms of probabilities of pairwise interactions which are also used by the quasi-chemical approximation by Guggenheim and derived approaches. Next, the internal energy and the Shannon entropy of the system are formulated on the basis of these pairwise probabilities. The Shannon entropy is then used equivalently to thermodynamic entropy. Constrained minimization of the free energy yields the equilibrium distribution for the probabilities of pairwise interactions. For non-spherical molecules, a random sampling algorithm is used to determine energetic interactions between molecules in a cluster together with its respective probability of occurrence.

3. Results and discussion

First, the model is derived for spherical molecules of equal size with uniform surface properties. For given system parameters like composition and interchange energies, the resulting equilibrium properties of the system, i.e. internal energy and entropy, are compared to those derived from Monte-Carlo simulations and to the quasi-chemical approximation by Guggenheim [6]. The latter represents an important limiting case, because practically all state-of-the art activity coefficient models reduce to the Guggenheim approach in the case of uniform spheres. Figure 1 compares the new model to data from Monte-Carlo simulations for spherical molecules. It is evident that the new approach considerably improves representation of Monte-Carlo data, compared to the quasi-chemical approximation, particularly at strong molecular interactions. Consequently, the new model could be used as a more precise alternative to the quasi-chemical approximation. In order to allow more realistic molecule models, it is coupled with a force field-based random sampling algorithm.

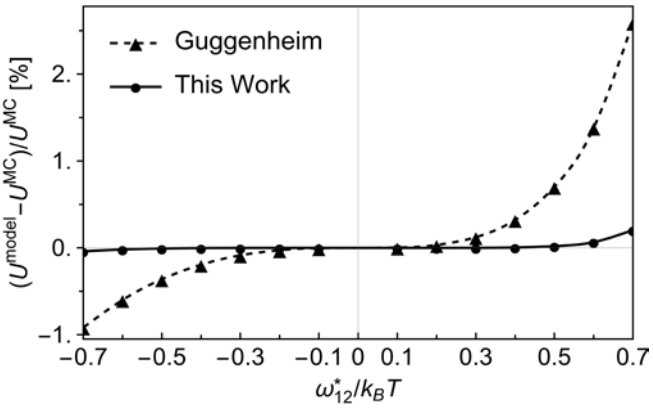

Figure 1. Relative deviation for the internal energy, U, between the models and Monte-Carlo (MC) data for a simple cubic lattice with 50^3 sites at a global composition of $x_1 = 0.3$. ω^*_{12}/k_BT is the dimensionless interchange energy.

4. Conclusions

Due to its better representation of spherical molecules and its intrinsic ability to distinct between isomers by using clusters as modeling basis, the proposed approach is a promising basis for further developing the method towards an activity coefficient model for liquid mixtures.

Highlights

- Application of a thermodynamic activity-based approach to enzyme kinetics.
- Prediction of combined high-pressure and co-solvent effects on reaction kinetics.
- Molecular interactions explain observed high-pressure and co-solvent effects.

1. Introduction

To optimize biotechnological production processes, knowledge about the effects of the reaction medium (temperature, pH, concentration and co-solvents [1]) on reaction yield and kinetics is very important. Even though liquid-phases are generally assumed to be incompressible, pressure is also an important influence factor to tune enzyme-catalyzed reactions taking part in liquid aqueous systems [2]. Certain enzymes are known to be pressure tolerant and additionally piezophile (i.e. pressure has a positive effect on enzyme activity) [3]. Consequently, the thermodynamic variable pressure should be an important influence factor, similar to temperature. In this work, the enzyme-catalyzed peptide hydrolysis of SPNA (N-succinyl-L-phenylalanine-p-nitroanilide) was investigated. The effects of high pressure and of co-solvents on the reaction kinetics were studied and explained by thermodynamics (interactions in the liquid phase).

2. Methods

In this work, experimental kinetic studies were performed at 20 °C for pressures of 1 bar and 1500 bar and the high-pressure influence on reaction kinetics was determined. Experimental data was analyzed according to the Michaelis-Menten procedure yielding the observed Michaelis constant K_M^{obs} and the turnover number k_{cat}^{obs}. Further, the thermodynamic model PC-SAFT (Perturbed-Chain Statistical Associating Fluid Theory) [4] was used to predict co-solvent effects on the reactive system. For this purpose, the constants K_M^a and k_{cat}^a were determined based on thermodynamic activities instead of concentrations in order to be independent of solvent effects, which requires activity coefficients: $K_M^a = K_M^{obs} \cdot \gamma_{substrate}$ and $k_{cat}^a = k_{cat}^{obs} \cdot \gamma_{enzyme}^*$.

The substrate's activity coefficient $\gamma_{substrate}$ as well as the enzyme's activity coefficient γ_{enzyme}^* were obtained by PC-SAFT. These account for molecular interactions that are expected to determine co-solvent effects on reaction kinetics. The kinetic constants were measured only in the neat cosolvent-free system while PC-SAFT was then applied to predict the kinetic constants in a reactive system of different composition or in different solvents. Applying the exponential

pressure dependence of K_M and k_{cat} additionally allowed for predicting the pressure influence on reaction kinetics.

3. Results and discussion

Experimental results showed the positive influence of high pressure on the reaction kinetics. For increasing pressures up to 2000 bar, K_M was found to decrease indicating a higher affinity of the substrate towards the enzyme. Furthermore, k_{cat} increased for increasing pressure indicating a faster product formation. In contrast, the co-solvents under investigation (0.5 mol kg^{-1} TMAO, 1 mol kg^{-1} urea and 4.2 mol kg^{-1} DMSO) had a negative effect on reaction kinetics (see Figure 1). These effects were rather small for TMAO and urea by only slightly increasing K_M and decreasing k_{cat}. However, DMSO strongly increased K_M, indicating a weaker affinity of the substrate towards the enzyme. k_{cat} was also considerably decreased by DMSO.

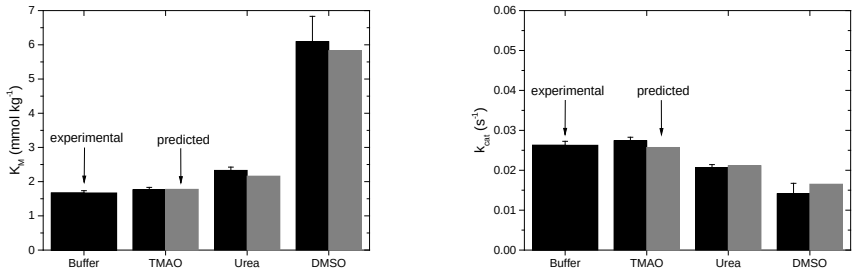

Figure 1. Left: Experimentally determined K_M (black) and PC-SAFT predicted K_M (grey) in mmol kg^{-1}, right: Experimentally determined k_{cat} (black) and PC-SAFT predicted k_{cat} (grey) in s^{-1} plotted against co-solvent at 500 bar and 20 °C.

PC-SAFT predictions of high-pressure and co-solvent effects on reaction kinetics were performed. For these predictions, the combined high-pressure and co-solvent effects on reaction kinetics were of special interest (see Figure 1). The PC-SAFT predicted Michaelis constants K_M are in almost quantitative agreement with experimental data for all co-solvents as well as for all observed pressures. The fact that PC-SAFT successfully predicts the combined co-solvent and high-pressure effects on K_M is a proof that the observed effects are dominated by molecular interactions. Additionally, even though the combined co-solvent and pressure effects on k_{cat} are small, PC-SAFT predictions agree very well with experimental data.

4. Conclusions

Applying a thermodynamic activity-based approach allows predicting the combined high-pressure and co-solvent effects on reaction kinetics of the investigated peptide hydrolysis. Predictions and experimental results were in very good agreement. That is, molecular interactions (substrate/co-solvent) are mainly responsible for the experimentally-observed effects of high pressure and co-solvent on reaction kinetics.

Highlights

- new data for the interfacial tension for aqueous binary mixtures were provided
- modelling of interfacial properties using DGT in combination with PCP-SAFT
- occurring maxima of interfacial tension is captured by the model

1. Introduction

Renewable resources like natural oils and fats are of great importance to combat the depletion of fossil fuel. Natural fats and oils primarily consist of triglycerides that are the basis for long-chain molecules like fatty alcohols, fatty amines and fatty acids. To characterize aqueous binary mixtures with these renewable substances the knowledge of phase- and interfacial properties are crucial in process engineering applications. Challenges arise in particular when water is mixed with a slightly polar or associating long-chain molecules (LCM), such as fatty acids, fatty acid methyl esters and fatty alcohols. Recently, the miscibility gap of water + n-alkanes could be modelled with a very high accuracy using PCP-SAFT approach [1]. This holds true for the solubility of n-alkane in water, the solubility of water in n-alkane as well as the solubility minima were captured [1]. The phase behavior of mixtures made of water and polar compounds, like aldehydes or esters, could be also modelled very close to experimental data, where the hetero-segmental version of PCP-SAFT was utilized [2]. The mixtures made of n-alcohol + water exhibit self-association as well as cross-associations. If these effects were included in the PCP-SAFT framework, the phase behavior can also modelled very close to the experimental data [3]. The aim of the present study consists of experimental and theoretical investigation of the interfacial properties of these mixtures, where these properties can be modelled by the density gradient theory (DGT) in combination with the above mentioned PCP-SAFT.

2. Methods

The binary phase behavior and the interfacial properties of the aqueous mixtures were modeled by a combination of DGT with PCP-SAFT [4]. Both the hetero-segmental and homo-segmental approach of PCP-SAFT are investigated and presented for this purpose. In case of the hetero-segmental approach, the n-alkylic residue within a homologous series was modeled using the PCP-SAFT parameters of n-alkanes and the binary interaction parameters, k_{ij}, were taken from water + n-alkane mixtures. Applying the hetero-segmental approach, polar and associative interactions among the identical head domains were explicitly taken into account. Due to its group-contribution-

like character, the hetero-segmental approach enables the prediction of thermodynamic properties of various compounds within a homologous series. The influence parameters occurring in the DGT of LCM were adjusted to the surface tensions. However, the influence parameter for water must be slightly readjusted. The spinning drop tensiometer was used to measure the interfacial tension of the binary LCM-water mixtures at different temperatures.

3. Results and discussion

Interfacial tension were measured for mixtures, where already data exist in the literature [5,6]. These data base was extended to different temperatures. Furthermore, interfacial tension data of so far non-investigated LCM-water mixtures (water + n-amines, water + methyl ester) were generated.

The solubility of LCM in water shows usually a solubility minima and consequentially the tie line runs through a maxima as function of temperature. One example is depicted in Figure 1. In Figure 1, it can be recognized that the experimental data, taken from the literature [7], as well as the modelled interfacial tension show a maximum value at a temperature, where the solubility minima occurs. Similar results were obtained for all investigated mixtures.

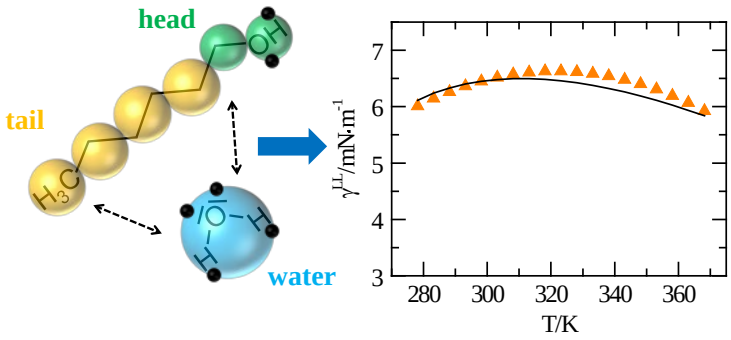

Figure 1 Interfacial tension γ^{LL} of the binary n-hexanol + water mixture at atmospheric pressure as a function of temperature T obtained with hetero-segmental approach of PCP-SAFT [3] .

4. Conclusions

It could be shown, that the suggested theoretical framework allows the modelling of the phase behavior and the interfacial properties close the experimental data.

Highlights

- Scarcity of fresh water requires to find new sources.
- Electrolytes affects the behavior of frothers in floatation process.
- New explanation for the bubble size generation.

1. Introduction

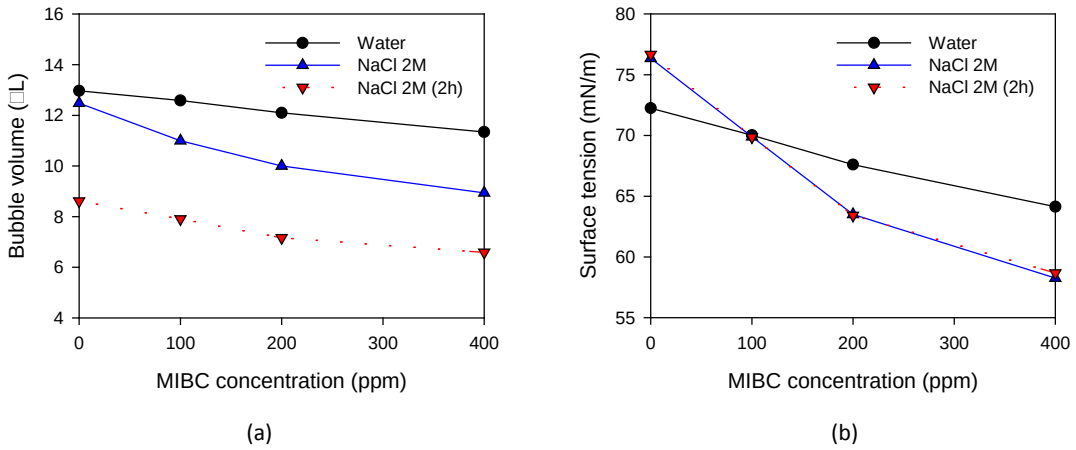
Due to water scarcity mining copper industries in the north of Chile as in many other countries are using new sources of water like groundwater, recirculating water and seawater. These sources of water have salt electrolytes which have unknown effects on reagents as frothers and collectors in the floatation process, where the valuable mineral is separated from the gangue. In the floatation process, frothers avoid bubble coalescence and provide foam stability. It is known that salt electrolytes like NaCl modify properties of the air-liquid interface of aqueous solution with frothers like methyl isobutyl carbinol, one of the most frequently used frothers in floatation [1]. Bubble size is reduced as frother and salt concentration increases [2]. According to a conventional explanation this phenomenon can be explained due to the reduction of bubble coalescence [3,4]. Here we present a new way to understand this behavior evaluating the maximum stable bubble size and their relationship with surface tension and wettability.

2. Methods

Aqueous solutions were prepared with distilled water and different concentrations of methyl isobutyl carbinol (MIBC) as a frother and NaCl. The maximum stable bubble size was determined in an optical tensiometer Theta from Attention. Bubbles were generated passing small amounts of air in a hooked needle with a blunt needle point submerged in a transparent glass vessel containing the aqueous solution. Bubble volumes and their surface tensions were obtained by fitting the edges of the bubble to the Young-Laplace equation.

3. Results and discussion

Figure 1a shows the maximum stable bubble size for different concentrations of MIBC, for pure water and a solution of NaCl 2M, for an instant measurement and for a measurement realized after two hours of exposure of the solution to the needle pore. Bubble size decreases with increasing MIBC concentration and with the presence of salt. Figure 1a also shows that measurements for the condition of two hours of exposure have a significant reduction of the maximum stable bubble size.



(a) (b)

Figure 1. (a) Maximum stable bubble volume and (b) surface tension at different MIBC concentration for pure water and NaCl 2M. NaCl 2M (2h) means the solution was in contact with the needle for 2 hours.

These results reveals that the generation of bubbles is influenced by surface tension of the solution and the time the solution is in contact with the pore substrate or the needle, which in turn is a manifestation of change in the wettability of the liquid over the substrate. A long exposure of the liquid over the needle pore increases its wettability. A detailed view of the analyzed images reveals that in the case of the instant measurement the base of the bubble fits with the outer area of the needle pore, and that in the measurements with two hours of exposure the base of the bubble has a reduced area. Figure 1b shows the surface tension for the same solutions revealing that the results of NaCl 2M are not affected by the bubble size, as expected.

4. Conclusions

The salt electrolyte NaCl has a significant impact on the decreasing of the maximum stable bubble size. These results reveals that the effect of the MIBC and NaCl in the decreasing of the bubble size is not only related to the reduction of the coalescence of bubbles, it is also related to the generation of the bubble; where surface tension, wettability of the solution over the porous and the size of the porous determine the size of the bubbles. In particular, the effect of the frother and the electrolytes over the wettability of the aqueous solutions over the different solids involved in a flotation cell can lead to an unexpected performance of the process.

Highlights

- Gamma-Lactones are derivatives and model compounds of biorefinery platform compounds.
- H_2 solubility is important in liquid-phase Hydrodeoxygenation for biofuel production.
- In γ-nonalactone, solubility increased more from 200 to 250 °C than from 250 to 300 °C.
- The solubility of H_2 was greater in γ-nonalactone than in γ-heptalactone.

1. Introduction

Levulinic acid (LA) dimers are a potential platform stream in lignocellulose biorefineries [1]. LA dimers are slightly branched C_{10} molecules, containing lactone, carbonyl, and carboxyl moieties, which cannot be blended in fuel. However, valorization could be possible by heterogeneously catalyzed hydrodeoxygenation (HDO). Recently, the HDO of LA dimers has been assessed through the study of a relevant model compound, γ-Nonalactone (GNL), at 6 MPa H_2 and at 200-280 °C [2]. Because HDO is performed in three phases, H_2 can only reach the catalyst after its dissolution from the gas phase into the liquid reaction mixture. Due to lack of empirical data on the solubility of H_2 in GNL, it is difficult to clarify the effect of hydrogen on the reaction. Thus, in the present work, the solubility of gaseous H_2 in liquid lactones was studied at temperatures and pressures relevant to HDO. The length of the aliphatic side chain was thought to improve the solubility. Hence, both γ-heptalactone (GHL) and GNL were studied.

2. Methods

The lactones were purified by vacuum distillation at 60 mbar before use. The solubility measurements were performed in a continuous flow apparatus with temperature and pressure control. The saturation point was identified by the appearance of gas bubbles in the liquid flow, which was monitored in an optical cell. Saajanlehto et al. [3] described the apparatus and the procedure in detail. For each lactone, H_2 solubility was measured at 200, 250, and 300 °C and for pressures in the range of 3 to 10 MPa. The isotherms (H_2 mole fraction vs. pressure at selected constant temperatures) are expected to intercept the y axis at a value equal to the vapor pressure of the pure lactone at the given temperature. Thus, the vapor pressures were calculated based on literature [4] and added to the isotherms. The 6 MPa measurements of GNL at 200 and 250 °C were repeated at different residence times in order to verify that the system was operated at steady state.

3. Results and discussion

The measured saturation points are presented in Figure 1 with regression lines. The standard deviations of the repeated measurements at different residence times were $4.43 \cdot 10^{-4}$ on average, i.e. two orders of magnitude lower than the values of the measurements. The saturation mole fractions in GNL were 10% to 41% higher than in GHL. However, when accounting for molecular mass, the differences were only 4% to 16% and in some cases, the solubility per lactone mass was greater in GHL. It is worth noting that the solubility of H_2 at 250 °C for GHL had an intermediate position between the solubilities at 200 and 300 °C, whereas for GNL, the H_2 solubility at 250 °C was closer to the solubility at 300 °C than to the solubility at 200 °C. At 6 MPa, the solubility in GNL went from 0.049 at 200 °C to 0.058 at 250 °C and to 0.064 at 300 °C. That is, it increased by ~20% from 200 to 250 °C and by ~10% from 250 to 300 °C. In order to provide a rough picture of the solubility, Henry's law solubility constants can be estimated from the reciprocals of the regression slopes (Table 1).

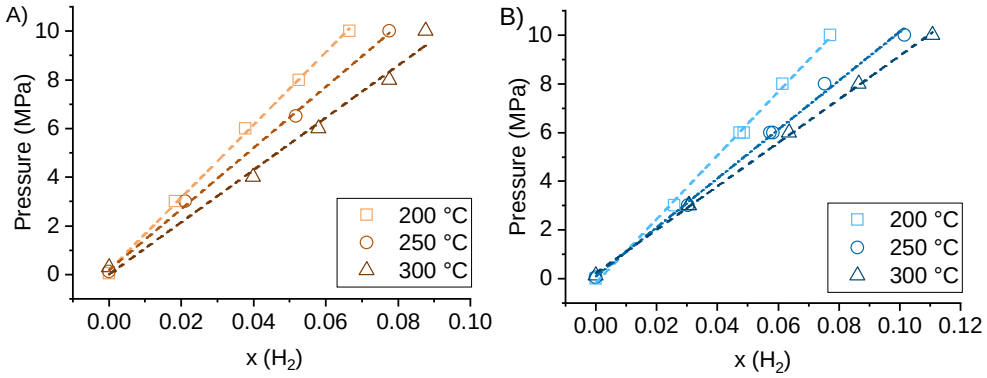

Figure 1. Solubility of H_2 in A) γ-heptalactone and B) γ-nonalactone at pressures and temperatures relevant to hydrodeoxygenation. The isotherms present the saturation pressures at given H_2 mole fractions.

Table 1. Slopes of regression lines.

	GHL slopes (MPa)	GNL slopes (MPa)
200 °C	149.3	130.7
250 °C	125.5	100.4
300 °C	107.4	89.2

4. Conclusions

The H_2 mole fractions in GNL at the HDO conditions studied in [2] were between 0.049 and 0.058. There was a strong dependence on temperature and pressure and, in the case of GNL, the solubility increase was more marked from 200 to 250 °C than from 250 to 300 °C. This observation might be significant for HDO kinetics. On the other hand, H_2 was more soluble in GNL than in GHL.

Highlights

- *In situ* analysis of VLE under high temperature and high pressure

1. Introduction

Due to the invasiveness of most of the analytical methods, the determination of vapor-liquid-equilibria under high temperature and high pressure is a challenging task. Another aspect is the danger that high pressure reactors might present if ignitable mixtures are analyzed. With the microcapillary setup that is presented here, real time VLE measurements are safely and easily feasible using *in situ* Raman-Spectroscopy. Thereby data such as *T-x*- and *p-x*-diagrams are obtained, that are scarce in literature for ignitable mixtures under high temperature and high pressure.

2. Setup and measurements

The setup consists of an optically accessible microcapillary, in which pressure and temperature are adjusted and controlled by a heating system and syringe pumps. The investigated mixture components with a global composition inside the two-phase region are unified in a T-junction, leading to a phase-separation and a flow of alternating liquid and vapor segments, depending on pressure and temperature. Light barrier technology is applied, using the difference in optical density of the vapor and liquid phases, to obtain an oscilloscope signal that is directly matching to the segmented flow. A piezoelectric system can be triggered to this oscillation, passing phase selectively only Raman signal of the investigated phase to the spectrometer.

3. Conclusions

We aim to contribute with our past and future research to the scarce data of VLE under high pressure and temperature.

Highlights

- A Novel design for separation of high CO_2 and H_2S contents from sour gas mixture
- Implementation of GEM algorithm for gas separation process design
- # of stages required for desired separation dependent on process conditions

1. Introduction

Removal of acidic gases from natural gas mixtures is one of the prime objectives of industry. Depending upon the nature of separation and contaminants present in gas mixtures, there are various separation techniques available, e.g.: cryogenic fractionation, polymeric membranes, metal organic frameworks. Among them adsorption and absorption processes are the most common. Removal of high H_2S and CO_2 contents require adequate methods to isolate them from natural gas (*NG*) mixtures. However, economic factors, high energy consumption and effective removal from the *NG* mixture is a restraining step [2-8]. To achieve an efficient separation, several attempts were made to find a reliable and energy efficient alternative compared to conventional separation methodologies [9]. The use of hydrate formation for acidic gases removal can be a promising technique over a range of *T*, *P* and acidic gas contents. The separation of H_2S & CO_2 gases from acid gaseous mixture can be achieved via gas hydrate formation and as represented by the simplified scheme shown in Figure 1 [1].

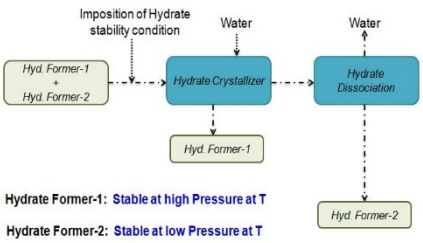

Figure 1. Conceptual picture for gas separation using hydrate formation [1].

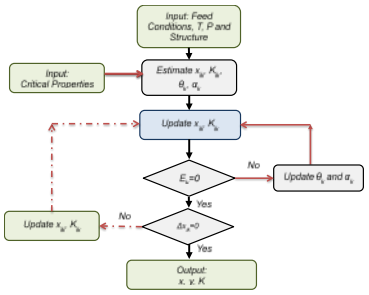

Figure 1. Gibbs free energy minimization algorithm.

2. Methods

Phase equilibria calculations were carried out using the modified vdWP model + Gibbs energy minimization algorithm over a range of temperature, pressure and CO_2/H_2S concentrations. Simplified algorithm for the Gibbs energy minimization algorithm was demonstrated in Figure 2 [1].

3. Results and discussion

The enclathration of carbon dioxide, hydrogen and natural gas are key applications for gas hydrates, since clathrates can adsorb gases in high concentrations. Hence, gas hydrates can provide an effective removal of acidic gases from natural gas mixtures. In this work gas separation via hydrate formation was proposed and a statistical thermodynamic model was used for hydrate

phase equilibria calculations to validate the performance of a hydrate-based separation process. During hydrate-based separation, gas mixtures with various acidic gas contents were brought in direct contact with brine or pure water under low temperature and high-pressure conditions to attain stable conditions for hydrate crystals nucleation. Multiphase equilibria calculations were also performed for various gas mixtures ($CH_4 + CO_2$, $CH_4 + H_2S$, $CO_2 + CH_4 + H_2S$ and $CO_2 + CH_4 + C_2H_6 + H_2S + N_2$) over a range of compositions and T, P conditions to establish the suitable region for separation. In addition, the fractional cage occupancy and the compositions of gases in each phase were also calculated to support the optimal selection of separation temperature and pressure conditions. Recovery and selectivity for gaseous mixtures were found to be significantly dependent on the hydrate former polarity and process conditions. Furthermore, a novel process design diagram (*PDD*) was also proposed for various gas mixtures to be separated and process conditions.

4. Conclusions

A process design has been proposed for removal of acidic gases from natural gas mixtures to achieve desired selectivity in gas mixtures, where removal of H_2S & CO_2 is carried out based on a component's ability to form hydrate crystals. Moreover, hydrate phase equilibria calculations for hydrates of CO_2, H_2S with various hydrocarbons compositions are calculated to locate optimum separation conditions. Fractional cage occupancy and acidic gas fractions were calculated in all the possible phases present to determine separation *T* and *P* conditions. Recovery and separation factor for various acidic gas mixtures were found to be strongly dependent on process conditions and feed gas compositions. A detailed analysis of the hydrate-based separation leads to the fact that the number of stages required to attain a desired separation efficiency was dependent on the nature of the gas mixture and the hydrate stability.

Highlights

- **The isothermal VLE data were measured for 1,2,4-trimethyl benzene + *m*-xylene and 1,2,4-trimethyl benzene + *p*-xylene systems at temperatures from 363.15 K to 473.15 K using a static apparatus.**
- **Experimental VLE data were correlated well with the NRTL-HOC model.**

1. Introduction

For conducting the process simulation for an oil refinery plant, we need vapor-liquid equilibrium (VLE) data of the mixtures containing alkyl aromatics and xylenes. Among several others, the VLE data of binary mixtures of 1,2,4-trimethylbenzene + *m*-xylene and + *p*-xylene are still unavailable from open literature. In this work, the total pressure method was used to measure the isothermal VLE data for the binary systems of 1,2,4-trimethylbenzene with *m*-xylene or *p*-xylene at 363.15 K, 393.15 K, 433.15 K, and 473.15 K with 8:2/6:4/4:6/2:8 in mole ratios of the consituent compounds in the liquid phase. Using the NRTL-HOC model, we determined the optimal values of the binary interaction parameters for each investigated system via data correlation.

2. Methods

The Isothermal VLE data were measured for the binary systems of 1,2,4-trimethylbenzene + *m*-xylene and + *p*-xylene by using total pressure method with a static apparatus. The operation of this static apparatus is briefly described as follows. The air impurities were adequately evacuated from the cell with a vacuum pump (Model GLD-N136, a minimum pressure of 6.7×10^{-1} Pa, ULVAC). The high-purity chemicals were degassed to remove the non-condensable dissolved gases before use. Each of binary mixture was prepared from the degassed compounds with an electronic balance (Model FA-2204C, Chrom Tech Co., Ltd., Taiwan), which can be accurate to ± 0.1 mg and then mixed well by using magnetic stirrer under a certain composition. The prepared solution was then charged into the evacuated equilibrium cell by pressure difference between vaccum and atmospheric pressure [1]. The charging process was terminated before the liquid level in the degassing bottle lower than the bottom of the feeding tube to prevent non-condensable gas from entering the equilibrium cell. After the charging process, the temperature of the bath was adjusted to the desired value. Since this equipment has no circulating pump, it is necessary to shake the cell manually to accelerate the system to achieve a vapor-liquid equilibrium state. As the equilibrium state is attained, the pressure reading will reach a constant value, which was recorded as the equilibrium pressure (P) at the specific temperature (T). The equilibrium pressure was measured at different temperatures by an increment of about 30 K. Additonally, the

composition of each loaded liquid sample was analyzed by gas chromatography. The uncertainties of the reported equilibrium temperature, pressure, and liquid phase composition are estimated to be 0.1 K, 0.01 bar, and 0.005 in mole fraction, respectively.

3. Results and discussion

The total pressures (P) at given T and liquid composition (x_i) were measured for 1,2,4-trimethylbenzene + m-xylene and 1,2,4-trimethylbenzene + p-xylene at 363.15 K, 393.15 K, 433.15 K, and 473.15 K over the entire composition range. The experimental results show that equilibrium pressure increases as increasing temperature and no azeotrope was formed in both two systems. The VLE data were correlated using the (γ-ϕ) method. The NRTL model [2] and the two-term virial equation of state with Hayden-O'Connell method [3] for estimation of the second virial coefficient (HOC) were adopted to represent the non-idealilties of liquid and vapor phases, respectively. Figures 1 and 2 indicate that the NRTL-HOC model correlates satisfactorily the VLE data. The average absolute relative deviations (AARDs) between measured and calculated values are 0.003 % and 0.14 % for the systems containging *m*-xylene and *p*-xylene, respectively.

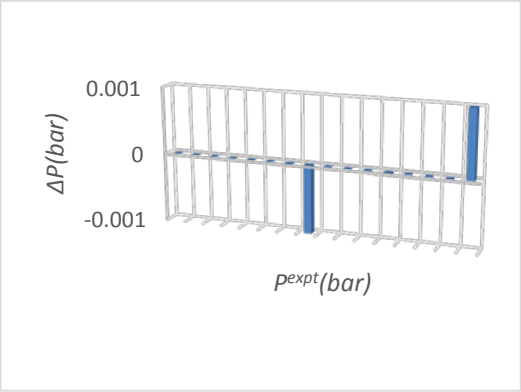

Figure 1. Deviation distribution of the calculated values from the NRTL-HOC model with the measured values for 1,2,4-trimethylbenzene + *m*-xylene system.

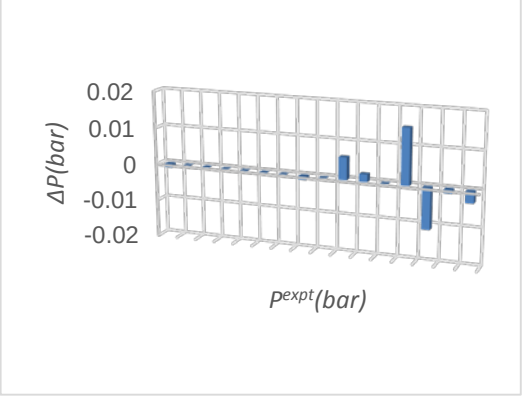

Figure 2. Deviation distribution of the calculated values from the NRTL-HOC model with the measured values for 1,2,4-trimethylbenzene + *p*-xylene system.

4. Conclusions

In the present study, the VLE data of 1,2,4-trimethyl benzene + *m*-xylene and 1,2,4-trimethyl benzene + *p*-xylene were measured at temperatures from 363.15 K to 473.15 K. The experimental results exhibit no azeotropic behavior over whole temperature ranges studied here. The calculated results reveal that the NRTL-HOC model can accurately represent the VLE behaviour for these two investigated systems. These experimental data are fundamentally important to conduct the optimal process simulation and design for an oil refinery plant.

On Passive thermal regulation for application to closed solar photobioreactor Algofilm©: An experimental approach

Kashif Hussain MANGI, Jack LEGRAND, Jeremy PRUVOST, El-Khider SI-AHMED*
University of Nantes, CNRS, ONIRIS, GEPEA, UMR-6144, 37 Bd de l'université, BP406, 44602 Saint-Nazaire, France

Highlights

- Passive thermal regulation technique for Algofilm Photobioreactor
- Experimental Study for Quantification of Condensation for estimation of Condensate Film thickness
- Droplet size evolution as a function of inclination

1. Introduction

Thermal regulations in Solar Photobioreactors has been a major problem specifically for overheating of microalgae culture due to variable weather factors such as year-round operation, and day/night cycles (Pruvost *et al.*, 2017). In Algofilm Photobioreactor, the phenomenon of evaporation-condensation has been observed (Goetz *et al.*, 2011), which allows a thin film of condensate to be developed on the inner surface of optical cover. It can absorb some amount of infrared radiations which results reduction in energy requirement to regulate the temperature of Microalgae culture inside the Algofilm. Subsequently water (condensate) has an ability of transmitting the visible light spectrum which is essentially required for microalgae. So, an autoregulation technique of the AlgoFilm temperature through a condensate film on the inner surface of reactor has been hypothesized. In first step the experiments for quantification of condensation have been conducted on lab-scale Algofilm© by optimizing the water flowing film temperature, inclination angle and the flowing film thickness, because absorption of solar radiation (Infrared range) is the function of condensate film thickness.

2. Methods

Experimental study on Lab-scale Algofilm for quantification of condensation is carried out by varying the fluid temperature and inclination angle to investigate their effect on the condensate and dripping volume. Temperature measurements were obtained through LabVIEW software and (ICP.CON Data Acquisition Model i-7019R), thermocouples were installed at glass, condensate film, humid air medium, flowing liquid and bottom surface. Flowing liquid thickness measurement was carried out for each inclination angle, and inclination angle was measured with digital inclinometer (Sensorex ALPHA 4000). Condensed volume of water was collected in a container placed under the Algofilm PBR.

3. Results and discussion

The thickness of the flowing water was measured at every inclination angle and it remained under the suggested limit of 2mm by (Goetz *et al.*, 2011; Pruvost *et al.*, 2017). Experimental results have shown encouraging condensation which indicated the possibility to develop considerable condensate film thickness, which will filter some amount of the Infrared radiations.

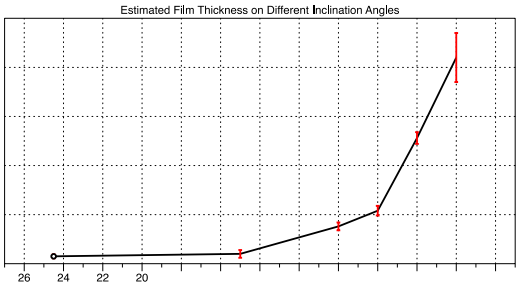

Figure 1:Film thickness as function the inclination angle

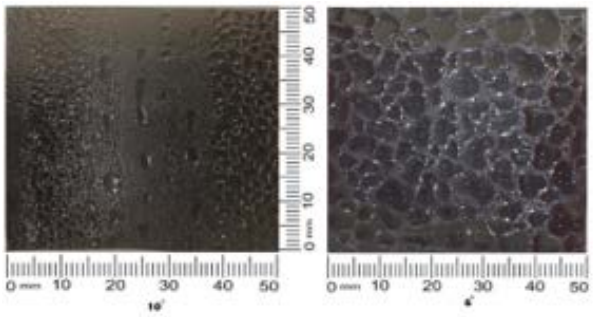

Figure 2. Droplets size evolution as a function of Slope after 4 hours at Different Angles

It is also observed during experiments that decreasing the inclination angle resulted a notable increase on the overall film thickness (figure 1), by increasing the droplet size as shown in figure 2 which will ultimately increase the absorption of Infrared radiations. However, the operational inclination angle for Algofilm is around 2° as per previous study on Algofilm by (Le Borgne, 2014), where condensate flowrate was almost equal to zero, so it is assumed that the condensed volume will be remained at glass cover and bigger droplets will be formed. Moreover, experiments for hourly condensation mass flux at different temperatures were also conducted and the percentage of the dripping flow could be deduced as shown in figure 3. This data will be of interest in the modelling aspect.

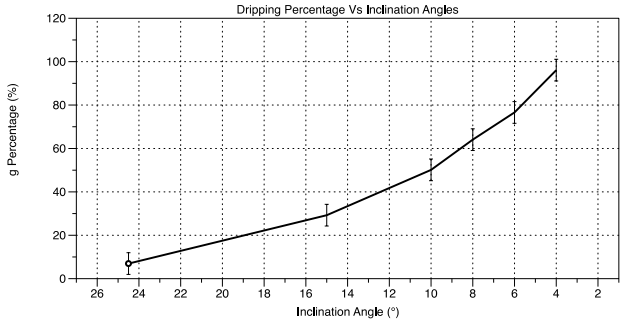

Figure 3 Dripping percentage as function of the inclination angle

4. Conclusions

The optimum objective of current study is to develop a passive thermal regulation for microalgae production in solar conditions through condensate film which will absorb the Infrared radiations. Results of experimental study for the condensation and dripping with variations of flowing liquid temperature and inclination angles of Algofilm Photobioreactor have shown that inclination angle is in direct relationship with the condensate flowrate and inversely with the dripping volume. Results are very favourable on lower inclination angle to achieve higher film thickness of condensate in which higher amount of infrared radiations would be absorbed. Furthermore, the simulation study is undergoing to validate these experiments and further experimental study is being conducted on the estimation of Infrared radiation absorption on the basis of these condensation rate results. This thermal regulation technique can be effective for Algofilm type photobioreactors to reduce the energy requirements to regulate the inside temperature.

Highlights

- the [Emim][DCA] IL behave differently both in the charged and uncharged graphene interface.
- The number density of anion near the interface is always greater than the cation when the pore size is 0.8 nm in both charged and uncharged systems.
- imidazolium rings prefer to lie parallel to the graphene surface in narrow silt pore.
- imidazolium rings gradually tends to be perpendicular to the surface as the pore width increases.

1. Introduction

Exploring ionic liquids (ILs) / graphene charged interface is importance in the energy collection and storage devices, because the structural properties and transportation of ILs at the interface have great influence on the performance of energy collection and storage devices. Unfortunately, it is still challenging to directly detect the interface properties of nanoconfined ILs by experimental methods. Therefore, we present a molecular dynamics(MD) simulation study of 1-ethyl-3-methylimidazolium dicyanamide ([Emim][DCA]) ionic liquid confined by two charged graphene planar surfaces with different pore widths. Graphene surfaces with positive and negative charges can be imagined as positive and negative electrodes of capacitors, respectively.

2. Methods

MD simulation for [EMIM][DCA]-graphene system were carried out using the LAMMPS software. Ionic liquids ([EMIM][DCA]) were confined to two parallel interfaces of graphene, respectively. Four different slit pore sizes were considered with 3.6、2.4、1.6、0.8nm, separately. Graphene sheets were modeled as rigid entities along all the considered simulations. The box size for the xy plane was reach to 49.12×48.22 $Å^2$, as a consequence, it can accommodate enough ion pairs to obtain dependable statistically significant results. According to previous reports, all the four systems have a comparable IL density to the bulk value.[1] Therefore, 270、190、130 and 65 [EMIM][DCA] ion pairs were randomly placed in the two-dimensional graphene slits with the pore size of 3.6, 2.4, 1.6, and 0.8nm, respectively. The force field parameter for [EMIM][DCA] ions was obtained from literature.[2,3] The Lennard-Jones (L-J) parameter and partial atomic charges used for graphene in this work were taken from literature.[4]

3. Results and discussion

We find that the [Emim][DCA] IL behave differently both in the charged and uncharged graphene interface. The number density profiles of [Emim][DCA] IL along the direction perpendicular to the graphene wall indicates that the anion DCA- peak intensity is always greater than the cation Emim+ when the pore size is 0.8 nm in both charged and uncharged systems. The 3D orientation analysis of cations and anions close to the graphene surface indicates that imidazolium rings prefer to lie parallel to the graphene surface, and imidazolium rings gradually tends to be perpendicular to the surface as the pore width increases. Finally, their diffusion coefficients exhibit anomalies in negatively charged pores.

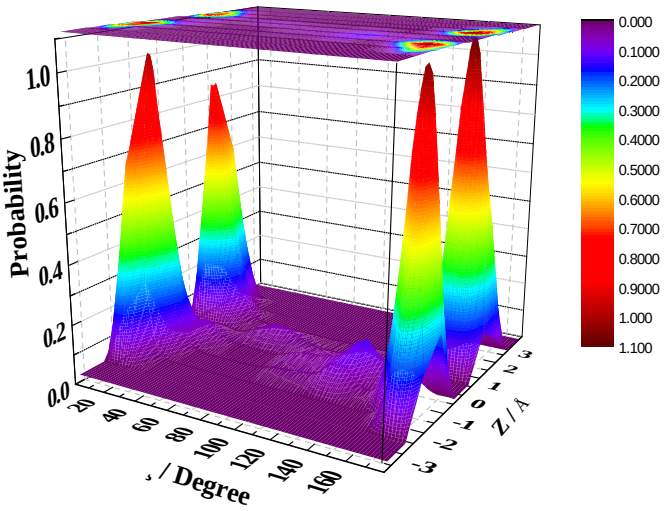

Figure 1. The probability distribution of angle orientation in a silt pore with charge density of 2.29 e/nm^2 (pore size= 0.8 nm).

4. Conclusions

The research work aimed at interface nanostructures is helpful for the design of electrode materials. From the results of simulation we found pore size is important for the Ionic Liquid's Structural Variations and diffusion coefficient inside Nano-slit, which are critical to the performance of energy collection and storage devices such as electrochemical capacitance.

Highlights

- Monitoring asphaltenes deposition using a fully immersed Quartz Crystal Resonator
- Experimental identification of deposition mechanism by liquid alkane titrations
- Experimental identification of deposition mechanism by depressurization of gas-dissolved oils
- Deposition modeling and comparison to experimental data

1. Introduction

Asphaltenes destabilization and deposition are mainly caused by the expansion of dissolved light alkanes, such as methane, during the petroleum extraction. Based on experimental observations replicating the expansion of light-ends by flowing fixed concentration mixtures of petroleum and liquid alkanes at ambient conditions; deposition models have been developed[1,2]. In those cases, diffusion-limited equations were computed with measured and realistically fitted input parameters in order to match the experimental observation. Upscaling the diffusive principles of these models to the flow of gas-dissolved oils implies calculations of multiple pressure dependent parameters instead, which increases uncertainties. Additionally, the nature of the precipitant showed a significant effect on the asphaltenes destabilization[3]. Experimental verifications of the modeled deposition of asphaltenes destabilized by the expansion of light alkanes are very limited in the current literature.

2. Methods

Two different apparatus were used to measure the deposited mass of asphaltenes destabilized by addition of liquid n-alkanes:

(i) a packed bed of beads apparatus recently developed[1] in which an isothermal mixture is continuously flowing at a controlled flow rate.

(ii) a continuously stirred reactor containing a fully immersed Quartz Crystal Resonator (QCR) indirectly recording asphaltenes deposited mass on its surface during isothermal titrations of liquid n-alkanes.

The QCR is an advantageous technique that requires very few deposit (sensitive to nano grams) and working in pressurized fluids[4]. Therefore, we also performed isothermal constant mass expansions of gas-dissolved systems while recording the deposition with the QCR. In parallel, a centrifugation method was used to measure the mass concentration of aggregated unstable asphaltenes for multiple mixtures of oil and liquid n-alkanes. The interplaying effects of time and evolution of the composition were studied. Based on experimental investigations, the initial goal was to verify the first principles of the existing models and apply them to the QCR geometry.

3. Results and discussion

The comparison of the concentration of unstable asphaltenes (obtained by centrifugation) with the deposition experiments, along with an analysis of the deposition profiles at several conditions enables an identification of the fraction of asphaltenes that can deposit. The possible deposition mechanisms are discussed based on experimental results, i. e. diffusion-limited and reaction-limited. Consequently, this work provides insights for a new model by proposing corrections on the key parameters. Computed deposition rates are then evaluated against the experimental results.

4. Conclusions

The validation of a novel deposition model is presented using experimental data recorded from a QCR sensor at ambient pressure and at gas-dissolved conditions. This study provides a major step in the understanding of asphaltenes deposition in industrial conditions, it helps identifying the predominant parameters and the mechanism of their deposition rate. This work does not only provide a validation of the deposition mechanism but mass transport equations combined to high pressure immersed QCR signal interpretation also give us access to a crucial information for the understanding of asphaltenes behavior: the concentration of unstable asphaltenes at all conditions. Thermodynamic models can therefore be challenged against implicitly measured quantities thanks to the findings.

Honorary lecture for Philipp Rudolf von Rohr: Multiphase Reaction and Transport Processes in Microreactor Systems.

Klavs Jensen[1]

1 MIT, Department of Chemical Engineering,

**Corresponding author: kfjensen@mit.edu*

Highlights

- Lecture honoring the contributions of Professor Rudolph Von Rohr ETH-Zurich.
- Insights into multiphase reaction and transport processes in microreactors.
- Automation for extracting kinetics and performing process optimization.
- Process intensification and steps towards autonomous chemical manufacturing.

Abstract

Chemical synthesis in microreactors has matured over the two past decades from simple demonstration examples to applications in pharmaceuticals and fine chemicals. Advantages of controlled mixing, enhanced heat and mass transfer, expanded reaction conditions, and safety have driven adoption of continuous flow techniques and the related process intensification. The field has moved beyond single transformations to continuous multistep synthesis of fine chemicals and active pharmaceutical ingredients by incorporating in-line workup techniques.[1]

The first part of this lecture reviews the understanding of multiphase reaction and transport processes in microstructured systems we gained from studies initiated by Professor Rudolph Von Rohr ETH-Zurich. Emphasis is placed on multiphase mass transfer in microreactors and packed beds along with membrane based extraction techniques. Presented examples include both experimental studies and computational fluid dynamic simulations.

The second half of the lecture focus on process intensification and automation, which offer opportunities for faster development and more efficient production[1] Automated optimization in continuous flow based on feedback of information is shown to be efficient for extracting chemical kinetic models and optimizing performance over continuous variables (*e.g.*, temperature, residence time, and concentrations).[2],[3] Use of microliter-scale droplets enables consideration of discrete variables (e.g., catalyst species, base, and solvents) in addition to the continuous ones without requiring system reconfiguration.[2],[4]

On demand production of pharmaceuticals serves to illustrate potential advantages of process intensification. The platform enables multistep chemical synthesis at elevated temperatures and pressures to enhance reaction rates in a plug-and-play, manually reconfigurable, refrigerator-sized manufacturing platform of integrated unit operations. As

a consequence, the resulting residence times are on the order of minutes, in contrast to the multiple hour-long processes typically needed for batch processing. [5,6]

Finally, integration of robotics with machine learning represents a step toward autonomous manufacturing. Computer-aided organic synthesis based on machine learning of millions of reactions in data databases predicts reaction paths to a given molecular target from purchasable starting materials. [7] With expert user input, the synthesis planning outcomes are converted into recipes executed by a modular continuous flow platform that is automatically configured by a robotic arm to setup the required unit operations and execute reactions.

A new optical sensor for bubble velocity and size measurements in heterogeneous bubbly flows.

Anthony Lefebvre[1], Stéphane Gluck[1], Yann Mezui[2], Martin Obligado[2], Alain Cartellier[2]

*1 A2 Photonic Sensors, 38016 Grenoble, France ; 2 Univ. Grenoble Alpes, CNRS, Grenoble INP**, LEGI, 38000 Grenoble, France.*

** Institute of Engineering Univ. Grenoble Alpes

Highlights

- A new sensor devoted to complex bubbly flows has been developed.
- The sensor combines phase detection and bubble velocity measurements.
- Bubble velocity distributions are measured in homogeneous and heterogeneous regimes.
- Bubble velocity statistics conditioned on local void fraction become accessible.

1. Introduction

Bubble columns are routinely exploited in industry and are often operated in the heterogeneous regime with gas hold-up up to 40%. Despite intense research since the 70's, the hydrodynamics of these buoyancy driven bubbly flows is still poorly understood. As shown by the numerous correlations proposed in the literature [1], there is no consensus on the influence of the column size or of the gas superficial velocity on key variables. Beside simulations based on two-fluid models still require ad-hoc closures, and the scale-up from lab units to industrial units still relies on empiricism. That situation is evolving thanks to new measuring techniques, to well-controlled experiments and to progress in modelling. For example, the relative velocity in the heterogeneous regime has been shown to widely exceed the bubble terminal velocity [2]. That has prompted the use of a swarm factor that diminishes the drag with void fraction: this correction neatly improves the prediction capability [3]. This relative velocity modification is possibly due to the presence of clusters (with local void fraction up to 10 times the mean gas hold-up) and of voids (with local void fraction down to 0.1 times the mean): such meso-scale structures generate strong concentration gradients and are reminiscent of buoyancy instabilities in turbulent convention [2]. To progress further, there is a crucial need to gather information on bubble velocity. Such measurements are difficult and remain scarce [4-6]. The present contribution deals with the development of a new bubble velocity sensor and with its test in the heterogeneous regime.

2. Sensor development and preliminary measurements

The new sensor combines conical optical probes that are efficient phase detectors [7] with velocity measurements based on Doppler shift. The latter arises from a light wave reflected at the (fixed) probe tip combined with a light wave that exits the probe, interacts with a moving interface and enters back the fiber. The recorded signal is modulated at the Doppler frequency $f_D=2V\cos(\alpha)/\lambda$ where V is the interface displacement velocity, α the angle between the interface velocity and the fiber axis, λ the wavelength in the external medium. The measure of f_D directly

provides the velocity. That principle has been exploited on gas slugs [8], on micro-bubbles [9], on capillary waves [10] and on solid particles [11]. Yet, all previous works used cleaved fibers that are not adapted to phase detection. Instead, we exploited conical tips whose shape was optimized (Fig.1) to enhance the Doppler amplitude. All prototypes were manufactured from 8.2µm core diameter single mode fibers. A signal processing was implemented to select meaningful Doppler signals detected at the bubble exit (Fig.1) based on the number of successive periods and on their stability. An analysis of the sensor response, including necessary optical conditions for obtaining Doppler signals, indicate that this sensor provides the translation velocity of the bubble mass center projected on the fiber axis with a 10% uncertainty. The sensor was exploited in a bubble column (0.4m I.D., 3m high). Bubble velocity distributions in homogeneous and in heterogeneous regimes gathered at H/D=3.62 above injection are presented Fig.1. For these data sets, 12000 bubbles were detected among which 60% (resp. 30%) provided a velocity in the homogeneous (resp. heterogeneous) regime. Note that bubble's velocities up to 3m/s are recorded in the latter case: such magnitude is expected as liquid velocities up to 2m/s are observed in the same conditions, and since the actual relative velocities are about 2 to 3 times the terminal velocity [2].

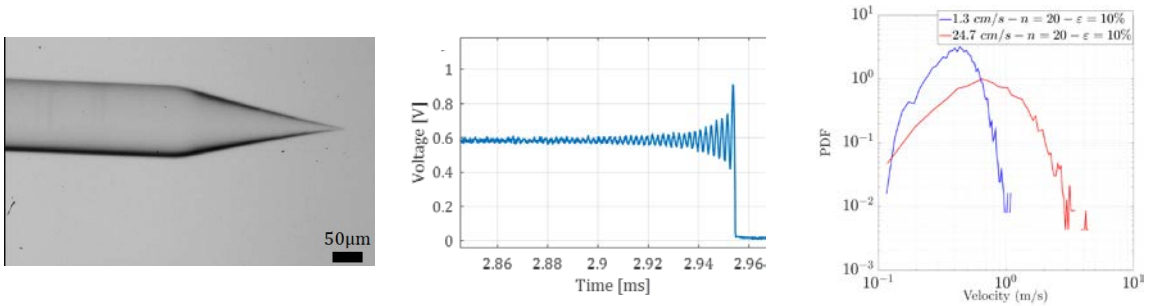

Figure 1. Conical fiber tip (left). Doppler signal collected at an air-water transition (middle). Bubble velocity distributions in homogeneous (blue) and heterogeneous (red) regimes (right).

3. Conclusions

A new sensor has been successfully developed that combines phase detection and bubble velocity measurements. Applied to a bubble column, the sensor indeed provides velocity distributions both in the homogeneous and in the heterogeneous regimes. Future work will be devoted to gather statistics on gas velocity conditioned by the local concentration in order to evaluate the impact of meso-scale structures on the relative velocity.

Highlights

- Interactions of single bubble with single vortex-ring are studied experimentally.
- Vortex-ring is characterized combining experiments and numerical simulations.
- Bubble deformation and breakup efficiency is investigated using high-speed camera.
- Results show the present data comparable with data obtained in homogeneous turbulence.

1. Introduction

Breakup of fluid particles (bubbles or drops) in a turbulent flow is a phenomenon encountered in many industrial applications. The understanding of the mechanism is essential to improve the modelling of complex multiphase flows by numerical methods [1]. To provide a controllable experiment where the bubble will break in a defined turbulent flow is quite difficult task because the turbulence has stochastic nature and huge amount of data needs to be treated to achieve a satisfactory level of accuracy. Therefore, more deterministic approach in the bubble breakup studies is needed.

The interaction of a single bubble with a vortex-ring can be assumed as more deterministic system simplifying the collision of bubble with turbulent eddy [2, 3]. Revuelta [2] found that the large vortex rings causes bubble deformations following the shapes identified in turbulent flow and he demonstrated, that the bubble breakup issuing from bubble-vortex-ring interactions can be used as idealized situations of bubble breakup in turbulent flow. However, the conclusion was obtained using numerical simulations and it should to be proved also experimentally. The aim of the contribution is to provide the experiments on bubble breakup induced by interaction with vortex-ring in order to contribute the understanding of the bubble breakup process in turbulent flows and to provide the reliable breakup parameters.

2. Methods

The experiment is based on the production of single bubble and single vortex-ring both moving against each other since they interact (Fig. 1). Vortex-ring is generated by pulse-flow from an immersed nozzle (1.2 in diameter, duration of pulse-flow is typically 25 ms). Bubble of defined size (ranging from 0.8 to 2.5 mm in diameter) is produced by the generator based on movable capillary [4]. The collision process is observed by high-speed camera in order to tract the mother bubble and all the daughter bubbles arising from breakup. Breakup frequency, number and size distribution of daughter bubbles are determined in dependence on mother bubble size and vortex-ring energy.

The vortex-ring energy is defined by the circulation strength of the vortex-ring, which is obtained combining the experimental visualizations and numerical simulations of the vortex-ring generation based on the same convective velocity of the vortex-ring (ranging from 0.9 to 1.5 m/s).

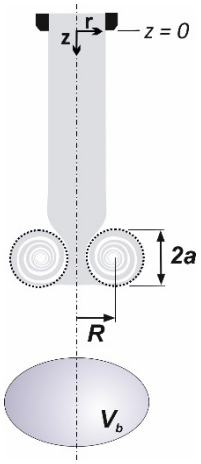

Figure 1. Illustration of coordinate system.

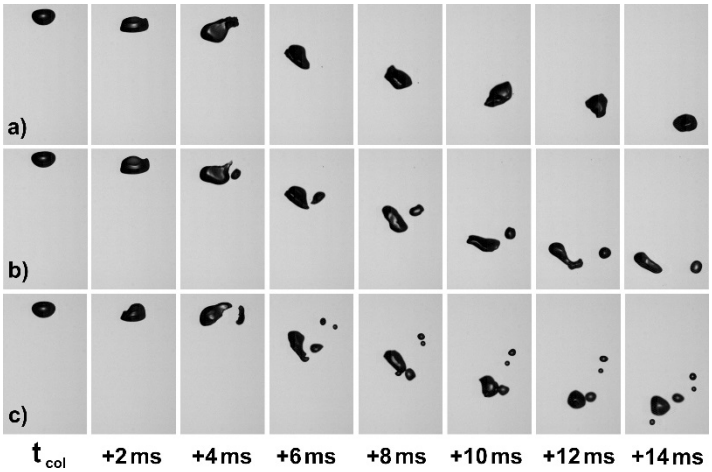

Figure 2. Examples of possible events after the bubble-vortex-ring interactions, a) no bubble breakup, b) binary breakup, c) multiple breakup

3. Results and discussion

The problem of bubble-vortex ring collision can be characterized by Weber number *We*, which is the ratio of vortex-ring energy and surface energy of the bubble. For low *We* ≈ 3, the bubble breakup efficiency is about 50%, where no breakup events (Fig. 2a) are of the same probability as the bubble breakup preferably into two daughter bubbles (Fig. 2b). Increasing the Weber number (*We* > 5), the breakup efficiency is nearly 100% and preferably breakages into multiple daughters occurs (Fig. 2c).

The breakup parameters obtained from the bubble-vortex-ring interactions are compared with breakup parameters obtained in homogeneous turbulent flow [5]. The results show satisfactory agreement in data of breakup frequency and also in number of daughter size distribution.

4. Conclusions

The comparison of present experimental data obtained for interactions of single bubble with single vortex-ring and the data obtained in homogeneous turbulence proved that the bubble-vortex-ring interaction can be assumed as an idealizes situation of collision of bubbles with eddies in turbulent flow.

Transport processes in disperse multiphase systems in the presence of surfactants: A single drop study

Joschka M. Schulz*, Matthias Kraume

Technische Universität Berlin, Chair of Chemical and Process Engineering, Ackerstraße 76, 13355 Berlin, Germany

**Corresponding author: j.schulz@tu-berlin.de*

Highlights

- Prediction of mass transfer rates by consideration of drop movement
- Spatially resolved concentration field measurement by Rainbow Schlieren Deflectometry
- Interfacial phenomena due to the presence of surfactants
- Evaluation of drop production phase

1. Introduction

The presented work focuses on the interaction between mass transfer and fluid dynamics in disperse liquid/liquid systems in the presence of surfactants and is part of the Collaborative Research Center Integrated Chemical Processes in Liquid Multiphase Systems financed by the German Research Foundation. In industrial processes surfactants occur intentionally or as an impurity and change the interfacial behavior. The induced interfacial phenomena such as Marangoni convection or adsorption may lead to a change of important process parameters. Since these phenomena have contrary effects on the mass transfer in multiphase systems, the prediction of their occurrence and the resulting mass transfer rates is a challenging task. To get a deeper insight into the transient mass transfer processes, fluid dynamic measurements of single droplets are used as an indicator for the prediction of interfacial phenomena and mass transfer rates. Furthermore, the mass transfer during droplet production is considered and a refractive index-based optical measuring technique is applied for the non-invasive in situ visualization of the concentration field in the continuous phase.

2. Methods

For experimental purposes a single drop rising test cell with a length of 700 mm is used. Samples are taken at different contact times and the rising speed and path of the droplets are determined optically with a high-speed camera. For detailed analysis, the experimental setup introduced in Merker et al. [1] is used, which extends the concept of the rising test cell by adding a vertical traverse system with real-time control, thus enabling the three-dimensional measurement of shape, velocity and trajectory of the particle during the ascent with high temporal and spatial resolution. Additionally, mass transfer during drop production is measured separately. An experimental setup applying Rainbow Schlieren Deflectometry has been developed for non-

invasive real-time measurement of the concentration field in liquid/liquid systems and is used for the visualization of interfacial phenomena.

3. Results and discussion

Figure 1 (left) the shows the transient drop rise velocity of single 1-octanol droplets in water for varying surfactant concentrations of Butyldiglycol, which is chosen as a model surfactant. The terminal drop rise velocity decreases with increasing surfactant concentration showing good agreement with the calculated velocity of a movable interface (Feng and Michaelides [2]) for negligible surfactant concentrations. For high surfactant concentrations the velocity is reduced to the value for rigid spheres (Martin [3]). In case of deformation, the measured velocities can decline even further. Although the observed effect is in good agreement with the literature, the mass transfer rates show contrary behavior due to the occurrence of Marangoni convection, which can be identified by detailed consideration of the drop movement.

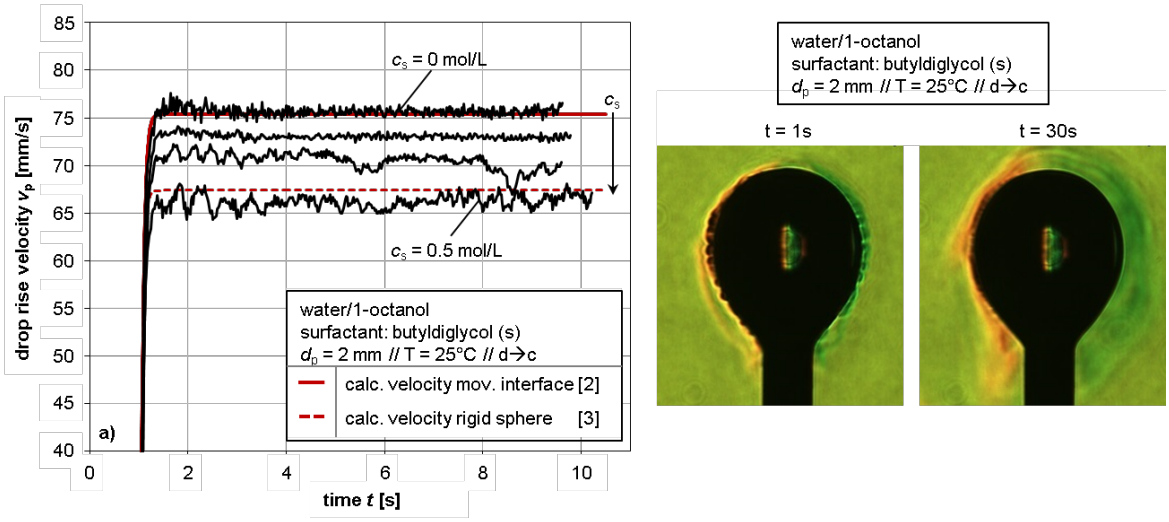

Figure 1. Left: Experimental drop rise velocity of 2 mm 1-Octanol droplets in water for varying surfactant concentration. Right: Concentration gradient field for mass transfer of model surfactant for different contact times visualized with Rainbow Schlieren Deflectometry.

Experimental results for the visualization of the instationary concentration gradient field of the surfactant butyldiglycol around a stagnant 1-octanol droplet in water are shown exemplary in Figure 1 (right) for different contact times. The different color values indicate differing values of concentration and result from the application of Rainbow Schlieren Deflectometry.

4. Conclusions

Fluid dynamic measurements and application of Rainbow Schlieren Deflectometry show great potential for a deeper insight into mass transfer processes and interfacial phenomena induced by surfactants and may lead to a better description of transport processes in multiphase systems.

Tomographic visualization of droplet break-up during high-pressure homogenization with orifices in a scaled test section

Benedikt Mutsch[1], Christian J. Kähler[2]

1 Institut for Fluid Dynamics and Aerodynamics, Bundeswehr University Munich, Werner-Heisenberg-Weg 39, 85577 Neubiberg, Germany; 2 Institut for Fluid Dynamics and Aerodynamics, Bundeswehr University Munich, Werner-Heisenberg-Weg 39, 85577 Neubiberg, Germany

Highlights

- Flow field measurements inside a scaled high-pressure homogenizer.
- Droplet and droplet breakup visualization method.
- Tomographic reconstruction of droplets during breakup
- Determination of droplet breakup regions and mechanisms.

1. Introduction

Emulsions are produced and used in chemical, pharmaceutical and food technology. Since the droplet size and the droplet size distribution have an important influence on the properties of the emulsion, these parameters are of special importance. Drop sizes in the range from 100 nm to 10 µm can be produced by means of high-pressure homogenization.

This process uses high pressure to press the raw emulsion through small channels in the disintegration unit to break the coarse droplets of the raw emulsion into fine droplets of the desired size. However, the physical mechanism responsible for the break up is not known as the accurate visual inspection of the tiny droplets in space and time is not possible due to the small size.

In order to visualize the disintegration process, and to understand the physical phenomena responsible for the droplet break-up, high-speed images of well defined and reproducible droplets emerging from an orifice plate scaled to a scale factor of 50 were taken using the shadow image method. In order to investigate not only the geometric similarity but also a physically similar model, the material parameters density and viscosity of the model material system and the operating pressure are adapted so that the diameter, viscosity and density ratio as well as the Reynolds number and the Weber number are kept constant in comparison to the original process.

For a better understanding of the processes, these images were taken from several angles of view, so that a 3D model of the drop deformation during disintegration could be created for the first time.

The correlation of the drop break-up measurements with 2D2C-PIV measurements shows that the local turbulence intensity has a large influence on the break-up.

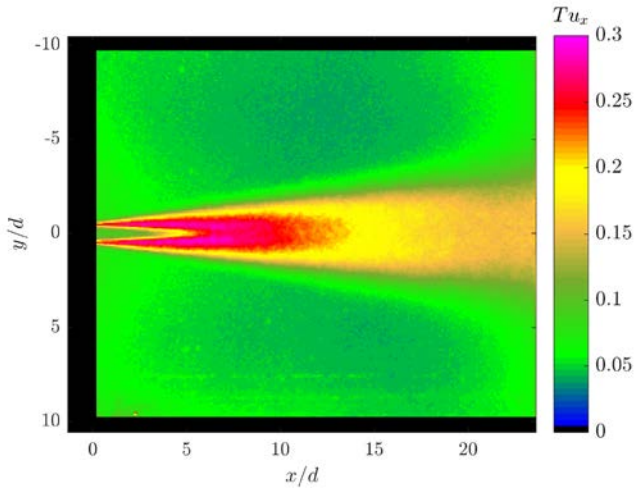

Figure 1. Local mean turbulence intensity behind the orifice

The drop emerges as an elongated filament from the Orifice in the core of the free jet. The images show that the drop is hardly deformed in this area due to the low turbulence. At the transition of the drop from the core area of the free jet to the shear layer, the drop begins to oscillate and meander. As a result of this incipient deformation, the droplet is strongly deformed in the shear layer, resulting in twisting and swirling of the filament. Ultimately, the deformed droplet decays into individual areas that are further deformed until a mist of fine droplets is formed.

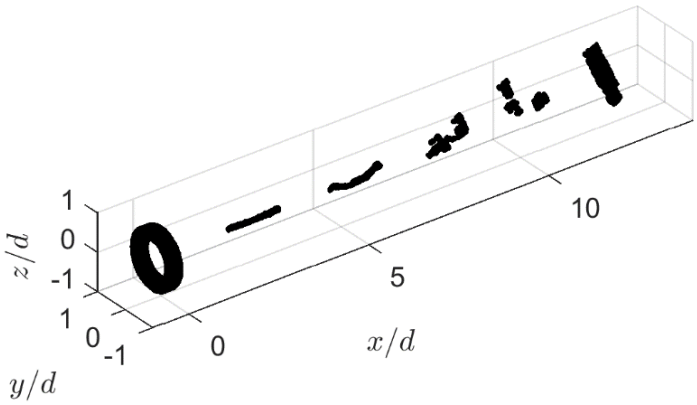

Figure 2. 3D reconstruction of the droplet breakup evolution behind an orifice from a long filament to a spray of small droplets

In order to investigate the droplet break-up mechanisms more closely, further investigations will be carried out. On the one hand, the droplet feed position is varied so that the droplet emerges from the orifice at different radial positions. This allows the expanded droplet to experience the local turbulence of the shear layer earlier and with a different intensity. The result is that the point of break-up shifts towards the orifice.

Furthermore, the Reynolds number is varied in the experiments so that the limits of drop break-up can be investigated with regard to the required turbulence intensity. Depending on the Reynolds number and the resulting different elongation of the droplet, different break-up mechanisms can be observed which have to be investigated in further investigations. The results of the various experimental investigations will be discussed and explained on physical grounds.

Highlights

- Characterization of complex behavior of micellar solvent systems and Pickering emulsions
- Influence of phase behavior on the mass transfer in innovative solvent systems
- Quantification of the effect of coverage and drop sizes on the transfer process

1. Introduction

Homogenously catalyzed reactions in multiphase systems, as they are used for example in the Ruhrchemie/Rhône-Poulenc process, offer a promising approach to produce base chemicals from renewable resources. The organic and gaseous educts react with the catalyst, which is designed to be soluble in water to provide a good separation from the likewise organic products. In the resulting gas/liquid/liquid systems, the reaction is controlled through interfacial and transport phenomena. These processes fail for long chained Olefins – e.g. vegetable oils and fats - because of their low solubility in water. Surfactants or nanoparticles can be added as emulsifier to form innovative solvent systems – micellar solvent systems (MSS)[1] or Pickering emulsions (PE)[2] respectively – and increase reaction speed [3,4] and phase separation [5]. The additives adsorb at the interface, increase the mass transfer area but add an additional mass transfer resistance. Furthermore, MSS form up to three liquid phases, depending on temperature and composition, whereas one phase is always a microemulsion. In consequence, the mass transfer in these systems is complex. This work focuses on the quantification of the impact of additives on the mass transfer in these innovative solvent systems.

2. Methods

For simplification reasons, measurements were conducted focusing on the non-reactive system consisting of long chained oils and water with either a non-ionic surfactant or silica nanoparticles. The Gas/liquid mass transfer was measured in a pressurized stirred tank reactor for several temperatures and compositions. Using the dynamic pressure method [6] the k_La values could be determined. The phase behavior of the MSS was characterized using settling experiments and by measuring the conductivity of the emulsions. To determine the interaction of the disperse phases in the stirred reactor, drop and bubble sizes were recorded using optical endoscope measurements [7]. Influence of occurring liquid/liquid mass transfer could be determined with single rising drop experiments [8]. A high speed camera was used to record the fluid dynamics of the drops. A tracer

component was added and the drops were collected at different heights to analyze the mass transfer.

3. Results and discussion

For the gas/liquid mass transfer, the k_La values rose with temperature in pure liquids but experienced a sudden change upon adding small amounts of a liquid dispersed phase. Depending on the formation of a water-in-oil or oil-in-water emulsion, the k_La experienced an increase or decrease, respectively. The change can be credited to the interaction of bubbles and drops. In MSS the mass transfer is up to two times faster. With rising temperature, a first decreases happens and is followed by a mass transfer acceleration and another decrease. For higher surfactant concentrations, a third region with constant k_La follows (see Fig. 1). The behaviour can be credited to the phase behaviour of MSS, where the continuous phase changes with temperature from aqueous to bicontinuous microemulsion to organic phase.

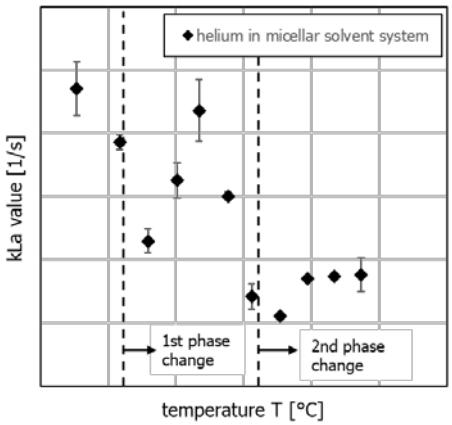

Figure 1. k_La value of micellar solvent system for different temperatures

Liquid/liquid mass transfer showed strong reduction due to interfacial coverage in both solvent systems, partly even falling below the expected results of a fully covered drop.

4. Conclusions

Phase behavior as well as drop and bubble interactions and coverage play an important role for the gas/liquid mass transfer in a stirred system with several dispersed phases. Both effects can significantly change the mass transfer and therefore reaction rates.

Highlights

- High shear mixing and emulsification processes in high phase volume products
- Experimental models for numerical applications
- Population balance and instability

1. Introduction

Experiments and numerical modelling are considered crucial steps to control production in modern industrial processes since ensure the best quality of the product and the repeatability at the desired scale. These ideas apply also to the study of product preparation, when suited models of emulsification, viscosity, oil droplet distribution and size have been obtained in experimental sessions by one of the authors [1] or from existing computing libraries [2], [3]. This work concerns the modelling through Computational Fluid Dynamics instruments and scales of a step in the complex mixing process necessary to prepare the high phase volume emulsions in a standard [4] rotating geometry. The final goal is to control some of the most important properties of the emulsion like creaminess and taste.

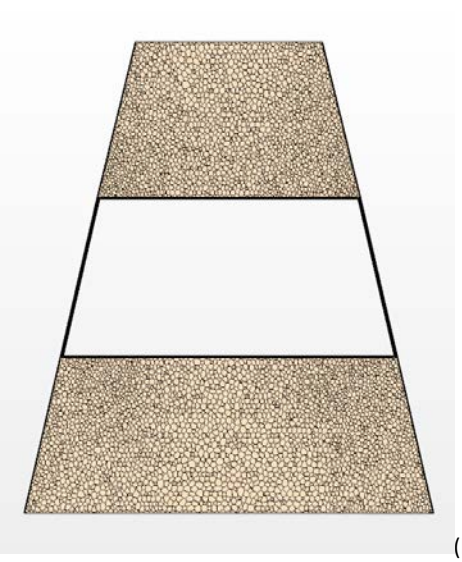
2. Computing methods

The problem considers and simplifies the geometry of Figure 1 (a) in a computing domain discretized with polyhedral cells as in Figure 1 (b) where a multiphase segregated flow reproduces product and oil droplet. Finite Volume approach is assumed to resolve a set of differential equations for mass transport, momentum (and eventually energy) of each phase. All the phases share a common pressure field while for each one is defined a volume fraction according to VOF (Volume of Fluid) approach [3]. Interaction between phases is also assumed with models for drag force and droplet length scale, S-gamma [2] particle breakage and coalescence is adopted, the flow is considered and modelled in turbulent regime. A constitutive equation for viscosity is obtained from a Cross model modified according to the results in [1].

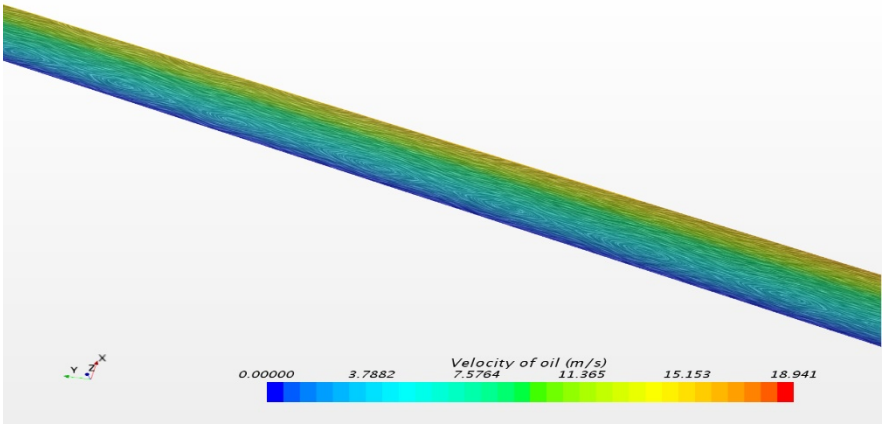
3. Results and discussion

Among the results, the oil droplet size at the outlet of the mixer is compared with the measures. An interesting feature of this flow is the possible development of instabilities in the small gap between the rotor and the cone mill walls as shown in Figure 1 (c).

(a)



(b)



(c)

Figure 1. IKA cone mill from [4] on (a). A sketch of the computing domain on (b). Instability patterns of oil droplet patterns on (c).

4. Conclusions

By varying the rotation speed of the mixer, some numerical simulations have been conducted vs experiments in order to validate the approach and provide an affordable instrument for further analysis on in-house production processes.

Coalescence modelling for settler design

David Leleu, Andreas Pfennig

University of Liège, Department of Chemical Engineering - Products, Environment, and Processes (PEPs), Quartier Agora, Allée du six Août, 11, Liège, Belgium,]

Highlights

- single-drop based (ReDrop) concept to predict the settling of liquid dispersion for settler design
- consistent coalescence model for ReDrop, developed on the fundamental analysis of the phenomena
- Settling experiments with iso-optical system used to validate the model

1. Introduction

Continuous and batch settlers are used in processes in order to separate liquid-liquid dispersion. Their design can be challenging, e.g. quantitatively predicting the remaining fraction of fine drops found at settler outlet as function of the operating conditions. For batch settler design, a numerical tool has been developed, which is based on considering the behavior if individual representative drops (ReDrop concept) [1]. This tool, which applies a Monte-Carlo method to solve the drop-population balances, allows to simulate the separation of liquid-liquid dispersions and thus to optimize the design of continuous settlers. Sedimentation and coalescence are evaluated for a sufficiently large ensemble of representative individual drops at each time step. The information obtained is then collected to determine e.g. the required settler size. In these simulations, the coalescence modeling is a major challenge due to the complex interactions of drops upon approach and coalescence.

2. Coalescence model

As shown in Figure 1, the probability that two drops coalesce depends on three contributions. The first is the frequency with which they meet, defined by the so-called collision rate. The second parameter is the bouncing probability. It characterizes the probability that the drops stay in contact during the time following the collision. If they are not, the collision leads to the direct bouncing without any chance to coalesce. The final variable influencing the coalescence probability is the efficiency with which the drops coalesce once they met. The coalescence efficiency in turn depends on the time, during which the drops stay in contact and the time they would need to coalesce. The developed equation describing the coalescence efficiency is fundamentally different from the model of Coulaloglou and Tavlarides, which is inconsistent at a basic level.

It turns out that solely the fluid dynamics of the regarded equipment determines the frequency with which drops meet, the bouncing probability and the time they stay in contact. The differences in equipment to which this model is applied characterize the fluid dynamics, which thus has to be characterized only once for a given type of equipment. The time the drops need to coalesce on the other hand only depends on the specific material system used [2].

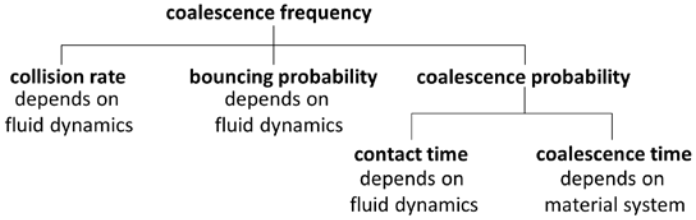

Figure 1. Coalescence model developed

3. Experimental device

The coalescence time can be evaluated experimentally from any suitable settling experiment. Here the experiments are conducted in the standardized settling cell proposed by Henschke [3]. It consists of a glass vessel with a capacity of 800ml, with 2 shafts for stirring with 4 stirrers on each shaft. A SOPAT probe is used to measure the drop-size distribution in situ. Iso-optical two-phase systems are analyzed and the settling after dispersing followed over the time. A dye present in one of the two phase allows to measure the local holdup. The experimental results are used to validate the model and the numerical approach.

4. First results and outcome

First experiments were performed with a system of paraffin oil droplets dispersed in water. The results depicted in Figure 2 show on the right hand side a simulation performed with the ReDrop program. The model parameters were fitted in order to follow the experimental data shown by the black dots. The latter represent the sedimentation and the coalescence curves observed visually from the movie recording of the settling experiment. The initial drop-size distribution used in the simulation was measured with the SOPAT probe. It is represented on the left side of Figure 2.

This results of the ReDrop simulation is in good agreement with the experimental data and shows good basis for the further experiments, detailed evaluation, and model validation using iso-optical systems.

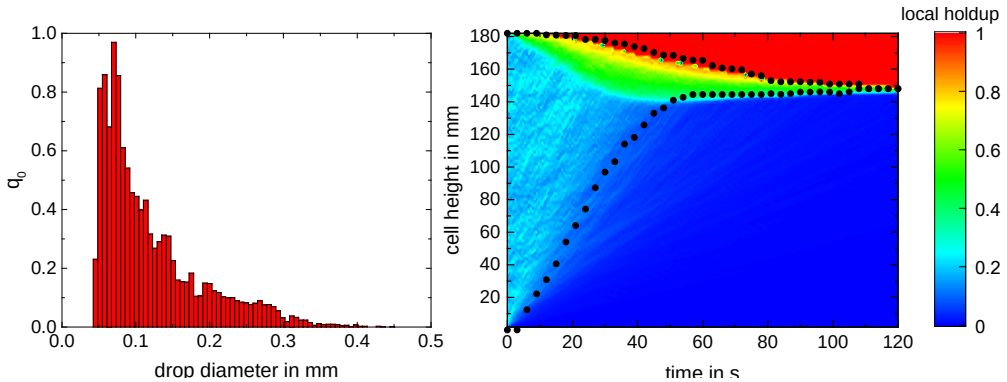

Figure 2. Fitting of experimental results (right) with the initial drop-size distribution measured with the SOPAT probe (left)

Highlights

- Detailed analysis of nanoparticles and surfactants as emulsion additives.
- Impact of additives on coalescence investigated via transient drop size distributions and phase separation curves.
- Self-similarity of drop size distributions and impact on the separation process.

1. Introduction

To optimize industrial processes it is often crucial to know the dispersion and coalescence behaviour, respectively the resulting drop size distribution, of liquid multiphase systems. Nanoparticles or surfactants can be used as innovative additives to reduce the droplet size in agitated multiphase systems and enhance the interfacial area available for mass transfer [1,2]. Beside a high interfacial area, the separation of the phases and a subsequent recycling of components is mandatory for economic efficiency [3]. For both agitated systems and the separation process different modeling approaches exist, but the description of additives often is realized using system-specific fit parameters since their actual impact on dispersion and coalescence is not yet fully understood. Aim of this work is a detailed analysis of liquid/liquid systems with nanoparticles [5, 6] and/or surfactants [7, 8] as additives including a detailed description of the droplet size distributions and their impact on the separation process.

2. Methods

Drop size distributions are experimentally determined in-situ in a stirred tank set up using an endoscope measurement technique in combination with an image analysis tool and automated drop detection (SOPAT GmbH). With an external camera, the dynamic phase separation is recorded after agitation stop and the overall separation time and phase separation curves are determined [1]. The system composition is described using the mass fraction of nanoparticles in the dispersed phase and the oil/water ratio $\alpha = m_{oil}/(m_{oil}+m_{water})$.

3. Results and discussion

The dynamic behaviour of the Sauter mean diameter after changes in agitation speed are shown in Figure 1 (left). The o/w emulsion consisted of water, n-heptan and different weight percent of

fumed silica nanoparticles (HDK H20, Wacker). With rising nanoparticle concentration, the coalescence rate after the reduction of agitation speed clearly diminishes. This is caused by the presence of nanoparticles at the liquid/liquid interface and its increased resistance against deformation [5, 6]. The dynamic phase separation curves after a complete agitation stop are shown in Figure 1 (right). The swarm sedimentation towards its continuous phase is illustrated via the sedimentation curve and the height of the completely coalesced interface via the coalescence curve. Higher particle concentrations clearly lead to higher separation times.

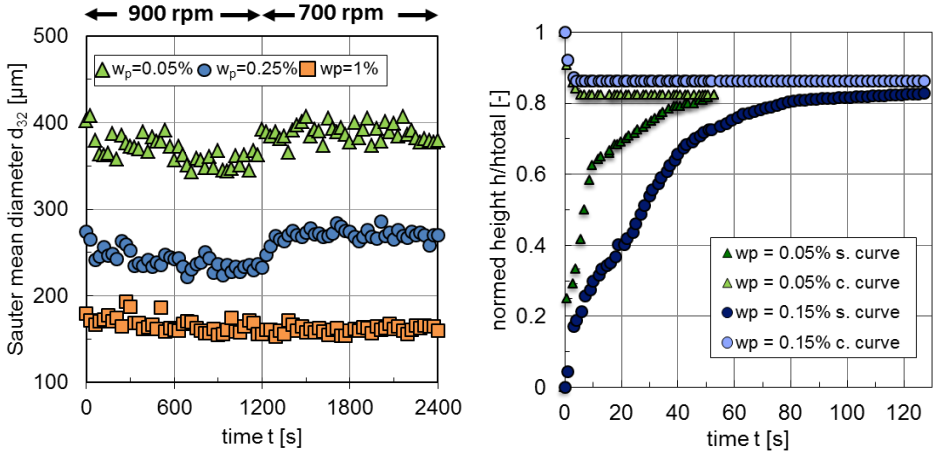

Figure 1. Transient Sauter mean diameters in agitated systems (left) and phase separation after agitation stop ($n_{initial}$ = 900 rpm) (right) in a water, n-heptane, silica nanoparticle HDK H20 system (o/w emulsions, α = 0.15, T = 20°C).

4. Conclusions

Nanoparticles and surfactants are promising additives for homogeneously catalysed liquid/liquid reactions. A detailed analysis of the coalescence behaviour under different flow conditions can be performed using the combination of endoscope measurements and separation curve analysis. Although both additives reduce the coalescence, the mechanisms are quite different due to their adsorption energy, size, shape and molecular structure. With the presented measurements and a detailed analysis of the complete drop size distributions, crucial information for the modeling approaches can be achieved.

The Similarity of Power and Flow In Batch and Inline Rotor-Stator Mixers.

Thomas John[1], Adam J Kowalski[2], Tom L Rodgers[1], Claudio P Fonte[1].

1 University of Manchester, Manchester, M19 2FT, UK; 2 Unilever R&D, Wirral, CH63 3JW, UK.

Highlights

- Inline and batch rotor-stators modelled using CFD.
- Power and flow numbers investigated for various screen hole sizes.
- Inline and batch rotor-stators can be characterized using the same model
- A correlation is developed to predict the recirculating flow in inline mixers.

1. Introduction

Rotor-stator mixers are mixing widely used across many industries for emulsification and de-agglomeration which can be operated in batch or inline mode. Often, the scaling of rotor-stators involves a change from batch to continuous mode, so it is highly desirable to understand how the power and flow characteristics differ between the two modes of operation. Power number in inline mixers can be characterized using the following equation[1].

$$\mathrm{Po} = \mathrm{Po_Z} + k_1 \mathrm{N_Q} \quad (1)$$

However, no such model has been developed or tested for batch mixers. The primary aim of this study was to investigate how this characterization differs between the two modes of operation.

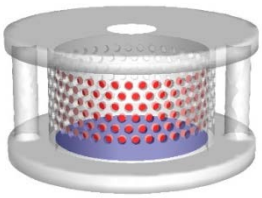

Figure 1. Surfaces across which flow was measured.

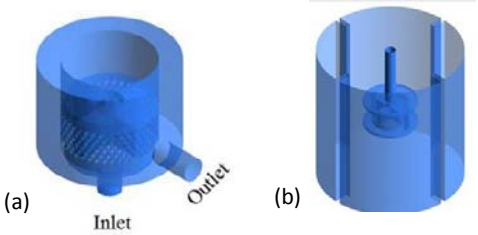

Figure 2. CFD geometries for (a) inline and (b) batch

2. Methods

The mixer studied was the Silverson L5M with standard emulsor head (Figure 1 and 2). Fluent v18.1 was the software used in this study. The standard k-ε turbulence model was utilized along with third order MUSCL discretization schemes for special discretization of momentum and turbulence. Rotation of the rotor was modelled using the multiple reference frame technique. Flow rate was measured across the red and purple surfaces shown in Figure 1. Power was measured from the bending moments on the rotor. In this study, using CFD, we were able to change the flow number in the batch configuration by constricting the base hole of the stator in small increments.

3. Results and discussion

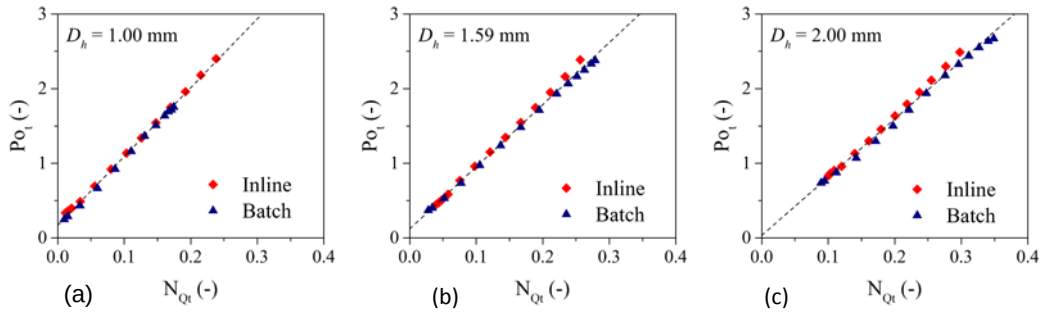

Figure 3. Power number vs flow number for both modes and hole sizes of (a) 1.00 mm, (b) 1.59 mm, and (c) 2.00 mm.

Figure 3 shows the power number as a function of the total flow number for the batch and inline simulations with various screen hole sizes. It can be seen that there is no difference between batch and inline RSMs in terms of power characterization. These results could suggest that with the same flow number, there will be no difference in the droplet size of an emulsified product, something which has also been suggested by Carillo De Hert[2].

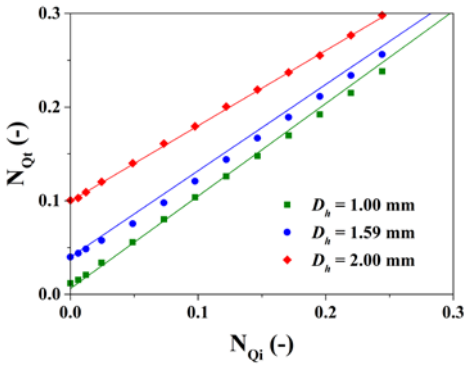

Figure 4. Total flow number vs imposed flow number for inline. Symbols - CFD data, lines - prediction by Equation 2.

Figure 4 shows the total flow number as a function of the imposed inlet flow number in the inline mixer. Since obtaining the total flow number would usually require CFD or PIV, a correlation was developed in order to predict the total flow number from imposed flow number and the geometry of the mixer using the following equation. The predicted results are shown in Figure 4.

$$N_{Qt} = N_{Qi} + 0.33\left(\frac{Area\ holes}{Rotor\ diameter^2}\right)^2 [0.51 - N_{Qi}] \quad (2)$$

4. Conclusions

Batch and inline rotor stators share the same characterization of agitation power. We have developed a correlation which enables the prediction of the total flow number from the imposed inlet flow number for inline rotor stators. This predicts how much flow recirculates back into the holes of the screen, and provides us with the true flow number that matches the batch data.

Highlights

- Efficient CFD modeling of Bubble Columns coupled with Population Balance
- Identification of a set of kernels validated over a wide range of cases
- Dimensionless analysis and proposal of a simple 0D approach to screen kernels

1. Introduction & Methods

This project aims at developing a bubble column model that couples CFD 3D Unsteady Reynolds Averaged Navier-Stokes equations (3D URANS) with a Population Balance (PB) approach. Experimental data obtained in a former work[1] including gas holdup, liquid velocity and bubble size measurements have previously been used to validate a 3D URANS CFD model[2] without PB, thanks to the use of a specific drag law[2]. Now the Quadrature Method of Moments (QMOM) is applied[3] to solve PB. This method allows to calculate, at low CPU cost, the k-first moments (m_k) of the Bubble Size Distribution (BSD), and thus the Sauter mean diameter d_{32} (=m_3/m_2). We propose to present 1) the validation of breakage and coalescence kernels for this application, and 2) a model simplification and analysis that points out the link between physical models and the resulting Sauter mean diameter. The CFD and QMOM equations are solved with the commercial software ANSYS Fluent® 18.2.

Transport equations of the moments of the BSD are synthetized in Figure 1:

$$\frac{\partial m_k}{\partial t}+\frac{\partial\left(m_k \boldsymbol{u}_g\right)}{\partial x}=\frac{1}{2}\sum_{i=1}^{3} w_i \sum_{j=1}^{3} w_j h\left(L_i,L_j\right)\left[\left({L_i}^3+{L_j}^3\right)^{\frac{k}{3}}-L_i^k-L_j^k\right]+\sum_{i=1}^{3} w_i g\left(L_i\right)\left(\bar{b}_i^k-L_i^k\right) \quad (1)$$

$$h\left(L_i,L_j\right)=h_0\left(L_i,L_j\right)\cdot\lambda\left(L_i,L_j\right)$$

$$h_0\left(L_i,L_j\right)=C'_2\,\gamma\,\Pi\left(L_i+L_j\right)^2\varepsilon^{1/3}\sqrt{{L_i}^{2/3}+{L_j}^{2/3}}$$

$$\gamma=\frac{\alpha_{max}}{\alpha_{max}-\alpha}$$

$$\Pi=1-e^{\left(-C\frac{\alpha_{max}^{1/3}\,\alpha^{1/3}}{\alpha_{max}^{1/3}-\alpha^{1/3}}\right)}$$

$$\lambda\left(L_i,L_j\right)=u_{crit}/u_{rel}$$

$$u_{rel}=\sqrt{2}\,\varepsilon^{1/3}\sqrt{{L_i}^{2/3}+{L_j}^{2/3}}$$

$$g\left(L_i\right)=C_1\varepsilon^{1/3}erfc\left(\sqrt{\frac{C_2\sigma}{\rho_L\varepsilon^{2/3}{L_i}^{5/3}}+\frac{C_3\mu_L}{\sqrt{\rho_G\rho_L}\varepsilon^{1/3}{L_i}^{4/3}}}\right)$$

$$\bar{b}_i^k=\int_0^{L_i}\beta(L,L_i)L^k dL=\frac{3240L_i^k}{(k+9)(k+12)(k+15)}$$

$$\beta(L,L_i)=180\left(\frac{L^2}{L_i^3}\right)\left(\frac{L^3}{L_i^3}\right)\left(1-\frac{L^3}{L_i^3}\right)^2$$

Figure 1. Scheme of the moment transport equations.

where L (m) is the bubble diameter, i and j are the indices of the 3 nodes of the quadrature method. w_i (m^{-3}) is the bubble density of the node i. h ($s^{-1}m^3$) is the coalescence kernel and g (s^{-1}) is the breakage kernel. h_0 ($s^{-1}m^3$) is the collision frequency model, λ (-) is the coalescence efficiency, β (m^{-1}) is the distribution of the daughter bubbles after the breakage of a parent bubble and ε is the dissipation rate (W/kg). α is the gas volume fraction, u_{rel} (m/s) is the turbulent

relative velocity and u_{crit} (m/s) is the critical approach velocity between bubbles above which coalescence is not possible. γ and Π are dimensionless correction factors to include the effect of gas volume fraction on collision frequency. α_{max} is the maximum gas volume fraction, taken equal to 0.8. C_{xx} are the constants of the different involved models. At each time step and in each spatial location, wi and Li are reconstructed from the m_0 to m_5 moments by a Product-Difference algorithm. Breakage and coalescence contributions to the moments are computed with the 3 nodes (w_i, L_i) in the source (right) term of Eq. (1) in Fig. 1.

3. Results and discussion

Comparing simulations and experimental data obtained in the breakage-dominated regime[2], it is possible to validate the breakage model of Laakonnen[4]. Concerning the coalescence model, the best agreement is obtained by coupling the collision frequency model suggested by Wang[5] and the coalescence efficiency of Lehr[5], based on the critical approach velocity model (Fig.1) . Sauter diameter radial profiles are well predicted over a wide range of operating conditions (not shown). Besides, as equation (1) is very complex, a drastic simplification is considered to analyse the consistency of the kernel with our phenomenology. In Eq. (1) the source term is computed by considering only a single bubble diameter (L=d_{32}) to calculate the right-hand term. Consequently i=j=1 in the transport equations, and the bubble density is equal to $w = 6\alpha/(\pi L^3)$. Note that m_3 is always equal to $6\alpha/\pi$ whatever the BSD. The steady state of the equation (1) for k=2 is strongly simplified and becomes a dimensionless relation:

$$\tau_b/\tau_c = 6\alpha.h(L,L)/(g(L).\pi.L^3) = \left(1-\bar{b}^2/L^2\right)/\left(2^{-\frac{1}{3}}-1\right) \quad (2)$$

where $\tau_b = 1/g(L)$ is the characteristic breakage time and $\tau_c = 1/w.h(L,L) = \pi L^3/(6\alpha.h(L,L))$ is the characteristic coalescence time. The term $\bar{b}^2/L^2$ depends only on the shape of the daughter-bubble distribution β and not on L^2. Using the β model of Laakonnen leads to $\tau_b/\tau_c \approx 1.15$. This equation only depends on L, α and ε and physical properties . It can be used to calculate directly the stable d_{32} and to compare various models of breakage and coalescence. α and ε can be computed by using CFD simulations for instance. d_{32} calculated from Eq. (2) is successfully compared both to the complete CFD+QMOM model and experimental results in Figure 2. This shows that the strong assumptions done to develop the Eq. 2 are acceptable if only the Sauter mean diameter of the BSD is required.

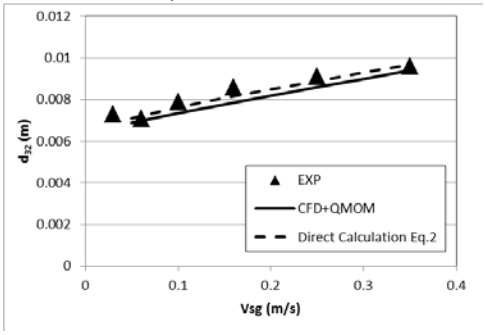

Figure 2. d_{32} comparison between CFD, Eq. (2) and experiments[1] (0.4 m column diameter, demineralized water)

Highlights

- CFD simulations are performed to study micromixing in a laminar microfluidic flow.
- Segregation indices are calculated using the Villermaux-Dushman protocol.
- Micromixing is modelled directly with CFD and indirectly with a lamellar model.
- The two solutions are compared in terms of computational cost and analysis times.

1. Introduction

Micromixing, i.e., the full homogenisation of mixtures of two or more components down to the molecular level, is a particularly important phenomenon in systems that involve fast and competitive chemical reactions, since it will directly impact on the achieved conversion and selectivity [1]. Directly modelling micromixing in laboratory or industrial equipment using Computational Fluid Dynamics (CFD) can, however, be computationally expensive. This is due to the need to resolve all the mixing scales down to those at which molecular diffusion becomes the dominant mechanism for the dissipation of concentration gradients. In the past 50 years [2], many efforts have been made to develop sub-grid models capable of describing micromixing in turbulent flows with Reynolds-Averaged Navier-Stokes or Large Eddy Simulations. Laminar flows have, however, received far less attention from the CFD community. In this work, we show that, in spite of their apparent simplicity, direct simulation of micromixing in the laminar regime can still be a challenging task when complex chaotic motions are present in the flow. Micromixing is assessed using the well-known Villermaux-Dushman reaction protocol in a milli-sized T-mixer with square bends. Direct numerical simulations of micromixing from the CFD flow field are compared with the predictions using a lamellar mixing model and previous experimental results.

2. Methods

The mixer geometry and flow conditions used in this work were chosen to replicate the experimental investigation of Commenge and Falk [3]. The flow domain has been discretised with hexahedral meshes with 20 and 40 cells across the duct. The continuity and momentum conservation equations were solved with ANSYS Fluent 19.0 to obtain 3D steady state flow fields in the microchannel at low Reynolds numbers ($60 \leq \mathrm{Re} \leq 300$). The transport and reaction of the species involved in the Villermaux-Dushman protocol have been directly solved using the built-in

Stiff Chemistry solver directly integrated with the CFD flow field. The segregation index, X_S, has been calculated from the concertation of all the species as described by Commenge and Falk [3] as the metric to assess micromixing.

The flow field obtained from the CFD simulations was additionally used to perform a Lagrangian tracking of the position and deformation of infinitesimal fluid elements injected at the inlets. These results were further processed to obtain an average rate of decay of the striation thickness of laminas of fluid necessary to model micromixing in the microchannel using a lamellar-structure mixing model as described by Ottino *et al.* [4]. Up to 800 particles were tracked with an adaptive 7^{th}-8^{th} order explicit Runge-Kutta method. The lamellar mixing model equations were solved using the pdepe function in MATLAB. It is worth mentioning that both developed models of micromixing in this work are fully-predictive and have no adjustable parameters, requiring only information on the kinetics of the Villermaux-Dushman reaction scheme found in the literature [3].

3. Results and discussion

The obtained simulation results for both models are in quite good agreement with experimental data of Commenge and Falk [3] (see Figure 1). The lamellar model tends to over predict micromixing at the lower range of Reynolds numbers but predicts well the rate of decay of the segregation index with the increase in Re. The direct numerical simulations of the species transport and reaction show quite good agreement with experimental results in the lower part of the Re range but seem to over predict the degree of micromixing in the upper part of the range, indicating that further refinement might still be necessary for those flow conditions.

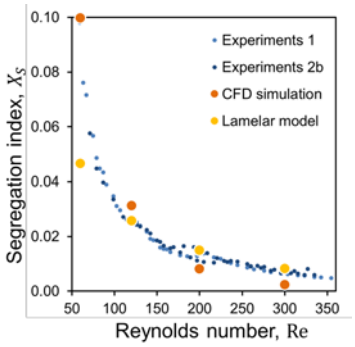

Figure 1. Comparison between the segregation index obtained experimentally by Commenge and Falk [3], the direct CFD simulation of the species transport and reaction, and the simulations using the lamellar mixing model.

The direct numerical simulations of micromixing using the CFD flow field have been found to be computationally very costly, requiring very fine meshes (up to 11.5 million elements).

4. Conclusions

CFD simulations have been successfully used in this work to simulate the flow and micromixing in a T-mixer with square bends in the laminar regime. This work shows that, even for simple geometries and low Re, the direct simulation of micromixing can be very computationally expensive when chaotic structures are produced by the flow. The use of micromixing models can offer an attractive alternative to direct simulations.

Highlights

- Experimental insight into CO_2 dry-ice particle impact and breakup behaviour
- Development of a new particle breakup model for Lagrangian particle tracking
- Wind-tunnel experiment for the validation of the new particle breakup model

1. Introduction

A new particle breakup model is presented for Lagrangian particle tracking, which was developed in the context of the design process of a new CO_2 dry-ice based cleaning system for commercial aircraft engines. Particle breakup resulting from solid wall impacts is considered. The model is based on a large statistical database, which is derived from experimental particle impact data captured using two high speed cameras. In this work, approximately 4000 primary particles were recorded impacting a solid wall with various wall temperatures and using a range of impact velocities and impact angles. The recordings were post-processed by in-house-developed digital image processors to obtain secondary particle numbers, sizes and velocities. These secondary particle characteristics are discussed in the context of the experimental parameters and show significant dependence on impact angle and velocity and negligible dependence on target temperature. Using this data, a mass- and energy-based formulation is applied to predict particle breakup statistics in numerical simulations. The approach chosen is shown to be mass-, momentum- and energy conservative and is implemented in the commercial numerical code Ansys CFX. An additional validation experiment for the new particle breakup model is presented, in which a dilute dry-ice laden air flow is established in a wind-tunnel set-up containing a flat plate target. Particle collisions upon this plate are recorded using two high speed cameras and post-processed as described above. A comparison of the experimental data with numerical predictions of the same situation shows satisfactory overall agreement. The limitations of the new model are discussed and future developments are addressed based on these results.

2. Methods

The procedure presented is mainly influenced by the extensive investigations towards dry-ice by KRIEG [1], REDEKER [2] and HABERLAND [3] and the most recent water-ice particle breakup studies by HAUK et al. [4], VARGAS et al. [5] and those from PAN and RENDER [6] and GUEGAN et al. [7]. The modelling assumption used is comparable to what was introduced by CHAPELLE et al. [8]. The particle breakup process is governed by an overall mass- and energy balance of the impacting particles. It is derived from a theoretical model analysis and simplified based on a sensitivity analysis. A fundamental HSC experiment is made, where single dry-ice

particles are recorded while impacting solid walls at a range of impact velocities, angles and wall temperatures. The data acquired from post-processing of these recordings represents the statistical database for the new particle breakup model and the model is used in numerical simulations in the Lagrangian particle tracking toolbox in Ansys CFX.

3. Results and discussion

Representative experimental particle data and total results are presented. The dry-ice breakup process is discussed in physical terms, such as shown for example in Fig. 1, left. The main validation study compares numerical particle numbers and sizes to experimental results. The predictive capabilities of the new model implementation are determined in conjunction with simulation set-ups of the validation case; a numerical example is shown in Fig. 1, right.

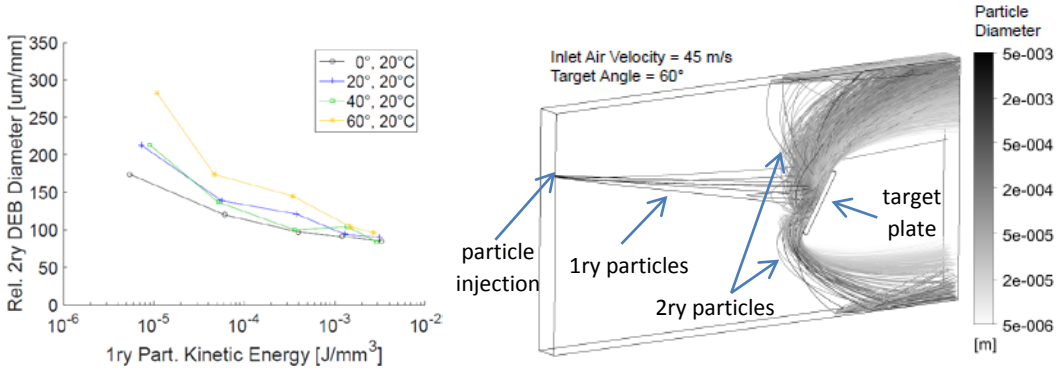

Figure 1: Particle sizes after 1ry particle breakup (left), particle breakup simulation in wind-tunnel setup (right).

4. Conclusions

A single particle experiment was presented to generate breakup statistics for dry-ice particles which are typically used in aircraft defouling applications. The statistical database was analyzed and it was found that the secondary particle numbers, sizes and velocities are mainly dependent on the primary particle impact velocity and on the impact angle. There was almost no dependency found on the target temperature, however, additional temperature effects at high impact velocities cannot be ruled out. Secondly, a wind-tunnel validation study of the new model was presented in which predicted values were compared to corresponding experimental data. Mean deviations of 5 to 10 % are encountered for the prediction of the secondary particle sizes. The prediction of the particle sizes of specific size classes is more precise than the prediction of the overall particle size. This can be attributed to more significant inaccuracies in the predictions of the numbers of secondary particles, which show mean deviations as high as 27 %.

Highlights

- Micro CT system for the investigation of liquid/liquid flows
- 2D and 3D investigation of liquid/liquid interfaces and transport phenomena
- Detailed analysis in MATLAB

1. Introduction

For process intensification in chemical engineering, miniaturization of equipment to the millimeter or micrometer range offers great potential for high mass and heat transfer and, thus, safer processes. Multiphase applications are often occurring and allow for executing gas/liquid reactions or liquid/liquid separation processes. To ensure successful process intensification via miniaturization, knowledge about the interfaces between the phases is crucial. Usually, interfaces in miniaturized equipment are examined by optical cameras, but often optical access is limited. To overcome this limitation, micro computed tomography (micro CT) is used to investigate interfaces and transport phenomena in miniaturized equipment in this contribution.

Nowadays, computed tomography CT is widely used not only in medical diagnosis [1], but also in material science [2] and geology [3]. Even in the field of process engineering, CT increasingly becomes an important tool, for example for the investigation of the distribution of liquid distribution in packed columns [4,5,6]. However, the extension of CT imaging to the field of micro process engineering needs high spatial resolution. In this work, we present a methodology that enables 2D and 3D investigation of multiphase flows in capillaries. The focus is set on liquid/liquid applications.

2. Methods

Image acquisition is carried out with the Bruker Skyscan 1275 (RLJ Micro & Analytics, Germany), that allows resolutions up to 4 µm. It is equipped with a stationary X-ray source and detector and a rotating sample stage, as shown in figure 1. For safety reasons, the image acquisition unit along with the mounted sample equipment is enclosed in a lead housing. For liquid

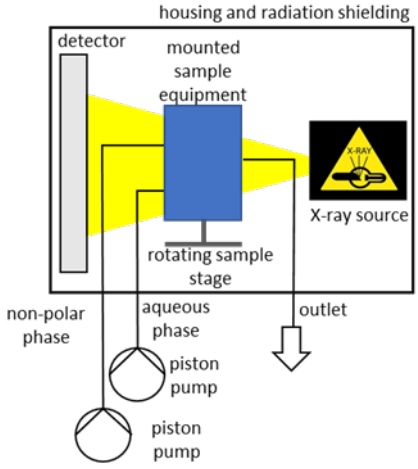

Figure 1. *Schematic of the experimental set up for the investigation of multiphase phenomena in small ducts.*

supply and liquid removal, it is additionally equipped with fluorinated ethylene propylene hoses. An aqueous and a non-polar phase are pumped through the scanner using piston pumps and contacted inside the scanner in a narrow duct.

After image acquisition, the images are reconstructed using *NRecon*, the reconstruction software that comes along with Bruker Skyscan 1275, to obtain 3D information and analyzed using a self-developed procedure in MATLAB. For 2D investigation, image analysis can be performed directly after image acquisition.

3. Results and conclusion

The presented procedure allows the 2D and 3D investigation of liquid/liquid interfaces. Figure 2a) shows a liquid/liquid interface extracted from a stack of reconstructed projection images. In figure 2 b) a 2D projection image of a liquid/liquid bubbly flow in a low density polyethylene hose (inner diameter 1.5 mm), generated by a stainless steel cannula is shown.

Future work will incorporate a more detailed investigation of liquid/liquid interfaces in different flow regimes, such as parallel flow or periodic bubbly or slug flow. This will be supplemented by first mass transfer experiments inside the CT.

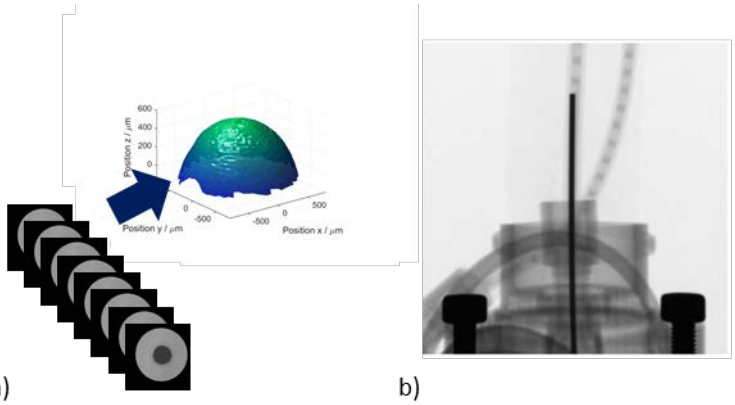

Figure 2. *a) Stationary liquid/liquid interface extracted from a stack of reconstructed slices, b) Projection image of the experimental set up for the generation of a liquid/liquid drop flow in a low density polyethylene hose generated by a cannula.*

Highlights

- Comparison of numerical studies. Volume-of-Fluid vs. Lattice-Boltzmann
- Drop breakup is related to interfacial shear stress and pore geometry
- Generic simulations are performed to analyze the breakup processes in complex structures
- Stress related breakup mechanisms enable opportunities in membrane design

1. Introduction

Emulsions are widely used in industrial applications. In particular in the food technology and in the pharmaceutical industry the quality of the emulsion is relevant. The membrane emulsification process obtains the advantage to adjust the droplet size distribution according to the pore structure and the geometry of the membrane. The membrane emulsification process is a low stress process which is relevant for the handling of shear sensitive media (i.e. in biological systems). Whereas the emulsification process and influence of the membrane structure and geometry on the final product is well investigated, the liquid deformation and liquid dispersion process inside of the membrane structure is quite unknown. In particular the shear and strain stress at the droplet interface is important, especially in combination with adsorption processes of surfactants. Local stresses determine the droplet deformation and eventually the breakup. On the other hand, shear and strain stresses can influence the adsorbed structures (surfactants) at the interface, in example proteins. In this work numerical investigations with the Volume-of-Fluid-Method were performed to understand stress related breakup mechanisms in microporous structures. Furthermore Lattice-Boltzmann studies were carried out to investigate the effect of non-Newtonian fluid on the breakup process. The results of both methods are complemented to get an overall understanding of the complex breakup mechanisms in membrane emulsification processes.

2. Methods

A Volume-of-Fluid method formulation within OpenFOAMS InterFoam solver was implemented. This model enables the calculation of local shear and strain conditions (stress tensor) at the interface of a liquid-liquid system. With this extension the stress residence time behavior at the liquid-liquid interface in idealized pore structures and elementary flow constrictions has been analyzed. The parameters influence on the droplet deformation is carried out and critical shear and strain stresses for droplet breakup are analyzed. The simulation procedure was extended to real membrane pore geometries and compared to the stress conditions and break up mechanisms received from the idealized pore geometries. The inter-particle Shan Chen Lattice Boltzmann model for immiscible fluids is used to analyze the droplet dynamics in porous model structures and real

membrane structures. Furthermore, models for shear-thinning and viscoelastic fluids are used to study the differences in the break-up mechanism. Newtonian droplets in non-Newtonian continous phases and vice versa are investigated at different Deborah numbers. Parameters in both numerical studies were varied by the pore geometry, capillary number, contact angle and droplet size.

3. Results and discussion

An example of the porous structures investigated and a simulated (VOF) drop within this structure is shown in Fig. 1. For the Volume-of-Fluid Method the results show that liquid-liquid (disperse-continuous) interface stress determines the drop deformation process rather than liquid-solid (disperse-wall) interface stress. The main stress related drop breakup mechanisms were derived. At a critical capillary number the drop detaches from the pore wall based on contact line instabilities, followed by a deformation of the droplet at the liquid-liquid interface due to stress and strain histories, ending up in the breakup of the droplet due to local constrictions. The analysis of local and integral interfacial stress condition gives insight of the geometry and time dependent drop deformation behavior. [1]

The results of the Lattice-Boltzmann studies show that the feedback of the viscoelastic fluid changes the breakup process and thus the resulting drop size distribution. This leads to smaller drop sizes. The local shear rates in the membrane structure induce local shear thinning of the non-Newtonian fluid, which results in a change of the local stress conditions and hence of the drop deformation behavior.

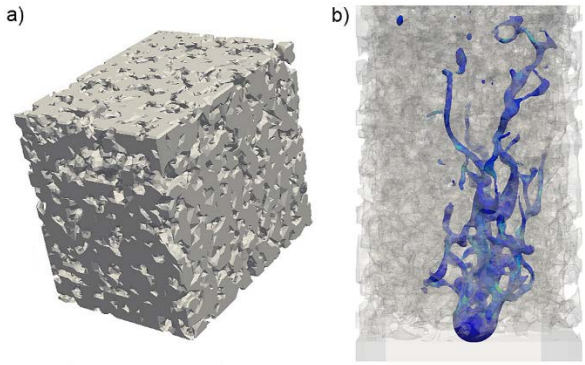

Figure 1. CT-scan of a porous membrane structure (a) and a simulated droplet within the membrane structure (b) [1]

4. Conclusions

The analysis of the stress dependent drop breakup mechanisms in micro-pores and the investigation of the effect of non-Newtonian fluid on the breakup process enable new opportunities in the design of porous structures to reduce the stress conditions during the emulsification process for the utilization stress sensitive media and for the formulation of certain emulsion properties.

Computational fluid dynamics analysis of 3D flow patterns in a stirring blade turning space in a wide range of Reynolds number

T. Hakamada[1], R. Misumi[*1], M. Kaminoyama[1]

1 Yokohama National University, 79-5, Tokiwadai, Hodogaya-ku, Yokohama-shi, Kanagawa, 240-8501, Japan

**misumi-ryuta-zm@ynu.ac.jp*

Highlights

- We used CFD to qualify 3D flow patterns in the stirring blade turning space.
- We validated the CFD results from PIV measurements in the blade turning space.
- Effects of viscosity on the flow pattern were ascertained for a wide range of *Re*.

1. Introduction

During mixing operations, the flow pattern in the stirring blade turning space affects the circulation flow in the tank. The pattern is linked directly to the success or failure of the operation. However, because it is difficult to measure the flow pattern in the turning space, the flow pattern in the turning space has not been revealed sufficiently. Especially in the transitional regime, the effects of the fluid viscosity, vessel size, and impeller speed on the flow pattern have remained unclear. Computational fluid dynamics (CFD) is a very useful technique to predict fluid flow. However, when using CFD, validation with reliable experimental data is fundamentally important. For this study, the three-dimensional fluid velocity distribution in the turning space of a six-blade paddle in a non-baffled vessel was quantified by CFD from the laminar, transitional, and then to turbulent regime. Furthermore, horizontal two-dimensional particle image velocimetry (2D-PIV) in the turning space was performed in the rotational coordinate system. The CFD analysis was validated based on the PIV data.

2. Methods

Software (Fluent 18.0; ANSYS Inc.) was used for CFD analysis. For this study, a non-baffled cylindrical tank with a flat bottom of inner diameter T = 0.20 m was used. The blade diameter and width were, respectively, D = 0.10 m and b = 0.02 m. The rotational speed was N = 2 s^{-1}. The fluid depth was H = 0.25 m. The blade height was h = H/2. Water or glycerin aqueous solution was assumed as the working fluid. We performed CFD analysis at Re = 24, 177, 511, and 22,400 by changing the glycerin solution viscosity. Laminar, transition-SST, DES, and LES models were adapted for each flow regime. Polyhedral mesh was adapted, and two conditions of 390,000 and 890,000 cell number were prepared. The radial, tangential, and axial velocities in the rotational coordinate system were calculated. Time-averaged velocities were quantified for 4 s under a steady state.

2D-PIV measurements were taken under the same conditions as those used for CFD. The tracer particle motion was captured continuously for 2 s using a high-speed video camera. Fluid velocity distributions in the Cartesian coordinate system were analyzed from 2000 images using PIV

software (Flow Expert 2D2C; Kato Koken). Then, the radial velocity $u_{r,ro}$ and the tangential velocity $u_{\theta,ro}$ synchronized with the impeller rotation were calculated using the original MATLAB® program.

3. Results and discussion

3.1 Radial velocity distribution between two blades in the rotational coordinate system

Fig. 1 shows the relation between time-averaged radial velocity $\overline{u_{r,ro}}$ normalized with the blade tip velocity v_{tip} and circumferential angle θ_{ro} [rad] at the center height of blade at *Re* = 177. Laminar, transition-SST, and LES were used with 390,000 cells at *Re* = 177. Fig. 2 shows the parity plot of $\overline{u_{r,ro}}$ between PIV and CFD by the transition SST model. Fig. 1 and Fig. 2 show the PIV measurements can be predicted most accurately by transition-SST model. Their accuracy is confirmed as approximately ±16%. Similar procedures were used for other *Re* number conditions.

3.2 Quantification of three-dimensional flow pattern

Fig. 3 shows the isosurface of $\overline{u_{r,ro}}$ = 0.3 v_{tip} of the CFD result in the wide range of *Re*. The isosurface shows the distribution of discharge flow from blades. At *Re* = 24, the fluid is pushed out by the blade and is discharged from the front side of the blade. At *Re* = 177, the fluid is discharged from both the front and back sides of the blade. At *Re* = 511, the discharge flow is mainly induced around the back sides, and at *Re* = 22400, the radial flow velocity from the back sides decreases. In other words, results show that the discharge flow shifts from the front side to the back side of the blade as the flow regime changes from laminar, transitional, and then to turbulence.

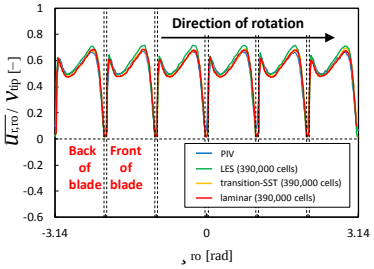

Figure 1. Relation between $\overline{u_{r,ro}}/v_{tip}$ and θ_{ro} (*Re* = 177, at the blade center height)

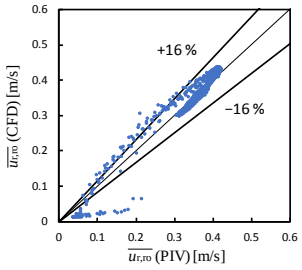

Figure 2. Parity plot of $\overline{u_{r,ro}}$ between PIV and CFD (*Re* = 177 with transition-SST model)

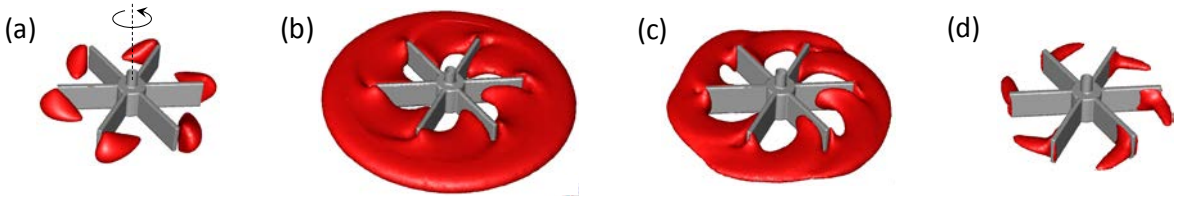

Figure 3. Isosurface of $\overline{u_{r,ro}}$ = 0.3v_{tip} ((a) *Re* = 24, (b) *Re* = 177, (c) *Re* = 511, (d) *Re* = 22400)

4. Conclusions

This study quantified three-dimensional flow patterns in the turning space of the stirring blades from laminar, transitional, and to a turbulent regime by CFD. Moreover, to confirm the validity of CFD, the discharge flow velocity distribution in the turning space was quantified using horizontal 2D-PIV. The accuracy of CFD results with various analytical models was evaluated for the respective *Re* number conditions. The most accurate CFD results showed that the discharge flow shifts from the front side to the back side of the blade as the flow regime change from the laminar, transitional, and then to turbulence.

This study was supported by JSPS KAKENHI (Grant Nos. 19K05118 and 17K06886).

Simulation of Developing Bubbly Pipe Flows with a Coupled Multi-Fluid/Population Balance Solver

Mohsen Shiea[1], Marco Vanni[1], Daniele Marchisio[1], Antonio Buffo[1]

1 Dipartimento di Scienza Applicata e Tecnologia, Politecnico di Torino, 10129 Torino, Italia.

**Corresponding author: mohsen.shiea@polito.it*

Highlights

- CFD with population balance equation is a powerful tool to simulate bubbly flows.
- QMOM with two-fluid approach predicts the average bubble size satisfactorily.
- Multi-fluid approach is necessary when the bubble size distribution is wide.

1. Introduction

Comprehensive CFD simulation of disperse gas-liquid flows requires the knowledge about the evolution of the disperse phase, i.e. gas bubbles, that can be achieved by solving the population balance equation (PBE) along with the relevant governing equations, which are limited, in this work, to mass and momentum balance equations. The PBE can be solved to predict how the population of the bubbles are distributed over the properties of interest, e.g. bubble size and bubble velocity. If the bubble size is the only property under study, i.e. assuming constant velocity for bubbles of different sizes, then the PBE can be integrated into a two-fluid model (TFM) solver. However, if the constant velocity assumption is not valid, for instance if the bubble size distribution (BSD) is wide, bubbles of different sizes should be transported with different velocities, hence the necessity of adopting a multi-fluid approach. This work aims at analyzing and comparing the simulation predictions of a developing turbulent air/water pipe flow using both two-fluid and multi-fluid approaches. The comparison of the predictions in this specific system is interesting since the lift force plays an important role in the radial distribution of the air as the flow develops. On the other hand, both the magnitude and the direction of the lift force depend on the bubble size [1]. Therefore, the effect of considering different velocities for bubbles of different sizes can be studied.

2. Methods and Experimental Data

The experimental data was adopted from the work by Bayer and co-workers [2]. The setup is a vertical air/water pipe flow with the inner diameter of 0.1953 (m). The air enters from the injection points located on the wall into the upward-flowing water. The flow develops gradually until it reaches a wire-mesh sensor that measures air volume fraction, air velocity and bubble size distribution. The injection points have different distances from the sensor, therefore, the information about how the flow develops in the pipe is available.

The simulations are performed with both two- and multi-fluid approaches. The two-fluid model consists of the momentum balance equations for the liquid and gas phases in addition to the volume fraction balance equation for the gas phase. The interfacial forces and corresponding models are selected based on some preliminary mono-disperse simulations, which include drag,

lift, turbulent dispersion and wall lubrication. The PBE is solved using the Quadrature method of moments (QMOM). It considers the effects of hydrostatic pressure, bubble coalescence and bubble breakage (modelled on the assumption of homogeneous isotropic turbulence) on the BSD. In this work, the QMOM approximates the BSD with three groups of bubbles (three-node quadrature). In multi-fluid model, the balance equations are written for each group as if there are three disperse phases with different characteristic lengths. All the simulations were performed using the modified versions of *twoPhaseEulerFoam* and *reactingMultiphaseEulerFoam* solvers of OpenFOAM v5.0 and v6.0. Further details of the implementation are described by Buffo and co-workers [3].

3. Results and discussion

Figure 1 depicts the radial profile of the air volume fraction (left) and the axial changes of the Sauter mean diameter, SMD, (right) obtained by the two-fluid approach for the operating condition with the inlet water and air velocities equal to 0.405 and 0.0368 m/s respectively. The predicted radial profiles of the air volume fraction show good agreement with the experimental data, particularly at the higher section where the flow is almost developed. The discrepancies, such as those seen at the lower section, could be attributed to fact that according to the experimental data, the BSD near the air injection point is wider in comparison to the higher sections, where the flow is more developed. It suggests using the multi-fluid approach to allow the bubbles to move with different velocities and assess its effect on the radial air distribution. Nevertheless, the PBE coupled with the two-fluid approach provides satisfactory predictions for the change of the SMD in the axial direction by using coalescence/breakage kernels based on the homogeneous isotropic turbulence.

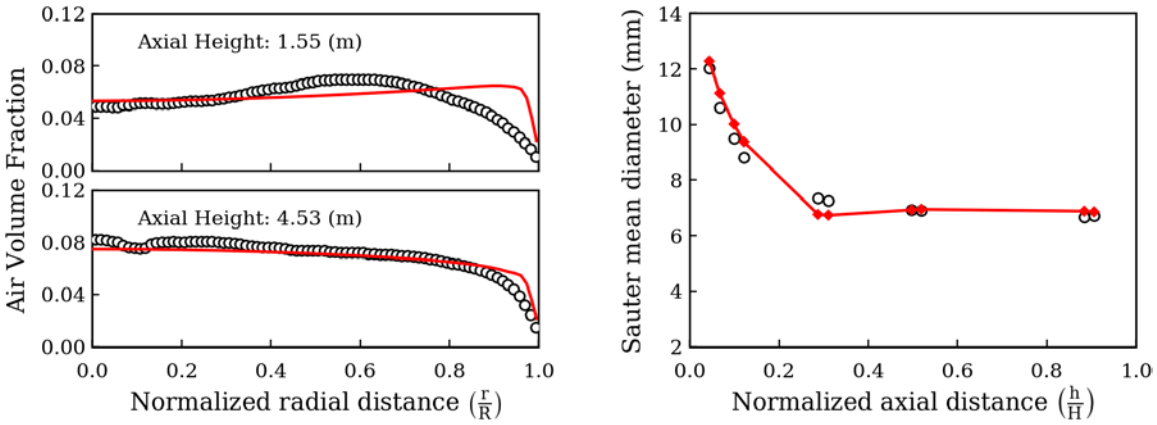

Figure 1. The radial profiles of the air volume fraction at two axial heights (left) and the axial profile of the average SMD (right) predicted by the two-fluid approach. Experimental measurements are shown by the circular markers.

4. Conclusions

A developing turbulent bubbly pipe flow was simulated using CFD-PBE method. Satisfactory predictions, particularly for higher sections (developed flow) were obtained by assuming one velocity for bubbles of different sizes. The multi-fluid approach will be used to assign different velocities to bubbles of different sizes, which is necessary when the BSD is wide.

Highlights

- New manufacturing process for microstructured devices.
- Etch rate of the RIE process increased by increasing SF_6 and oxygen flow rates at higher pressure.
- Resulting surface roughness minimized with high gas flow rates at high pressure.
- Linear relation between pressure drop and Reynolds number indicates laminar flow.

1. Introduction

Two-phase droplet flow in microchannels is of great potential providing high specific surface, low liquid hold-up and, intensified chemical reactions. A new manufacturing process for polyimide-based microfluidic devices was developed. Reactive ion etching (RIE) was used as production technique obtaining anisotropic etching and high spatial resolution. Polyimide (PI) withstands most solvents, acids and bases and is suitable for RIE. The combination of RIE and PI for microfluidic devices provides high geometric flexibility, reproducibility and, wide range of applications. The production process was applied on microfluidic geometry for droplet generation. [1–3]

2. Methods

The etching gas for the RIE process contains sulphur hexafluoride (SF_6), oxygen (O_2), and argon (Ar). A 2^4 full factorial designed experiment was used to analyze the effects of the investigated parameters on the surface roughness and etch rate and to determine the interactions between these parameters. The experiments were performed with an RIE apparatus Plasmalab® µEtch (Oxford Instruments plc, Abingdon, UK). The gas composition during the RIE process and the total pressure were varied between 133 and 266 Pa. The pressure drop of the manufactured geometry was measured as an indicator of the prevailing flow regime (see Figure 1, left).

3. Results and discussion

The physical etching during RIE is caused chiefly by the argon ions and partly by the oxygen atoms. The chemical etching is performed by fluoride ions generated from SF_6. The optimal parameter

settings was found with all parameters on high level since the positive effect on the etch rate exceeds the minor increase of roughness. A value of 0.7137 µm min^{-1} was found for the etch rate and for mean surface roughness 0.5878 µm were measured with a mean etch depth of 50 µm. The measured pressure drop was compared to calculated values using the Darcy Weisbach equation for flow inside a tube and with a fitted constant, respectively (see Figure 1, right). The linear course of the pressure drop indicates laminar flow regime and only a minor influence of the surface roughness and the channel widening on the liquid flow [4].

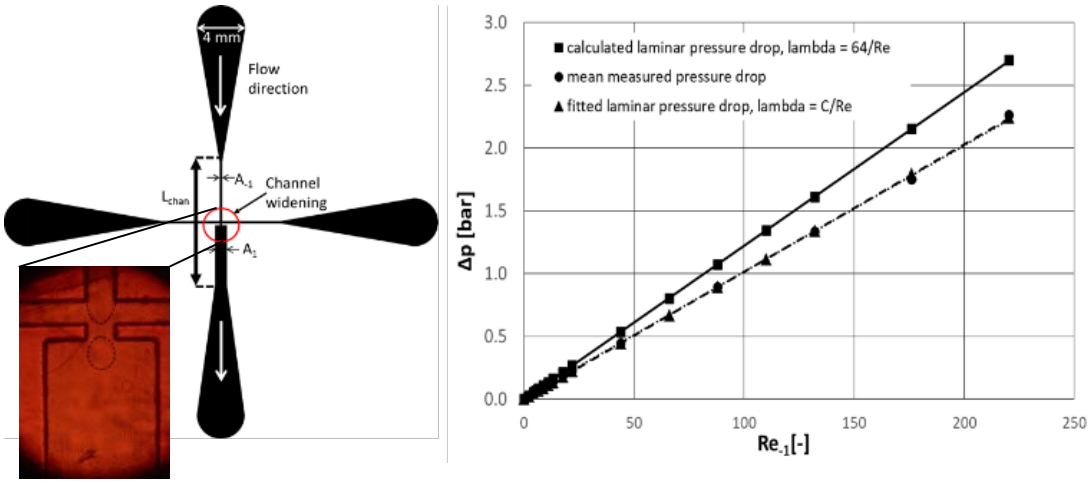

Figure 1: Manufactured geometry (left) with observed drop flow for water/silicone oil (0.01 ml min^{-1}/0.1 ml min^{-1}), measured and calculated single-phase (water) pressure drop plotted against the highest Reynolds number (right), constant C fitted on the measured values and found as 53

4. Conclusions

A RIE manufacturing process for microstructured devices was developed and characterized regarding to the etch rate and surface roughness. A microstructured droplet generator with a widening from 100 µm to 300 µm was manufactured with the optimized parameter settings and drop flow was observed for water in silicone oil. The course of the pressure drop implicates a laminar flow regime for the investigated flow rates. The linear part of the Darcy Weisbach equation dominates the pressure drop in contrast to the contribution of the quadratic part. This indicates that the small straight channel have the greatest impact on the total pressure drop in contrast to the surface quality and other geometric influences.

Highlights

- Hydromechanical stress crucial for shear-sensitive filamentous microorganisms.
- Impeller geometry determining factor for particle breakage in bioreactors.
- Quantification of particle breakage by means of in situ endoscopic technique.
- Investigation of novel impellers.

1. Introduction

As part of the DFG priority program SPP 1934 DiSPBiotech, this study focuses on the characterization of local mechanical stresses occurring in stirred tank bioreactors and their effect on biological agglomerates. This work intends to identify and develop low-shear stirrers for cultivations of filamentous microorganisms. As case study, the cultivation of the filamentous fungi *Aspergillus niger* is used. Direct measurements of mechanical stresses in real cultivation broths are barely possible. Thus, the investigations are carried out by using model systems [1], which simulate the most significant properties of the biological system (broth rheology, bio-agglomerates morphology). Conventional and newly developed stirrer types are characterized in terms of particle stress, which is quantified by measuring particle breakage in the agitated reactor by means of an in situ particle size measuring technique. The interpretation of the breakage mechanisms in the stirred vessel succeeds through quantification of shear and elongation stresses by using Particle Image Velocimetry (PIV).

2. Methods

Experiments were conducted in a 3-L lab scale baffled agitated tank, geometrically similar to a fermenter. 15 impellers were used for the investigations. Among the conventional agitators (Rushton, pitched blade turbines etc.), five novel agitators were developed in cooperation with EvoLogics GmbH (Fig. 1).

Development of model systems: As particulate systems fluid/fluid and solid/fluid systems were used. Particularly, droplets of silicon oil and clay/polymer flocs were chosen as dispersed phase to approximate a wide range of *Aspergillus* morphology (spherical pellets and mycelial forms). The cultivation broth appears to be low viscous up to a specific level of biomass concentration and then it develops a shear thinning behavior. Water and a Xanthan gum solution were used as model fluids for the continuous phase to approximate the broth rheology at initial and later cultivation phases.

In situ particle size measurement: An in situ analysis method was used to monitor the particle breakage kinetics in the stirred tank. The photo-optical SOPAT measurement technique for particle sizing (SOPAT GmbH) uses endoscopic probes, capable to obtain two-dimensional images of a disperse phase during a process and measure the sizes and shapes by an automated image analysis [2].

Fluid dynamic investigations: Mechanical stress is quantified by recording the velocity vector field by means of Particle Image Velocimetry (PIV) and calculating shear/elongation gradients in the tank.

3. Results and discussion

The particle breakage caused by the investigated stirrers was measured in the stirred tank for the developed particulate model systems. The particle stress caused by each stirrer is quantified as a function of a steady state characteristic particle diameter with the average energy dissipation rate. Fig. 2 indicates that an axial propeller causes stronger breakage, producing smaller droplets in comparison to a radial Rushton turbine, which in the biotechnological field has been wrongly considered as high shear impeller. Through PIV measurements, the particle breakage caused by 15 stirrer types is further analyzed. Fig. 3 shows that mixing with a propeller produces significantly high shear gradients, inducing consequently stronger particle breakage as depicted in Fig. 2.

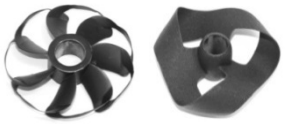

Figure 1. Patent pending novel impeller geometries; Bionic Loop (left) and Wave-Ribbon impeller (right) (EvoLogics GmbH)

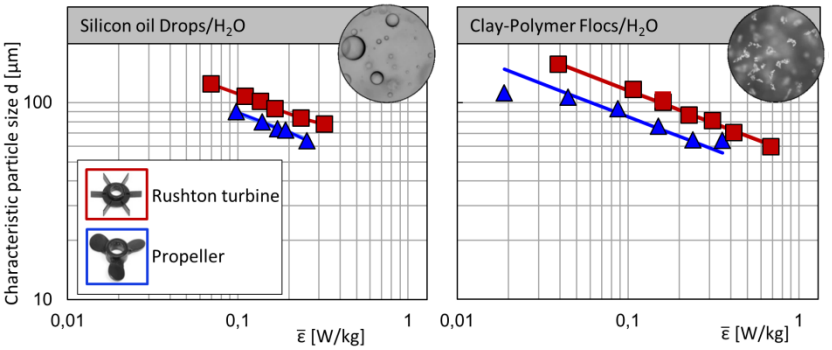

Figure 2. Steady state particle diameter as a function of the av. energy dissipation rate for two impellers; drops dispersion (left) and flocs suspension (right)

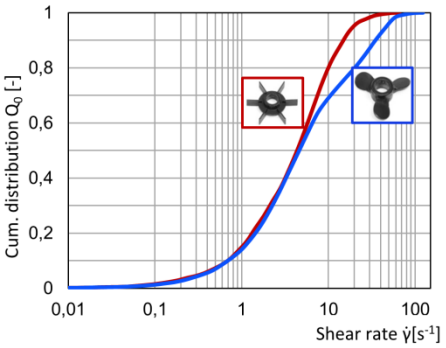

Figure 3. Cum. distribution of the shear rates produced by two impellers for $\bar{\varepsilon}$=0,1 W/kg

4. Conclusions

The results of the abovementioned experimental work contribute significantly in the design of low-shear impellers to be used for the cultivation of shear sensitive filamentous microorganisms.

Highlights

- Deep insights into industrial scale aerated stirred tank reactors
- Comparison of mixing performances for different scales
- Challenges of scale-up process from lab- to industrial scale

1. Introduction

Aerated stirred tank reactors (STR) are often used for mixing, heat- and mass transfer processes in chemical and biochemical engineering due to their robust operation and extensive description in the past. However, in case of mammalian cell expression systems special requirements have to be fulfilled. Beside media and feed, the hydrodynamic properties like power input, mixing and mass transfer performance have to be customized for each individual cell line [1] as well as reactor size during the upstream process.

Commonly used scale up parameters are constant geometrical ratios, constant volumetric power input P/V, constant superficial gas velocities w^0_g as well as constant volumetric gassing rates vvm. Whereas the scale-up of stirred tank reactors is still challenging justified by the fact that most design criteria as well as correlations are based on measurements on small scale reactors [3]. Especially for mixing time correlations, most investigations are based on operation conditions for bacterial or yeast fermentation with power inputs over 100 W/m^3 and gas flow rates over 1 vvm [2].

To overcome this gap, an acrylic glass reactor has been designed and erected on industrial scale (15 m^3) at Hamburg University of Technology in cooperation with Boehringer Ingelheim Pharma GmbH & Co.KG. With the help of the acrylic glass reactor (Figure 1) of industrial scale it is possible to visualize global and local flow structures and to investigate the influence of heterogeneities of the flow on the mass transfer as well as the mixing time. Furthermore, it is possible to investigate the influence of different stirrer geometries and configurations on the hydrodynamic behavior of an industrial scale aerated stirred tank reactor.

Figure 1: 15 m3 acrylic glass reactor at TUHH

2. Methods

The acrylic glass reactor with an inner diameter of D = 2 m and a total volume of V_R = 15 m^3 is equipped with a bottom mounted magnetic agitator as well as three baffles. The agitator can be equipped with either up to three Rushton turbines or pitched blade turbines (d/D = 1/3). An open tube sparger is used, which is located below the Rushton turbine [2].

The gas flow rate is controlled by an F-203AV mass flow controller from Bronkhorst®. The power input is measured at the stirrer shaft using a DR-3000 torque measuring instrument from Lorenz®.

The mixing time is determined by a decolorization method in combination with a high spatial and time resolution image processing [2].

3. Results and discussion

First investigations have been performed with a two stage impeller system. In figure 2 two different mixing processes of two different flow regimes are presented. On the left hand side a homogeneous bubbly flow is present where the bubbles are rising homogeneously dispersed over the cross section. The axial mixing is reduced and two compartments are forming.

This leads further to a high mixing time. On the right hand side a heterogeneous flow regime with large bubbles is presented. These large bubbles are rising with a much higher velocity and are not equally dispersed over the cross section of the reactor. This leads to a buoyancy driven flow structure and thus better axial mixing [2].

Further investigation into the hydrodynamics of different impeller combinations will be presented.

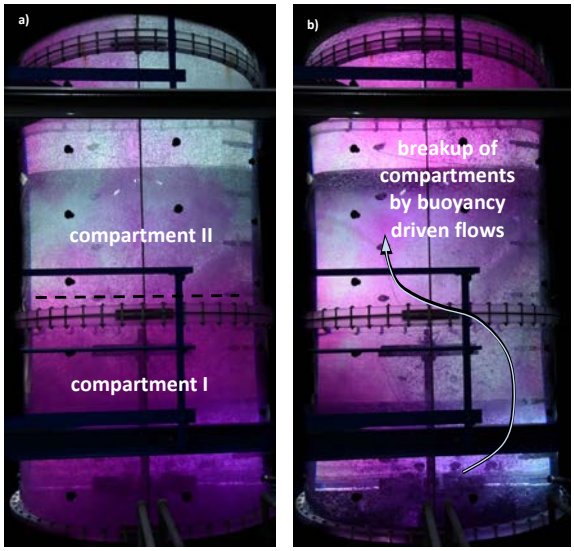

Figure 2: Exemplary decolourization processes after t = tmix · 0.5 for two different flow regime: homogeneous (left), heterogeneous (right).

4. Conclusions

A first characterization can be done by taking into account buoyancy driven flows superimposing the flow induced by the impeller. A correlation is presented to estimate the transition between a loading and flooding regime on large scale. This correlation enables the calculation of mixing times for a wide range of stirrer frequencies and superficial gas velocities. Furthermore, this presentation will emphasize the challenges of scale-up on the basis of laboratory experiments in small scale.

Highlights

- Drawdown and dispersion of oil droplets in water are investigated by ERT.
- A procedure for liquid-liquid flow maps identification in stirred tanks is proposed.
- The flow map for moderately concentrated water-diesel fuel systems is presented.

1. Introduction

The impeller speed required to successfully disperse one immiscible phase in another in stirred vessels is a very important process parameter, which experimental determination is not straightforward [1], particularly in dense liquid-liquid systems. This work has the goal to suggest a new procedure to obtain the flow map of immiscible liquid-liquid systems, based on the measurements of the dispersed phase distribution by Electrical Resistance Tomography (ERT).

2. Methods

The investigation concerns a moderately concentrated immiscible liquid-liquid system, consisting of diesel oil of density, ρ_{oil}, equal to 810 kg/m^3 at ambient conditions, and demineralized water, containing 0.5 g/L of NaCl for enhancing the conductivity difference with the non-conductive oil phase, as required by the ERT technique. The dispersion is obtained in a flat bottomed fully baffled tank of diameter, T, equal to 232 mm stirred with a Rushton turbine of diameter, D, equal to T/3, placed at the clearance, C, equal to T/2. The distribution of the diesel fuel in water is observed at different impeller speeds, N, going from complete segregated conditions to fully dispersion. Data are collected at different average oil volume fractions in the vessel, varying from 0.05 to 0.14, keeping the total liquid height, H_L, in still conditions always equal to T. The analysis is based on the time-averaged conductivity data on four horizontal vessel sections (axial elevations, z, equal to 60, 110, 160, 210 mm), consisting on 316 values per plane, with a square mesh with each cell of 11.5 mm side. For each condition, the time-averaged conductivity is obtained from 1000 instantaneous measurements. The ERT instrumentations and the data acquisition systems are similar to those adopted in previous investigations [2].

3. Results and discussion

Different flow conditions have been identified through the analysis of the time-averaged conductivity data on the four measurement planes. Starting from the complete segregated

conditions, the just drawdown and the complete dispersion of the oil have been detected subtracting the mean conductivity value obtained at fixed impeller speed from the value recorded at N=0 on the plane at z=160mm, being this plane just below the liquid-liquid interface at N=0. By monitoring the local maximum absolute value of the conductivity difference from the completely segregated condition (N=0) on the plane at z=160 mm at increasing N, an evolution curve is obtained, as shown in Fig.1, relevant to diesel fuel volume fraction of 0.14.

As shown in Fig.1, through a linearization procedure of the experimental data (open circles), we identified the just drawdown impeller speed as the intersection of the two lines, highlighted in red, and the just completely dispersed impeller speed as the intersection highlighted in black. The homogeneous dispersion condition was identified once the variation of the conductivity on the four measurement planes reached an asymptotical value. By the procedure described above, a flow map of the different regimes can be identified.

The flow map relevant to the conditions investigated in this work is shown in Fig.2, where the Froude number, Fr; [3] is defined as:

$$Fr=\frac{DN^2}{g}\left(\frac{\rho_{water}}{\rho_{water}-\rho_{oil}}\right)^{0.42}\left(\frac{D}{T}\right)^{3.65}.$$

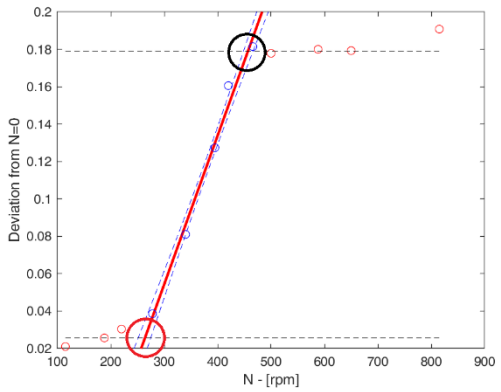

Figure 1. Experimental data and identification of the drawdown and completely dispersed impeller speeds.

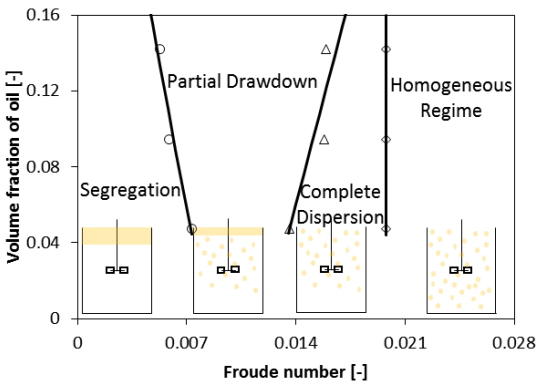

Figure 2. Flow map for the diesel fuel-water system.

4. Conclusions

A novel method is proposed for obtaining the flow map of immiscible liquid-liquid systems in stirred tanks based on the collection and a suitable analysis of ERT data. The method can be easily applied to any vessel size and liquid volume fraction, thus providing a useful guideline for the selection of the operating conditions of stirred vessels.

Euler-Euler Simulation of Bubbly Flow in Stirred Tanks

Roland Rzehak[1], Pengyu Shi[1,2]

1 Helmholtz-Zentrum Dresden – Rossendorf, Institute of Fluid Dynamics, Bautzner Landstrasse 400, D-01328 Dresden, Germany;
2 Technische Universität Dresden, Faculty of Mechanical Engineering, Institute of Power Engineering, D-01062 Dresden, Germany

Highlights

- A previously established baseline model for bubbly flow is applied to stirred tanks.
- One extension found necessary is the use of a Reynolds stress turbulence model.
- A second one is a correction factor to describe turbulence effects on drag.
- Good agreement is found for a comprehensive dataset from different literature sources.

1. Introduction

Aerated stirred tanks are frequently used equipment in industries ranging from chemical engineering and biotechnology to minerals processing. In principle, CFD simulation of such equipment on industrial scales is feasible within the Euler-Euler framework of interpenetrating continua. Practical application, however, requires suitable closure models to account for phenomena on the scale of individual bubbles, which are not resolved in this approach. Validation of such models is the purpose of the present contribution.

2. Methods

Starting point for the investigation is a baseline closure model that has previously been used in a large number of CFD studies on bubbly pipe flows and flow in bubble columns [1]. The model comprises drag, lift, wall, virtual mass and turbulent dispersion forces. Previous work from other researchers has shown that due to the high levels of turbulence in stirred tanks, a modification of the drag force is required [2], which is included in the present simulations. For the liquid turbulence an isotropic k-ω SST model has been adopted in the baseline model, however, it turned out that only rather poor agreement with experimental could be achieved for stirred tanks. To overcome this, two common variants of anisotropic Reynolds stress models are applied due to Launder, Reece, and Rodi (LRR, [3]) and Speziale, Sarkar, and Gatski (SSG, [4]). Correspondingly, anisotropic source terms modeling the bubble-induced turbulence are used [5].

3. Results and discussion

To validate the model, a database is accumulated from different literature sources, which comprises measurements of gas fractions and average velocities data relating to fluctuating velocities such as turbulent kinetic energy or Reynolds stress. In addition, information on the bubble size is needed, which appears in virtually all sub-models. For the present purpose the

average value suffices since only monodisperse simulations will be performed. Extensive study of numerical parameters has been undertaken such as grid-size, time-step and location of the boundary between rotating and fixed domains. Comparison between simulation and experiment for singlephase flows shows that mean velocities are captured well by the Reynolds stress models but turbulent fluctuations tend to be somewhat underpredicted. For the multiphase flows, the peak in radial mean velocities is underpredicted by the turbulence k-ω SST model (Figure 1a), which neglects the anisotropic effects, and the axial component of mean gas velocity is too small if the turbulent modification of the drag force is omitted (Figure 1b). If both effects are taken into account, similar agreement is obtained between simulation and experiment as for the singlephase flows. A detailed account of the results has been given in [6].

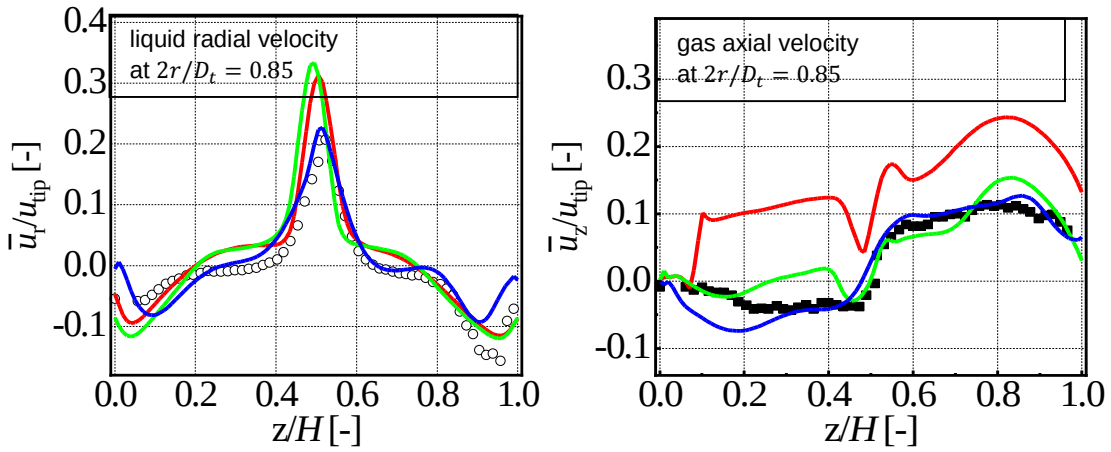

Figure 1. Comparison between simulations using different models (red: k-ω SST model without drag correction, green: k-ω SST model with drag correction, blue: SSG model with drag correction) and experiments (symbols) from [7].

4. Conclusions

With the modification factor for the drag force due to [2] and a Reynolds stress model with anisotropic source terms modeling the bubble-induced turbulence [6] reasonable agreement with the experimental data can be achieved. A slight preference for the SSG over the LRR turbulence model is identified. Concerning further model development, improvement of the BIT modeling appears most promising to improve the model predictions. The development of better models should be accompanied by the acquisition of improved experimental data for model validation. In particular the availability of mean liquid and gas velocities, turbulent fluctuations and gas fractions for the same configuration would be very beneficial to interpret the simulation results.

Investigation of reactive mass transfer processes at single rising gas bubbles by means of Time-Resolved Scanning Laser-Induced Fluorescence

Felix Kexel, Sven Kastens, Jens Timmermann, Marko Hoffmann, Alexandra von Kameke, Michael Schlüter

1 Hamburg University of Technology, Institute of Multiphase Flows, Eissendorfer Str. 38, 21073 Hamburg, Germany;

Highlights

- O_2 mass transfer
- 3D wake structure
- Time Resolved Scanning Laser Induced Fluorescence (TRSLIF)

1. Introduction

The mass transfer from a gaseous, dispersed phase into the surrounding liquid phase is a major task for chemical industry as well as for bio-, food- or environmental engineering. Nevertheless a reliable and exact design of multiphase reactors is one of the unsolved challenges in process engineering, since local mass transfer process could not be easily investigated within dense bubble swarms.

Therefore the empirical and semi-empirical correlations like for the dimensionless Sherwood number

$$Sh = 2 + C_1 Re^a Sc^b \quad (1)$$

based on integrally measured data, like Sauter bubble diameter, bubble rise velocity (Reynolds number Re) and the material system with liquid viscosity ν and diffusion coefficient of the gaseous species D (Schmidt number Sc) (Brauer, 1979). In contrast to these assumptions, today the dispersed gas phase is more and more considered as individual gas bubbles with local mixing elements and a major contribution to meso mixing in multiphase flows.

To gain a deeper knowledge of local mass transfer phenomena in bubbly flows the planar laser induced fluorescence (p-LIF) technique was widely and successfully used in different experimental arrangements, which was recently reviewed by Rüttinger (Rüttinger et al., 2018). Nevertheless, the applicability of this technique is limited to an accurate and reproducible bubble rise. Due to this limitation, the accurate investigation of 3D mass transfer processes close to deforming fluidic boundary layers at free rising bubbles is a challenging task. The Time Resolved Scanning Laser-Induced Fluorescence (TRS-LIF) enables such deeper insights into local processes in bubbly flows.

2. Methods

The basic setup has already been used in a slightly different configuration by Timmermann (Timmermann et al. 2017, Kastens et al. 2018). As measuring technique, the TRS-LIF is used. A scheme of top view of the setup for TRS-LIF, based on the work of (Soodt et al., 2012), is shown in Fig. 1, left. In contrast to the investigation with p-LIF, the laser sheet is reflected from a rotating

polygon (20 or 38 faces) into the volume of interest. With a precise synchronization of rotational speed and laser pulse emission, light sheets with reproducible deflection could be observed and parallelized by a cylindrical lens to obtain equidistant spacing. By variation of the laser pulse rate, polygon rotational speed and the number of pulses per polygon mirror, the generated light stacks are adjustable to the experimental scales, like bubble rise velocity and rise trajectory expansion. It should be noted, that the parameters are interlinked, where a higher sheet number reduces the maximum achievable volume scan rate, limited by the maximum rotational speed of the polygon of 10,000 rpm and the maximum pulse rate of the laser of 20,000 Hz.

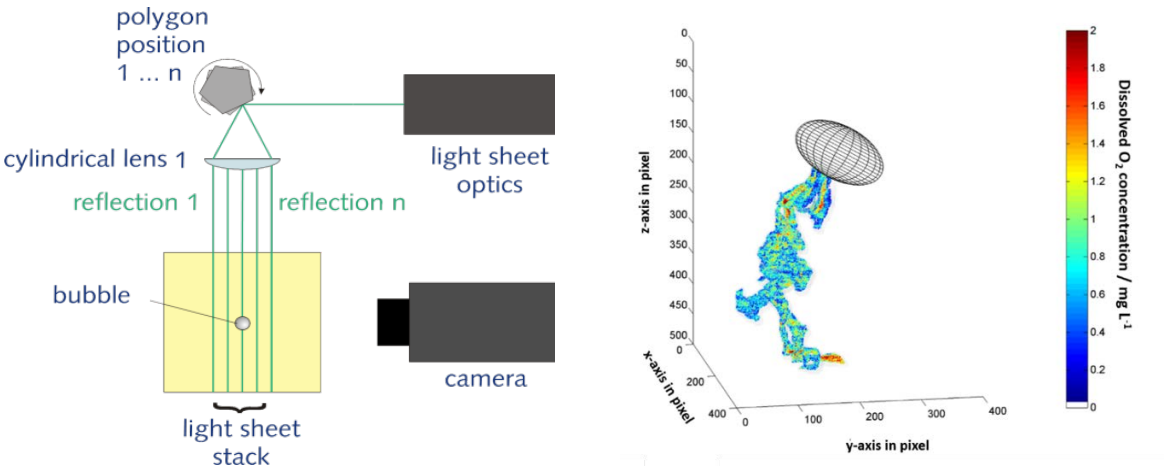

Figure 1. left: Schematic top view of the experimental setup for Time-Resolved Scanning LIF, **right:** 3D reconstruction of the oxygen concentration field within the wake of a free rising wobbling bubble (Timmermann, 2018).

Upgrading the number of faces on the polygon is a key parameter to optimize the temporal and/or spatial resolution for the realization of nearly instantaneous 3D scans.

3. Results and discussion

Fig. 1, right shows an example of the reconstructed wake structure behind a rising ellipsoidal O_2 bubble. Experiments are obtained at 20°C and atmospheric pressure. The two-dimensional images have been recorded with a frequency of approx. 15,000 fps. This leads to a volume scan rate of 335 Hz for one entire stack. The reconstructed 3D dissolved O_2 concentration within the wake structure shown in Fig. 1, is calculated by using calibration equations for each plane, allowing the determination of the concentration with uncertainties lower than 1 ppm. The mixing within the wake structure is in focus, where vortices with an enriched oxygen concentration are mixed with the bulk phase. The vortex shedding and mixing intensity depends on bubble shape and fluid properties, which are varied in this work. Moreover, a more precise analyzing method using online and parallel oxygen concentration calibration in the reaction vessel. Combined with analyzing each pixel within a plane the uncertainties are decreased below 0.2 ppm.

4. Conclusions

By investigating parallel-consecutive chemical reactions it is expected, that the times-scales of mass transfer and mixing will influence the local yield and selectivity within the bubble wake. With the TRS-LIF method a measurement system has been developed and successfully applied, that allows the analyzation of instantaneous 3D concentration fields within the wake of free rising bubbles. This method enables more detailed information about the influence of local hydrodynamic conditions in gas-liquid flows on yield and selectivity, which will be clarified in near future.

Highlights

- CFD workflow to compute Pe in small size fixed beds using DEM and OpenFOAM
- Accurate prediction of Pe numbers using first two moments of age distribution
- Local Pe depends on local structural features
- CFD prediction allows to study small trends without experimental errors

1. Introduction

Over the decades, fixed bed reactors for catalyst testing have faced a reduction in size and now they commonly have diameters below 1 cm, the limit being the catalyst pellet size (~1-3 mm). The advantages of these reactors are numerous: less catalyst used, less amount of reactant used and of wastes produced, better temperature control, reduced safety risks and easier implementation of parallel reactor systems [1]. Those reactors were designed for catalyst screening, so that hydrodynamics was not really an issue as long as the ranking and uncertainty were correct. As those reactors produce a large amount of data, a new question arises: can we use those results to build models for catalyst performance prediction? This work aims at improving our understanding of the hydrodynamics of these small reactors using CFD tools.

2. Methods

The work is based on a workflow mimicking the real usage of fixed bed reactors. In a first step, we pack spherical particles in cylindrical reactors using a Discrete Element Method package (Grains3D [2], Figure 1). Then we compute the steady state hydrodynamics in those reactors using the `simpleFoam` solver (Figure 1) from the OpenFOAM suite [3] augmented with the simulation of the moments of age distribution [4]. The outputs of the simulation are the mass flux weighted averages of the first and second order moments of age in many cross-sections of the reactors. Using the classical formula, we then compute the Peclet number (Pe) for any sub-volume in the reactor as:

$$Pe = 2\,\frac{\tau^2}{\sigma^2} = 2\,\frac{(m_{1,outlet} - m_{1,inlet})}{(m_{2,outlet} - m_{1,outlet}^2) - (m_{2,inlet} - m_{1,inlet}^2)}$$

Simulations have carried out for a common cylindrical reactor of 7.75 mm diameter and 187 mm long packed with spheres of 2 to 7 mm in diameter. Two layers, with 3mm thickness each, and free of particles, have been added at the top and bottom sides of the packing, respectively, to facilitate the numerical simulation of flow conditions near the inlet and outlet regions.

3. Results and discussion

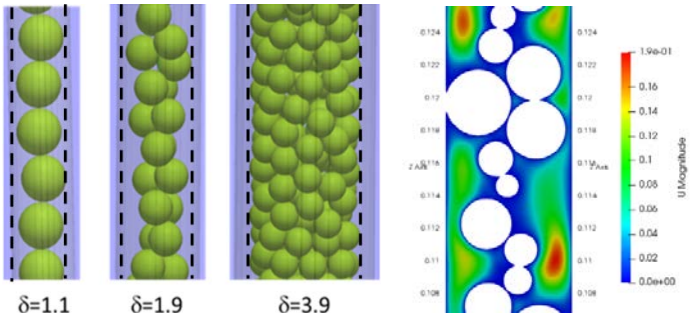

Figure 1: Left: Examples of packing, $\delta = D/d_p$, - Right : Velocity magnitude in a reactor cut (d_p = 4 mm)

The CFD results match very well experimental data based on RTD [5] (Figure 2 - left). Local packing structures have a staircase impact on local Pe evolutions (Figure 2 - middle). The effect of molecular diffusion on Bodenstein number (Bo =Pe d_p/L) matches the literature [6] in the global shape and effect of Schmidt number (Figure 2 - right).

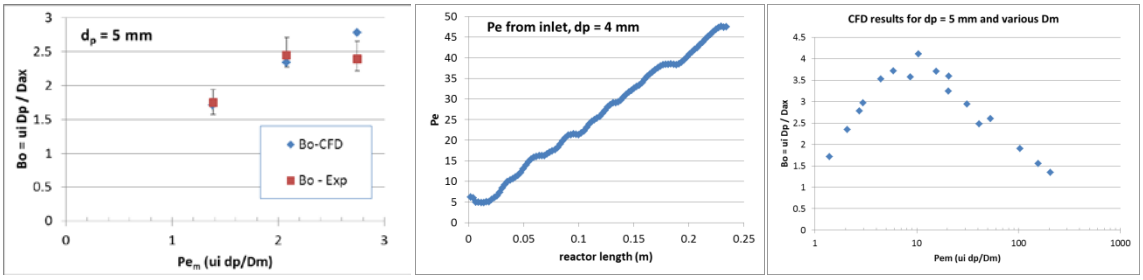

Figure 2: Left: Comparison experiments / CFD – Middle: plot of the evolution of Pe from inlet – Right: parametric study on velocity and molecular diffusion.

4. Conclusions

Our simulation workflow matches very well the experimental data and will be used to study precisely the effects of molecular diffusion, inlet velocity and reactor-to-particle diameter ratio on the plug flow behavior of fixed beds. We also plan to study the randomness effects on the results when the packings are repeated.

Highlights

- Liquid phase reaction
- Mass transfer enhancement
- Bubble fluid dynamic

1. Introduction

The design of gas liquid reaction is still a challenging task. In addition to the reaction itself, the fluid dynamics of the phases and thus the changed mass transfer conditions must also be taken into account. Occurring processes are not completely understood yet. To be able to describe a complex gas liquid, the DFG Priority Program 1740 "Reactive Bubbly Flows" SPP1740 focuses on different substance systems and scales. In this project the complexity is reduced by first analyzing single bubbles with a high spatial and temporal resolution.

2. Methods

The experimental setup built in this project can be seen in Figure 1. The main part is a 2 m long glass tube, in which a single bubble can rise freely through a stagnant fluid. [1]

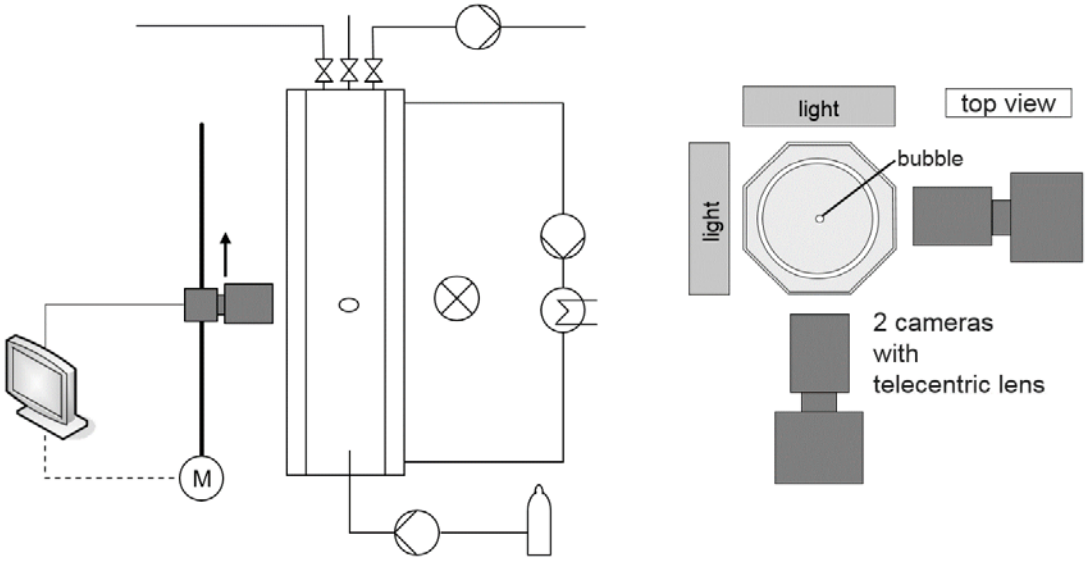

Figure 1. Experimental setup: schematic sketch (left), single bubble rises in a temperature-controlled glass tube (h = 2m) observed with high-speed cameras; Cross section of the system (right)

The temperature is controlled with an acrylic glass jacket that also provides a better optical access. The bubble is tracked with two high-speed cameras, which are moved along with the rising bubble. It is possible to perform experiments under a protective atmosphere. Apart from the solution of carbon dioxide (CO_2) in water/$NaOH_{aq}$, experiments with different iron complexes reacting with nitric oxide (NO) as the gas phase were carried out. The choice of ligand influences the reaction rate of the system.

3. Results and discussion

Figure 2 shows a nitric oxide bubble in an iron sulfate edta solution ($FeII(edta)_{aq}$). The product is colored and can be detected in the wake of the bubble. The two images were taken at the same time by the two cameras with an offset of 90°. The size, shape and 3D rising path can be resolved with a high temporal and spatial resolution.

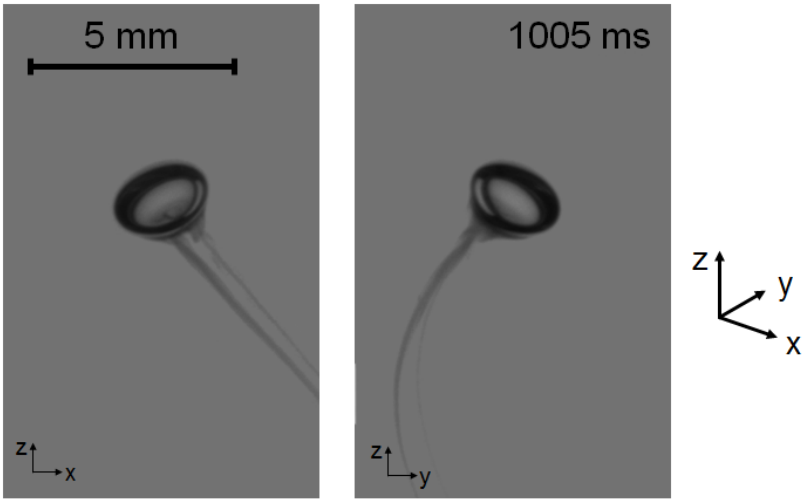

Figure 2. nitric oxide (NO) bubble in $FeII(edta)_{aq}$ with a concentration of 75 mmol/l, view from the two cameras simultaneous

The changing fluid dynamics of the dissolving bubble can be tracked. Different initial diameters were investigated. Various ligands have an influence on the reaction rate, as well as on the shape and fluid dynamics.

4. Conclusions

It is possible to measure the volume change and thus evaluate the mass transfer of a bubble depending on the contact time. Due to the detailed measurements, enhancement factors can be measured depending on the ligand and educt concentration.

Influence of microbubble aeration on hydrodynamics and mass transfer in a lab scaled Stirred Tank Reactor

Simon Matthes[1], Benjamin Thomas[2], Paul Bubenheim[2], Andreas Liese[2], Koichi Terasaka[3], Michael Schlüter[1]

Highlights

- Mass transfer measurements for microbubble aerated systems.
- Comparison of microbubble aeration and conventional aeration.
- Determination of the influence of BSD on the performance of gas-liquid systems.

1. Introduction

Many chemical and biocatalytic reactions are consuming gaseous species like oxygen, provided by the mass transfer across interfaces of multiphase contact apparatuses. In large-scale processes the gas is often supplied to the liquid bulk phase by bubble aeration. Especially for biocatalytic reactions the macroscopic aeration can lead to reduced enzyme activity by foaming and induced shear forces. For fast chemical reactions in multiphase flows, the mass transfer limitation is often the bottleneck for a process optimization and becomes “a critical factor in equipment sizing” [2]. Considering bubbles with diameters less than 100 µm, large volume-specific interfacial areas a and therefore high mass transfer rates $k_L a$ of the gaseous reactant on its way to the bulk phase are offered. In addition the high Laplace pressure at that size is leading to an acceleration of the mass transfer. Compared to large-scale bubble aeration, the potential of using bubbles with diameters smaller than 100 µm is less explored so far.

At that point this project starts investigating the aeration with fine bubbles, due to the rising demand in process engineering for aeration with high mass transfer performance, low pressure drop, low shear stress and the avoidance of foaming.

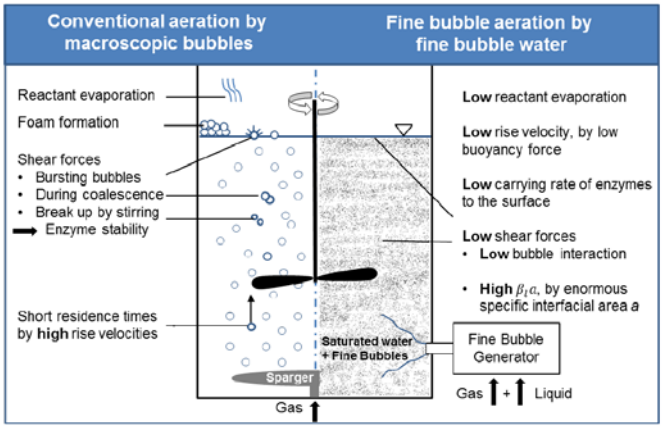

Figure 1. Comparison between conventional aeration and fine bubble aeration in biocatalytic processes in a STR.

Furthermore, the rise velocity of a bubble decreases with decreasing bubble diameter leading to higher residence time and low induced shear stress. To determine the potential of fine bubbles for biocatalytic processes, the promising properties of fine bubble aeration compared to conventional aeration (as shown in figure 1) is under investigation in close collaboration with the Institute of Technical Biocatalysis (ITB) at the Hamburg University of Technology and Prof. Koichi Terasaka from Keio University, Japan.

2. Methods and results

To quantify the influence of fine bubble aeration on the hydrodynamics and the mass transfer, measurements of the bubble size distribution (BSD) and the mass transfer rates from oxygen into the liquid phase are executed in a 3 L stirred tank reactor. The BSD is measured near by the stirrer using an endoscopic probe by SOPAT GmbH. The effect of different stirring speeds and gas flow rates are determined for the reference system deionized water/ air and the two aqueous solutions of glucose (133 mmol/L), with and without 67 mg/L bovine serum albumin (BSA), and rhododendrol (10 mmol/L) as bioactalytic model systems which are also aerated with air. All investigations took place in a turbulent state at stirrer speeds of 400, 600 and 800 rpm and gas flow rates from 25 mL/min up to 100 mL/min. Different fine bubble generators working under the principle of the pressurized dissolution and the spiral liquid flow method are used [1]. The microbubble aeration is compared with conventional aeration by membranes of pore sizes from 0.5 µm up to 2 µm regarding their performance and influence on the liquid systems. A well mixing of the system and therefore a homogeneous distribution of the bubbles is assumed. Figure 2 shows the BSD for the 2 µm membrane and its mass transfer performance.

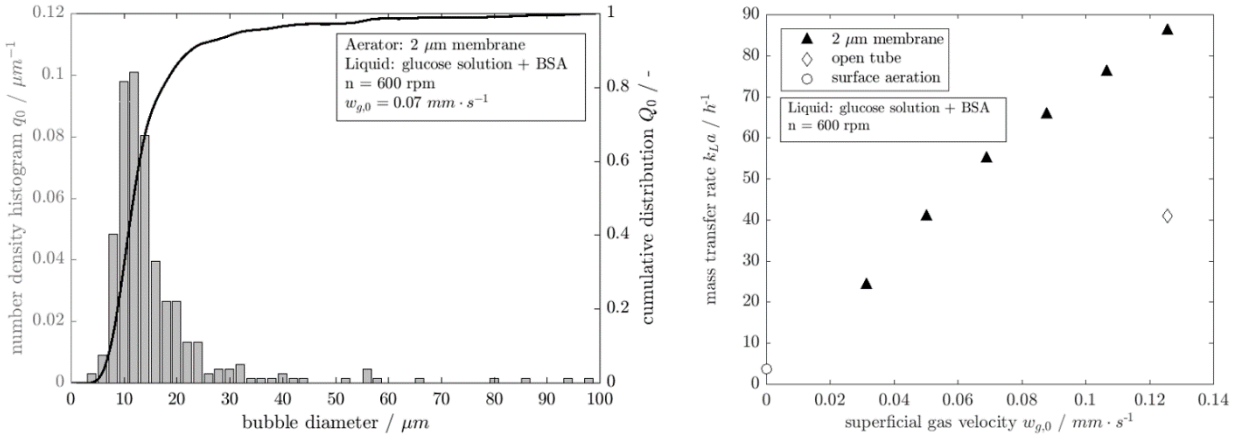

Figure 2. Bubble size distribution measured via SOPAT-VI Pl (left) and mass transfer rates for different gas flow rates for a sinterstone with a pore size of 2 µm producing microbubbles (right).

Fine and ultrafine particle deposition in packed-bed catalytic reactors

Gianluca Boccardo[1], Rajandrea Sethi[2], Daniele Marchisio[1]

Highlights

- CFD simulations of fine filtration in packed beds are performed
- In-silico generated random packings are used to successfully represent packed beds.
- Polydisperse particles are considered: results very different from theoretical predictions.

1. Introduction

In this work (whose main results were recently accepted for publication [1]) we have performed an extensive CFD simulation campaign studying particle transport and deposition in different catalytic systems and under different conditions. Two types of geometric models representing different porous media were created. The first is a number of random packings of spheres created via rigid body simulations: this approach was tested and validated in previous studies [3]. The second is a regular arrangement of spheres, which was also successfully employed in previous works to study fine particles dispersion. Using these random packings, simulations of particle deposition have been performed at different operating conditions. In the first part we calculated values of particle deposition efficiency and compared our results with the classical filtration theory, highlighting the issues in the use of the simplified models upon which the theory is based. In the second part we have studied the effect of polydisperse particle populations: this is also missing in the classical filtration theory, which always considers the transport of particles with uniform diameter. Thus, we have performed population balance modelling simulations for particle deposition, employing the quadrature method of moments (QMOM) [2]. Even more clearly in this case, the results show that the description of polydisperse populations has a very noticeable effect on the macro-scale description, which would dramatically improve the understanding of particle transport and deposition in filtration and catalytic processes.

2. Methods

The first step in this study is the creation of the random packing geometry: this was done via rigid-body simulations using the open-source code Blender, following a procedure described in detail in a previous published work [3]. Then, CFD simulations of fluid flow and particle transport simulations were performed, using the open-source CFD code OpenFOAM (version 4.0): a snapshot of a simulation can be seen in Fig. 1. The effect of gravitational settling was considered by the addition of the particles settling velocity to the advective term of the transport equation. In each case (with and without gravitational settling), a new and improved constitutive equation for the prediction of filtration efficiency was proposed. Then, in the second part of the work, we solved the population balance equation in order to consider the evolution of the full population of particles (expressed in terms of distribution of particle diameter).

3. Results and discussion

Simulation results were expressed in terms of particle filtration efficiency, extracted from the ratio between outlet and inlet particle concentration. Both in the case of normal diffusion, and when the gravitational effect is added, the newly proposed constitutive equation for filtration efficiency is very different from the theoretical expectation [1].

Also, when the population balance equation is solved, the resulting filtration efficiency for the polydisperse case as a function of the system Peclet number is quite different from both the CFD results for the monodisperse case and the theoretical laws, highlighting another point where the classical predictions can be improved upon, as it can be seen in Fig. 2.

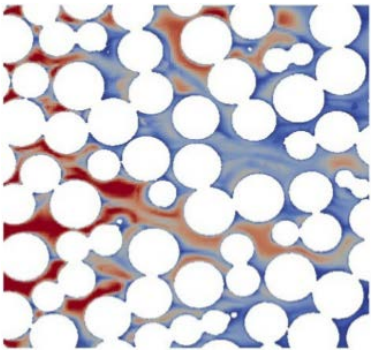

Figure 1. Contour plots of particle concentration in a median section of the domain.

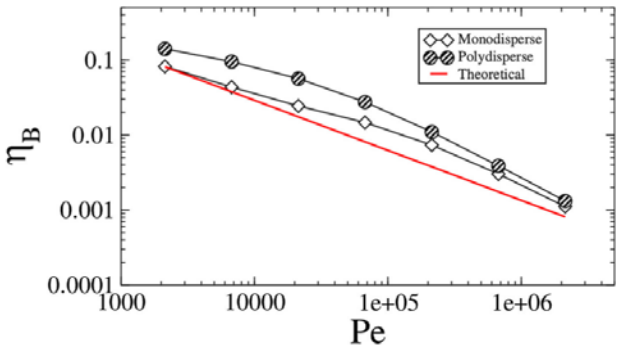

Figure 2. Contour plots of particle concentration in a median section of the domain.

4. Conclusions

This work employs an innovative technique for the generation of random packing, useful to represent a variety of random media, and specifically packed bed reactors, improving on the classical filtration theory, which is based on simplified models of arranged spherical collectors. Then, the main modelling advance of this work is presented, which is the description of the polydispersity of the particle population: this was done here via the solution of the population balance equation, solved by the quadrature method of moments. The results from these simulations show a marked difference with respect to the theoretical predictions and evidence the pitfalls of the simplified description valid for monodisperse populations, evidencing how the proposed model can greatly improve the description of particle transport and deposition in real filtration and catalytic processes.

Highlights

- Introduction of redistribution rings in a rotating packed bed reactor.
- Improved liquid distribution in angular and axial direction.
- Results show that angular maldistributions of up to 90° can be mitigated.

1. Introduction

Rotating packed beds (RPB) have been a promising technology for process intensification since their introduction [1][2], enabling increased gas-liquid mass transfer rates [3] due to the application of a centrifugal field. Although a significant amount of possible applications have been reported in literature [4], a major challenge in industrial application of the technology is the absence of proper design correlations leading to ineffective scale-up of the RPB. The effectiveness of gas-liquid mass transfer decreases with increasing radius [3], mainly due to severe maldistribution in the tangential direction at large radii [5][6]. In the current work, a novel design rotating packed bed reactor is proposed, which employs redistribution rings at regular radial intervals, similar to redistributor plates in conventional columns.

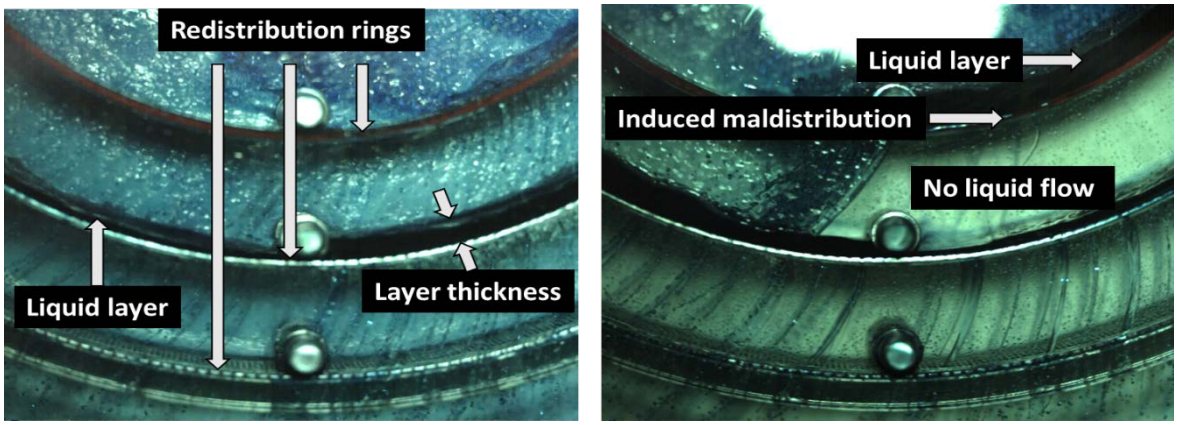

Figure 1. Experimental view of the water layer at a rotational speed of 1200 RPM and a liquid flow of 1000 L/h with (A) no induced maldistribution and with (B) a 90° induced maldistribution.

2. Methods

Perforated rings are placed at regular intervals inside the bed to redistribute the liquid both in angular and axial direction. This is shown in the top-down image in Figure 1A, where the liquid layer

accumulates against the ring and is subsequently redistributed. To further test the effectiveness of the redistribution rings a maldistribution was induced in the inner of the three rings and the effect of the liquid distribution in the other two rings was analyzed. An example of an induced maldistribution of 90° can be found in figure 1B.

3. Results and discussion

The mean and deviation of the liquid layer thickness in the middle ring are used to determine the effectiveness of the redistribution rings: the smaller the standard deviation, the more even the liquid is spread angularly, and consequently, the more uniform the liquid flow. An example of the results for an experiment with no maldistribution can be seen in Figure 2A, where the fitted normal distribution yields both the average liquid layer thickness (14.16 mm) and the standard deviation of this layer (1.10 mm). An induced maldistribution of 90° at the same process conditions yields the results as shown in Figure 2B. Without redistribution rings the results would show two peaks: one around 0 mm corresponding to the area behind the maldistribution and one at the average water layer. These results clearly show a single normal distribution with a slightly larger standard deviation as compared with the reactor without induced maldistribution.

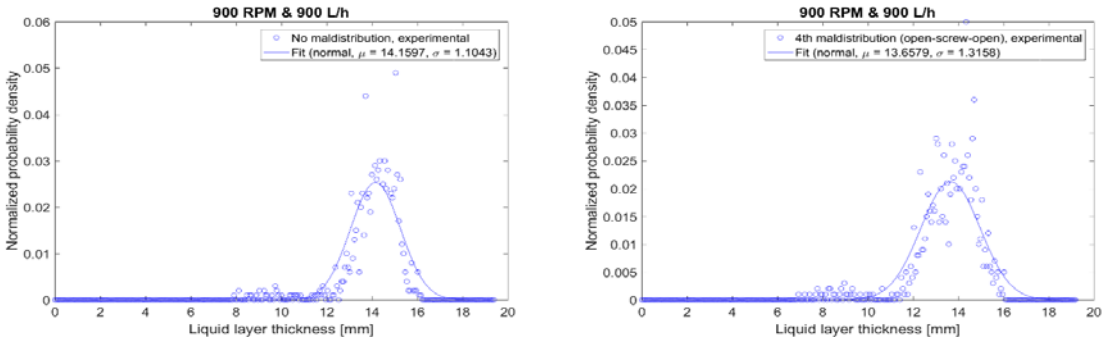

Figure 2. Results of the experiments at a rotational speed of 900 RPM and a liquid flow of 900 L/h for an experiment with (A) no induced maldistribution and with (B) an induced maldistribution of 90°.

4. Conclusions

The efficacy of the redistribution rings is demonstrated here without a packing present, mainly for visualization purposes. Experiments with a packing present have shown a similar behavior, indicating the redistribution rings can also be applied to actual rotating packed beds. It is therefore concluded that the redistribution rings improve the liquid distribution over the entire radial length of the packed bed, which in turn results in a more efficient use of the packing and a higher overall gas liquid mass transfer rate. Therefore, the novel design is a promising tool in enabling a more efficient scale-up of rotating packed beds.

Numerical prediction of a turbulent diffusion flame by rhoReactingFoam.

Esteban Maya[1], Jairo Valdés[1], Alexander Ladino[1*], Omar López[2]

1 School of Mechanical Engineering, Universidad del Valle, Calle 13, No. 100-00, Cali 760032, Colombia

**Corresponding author: jair.ladino@correounivalle.edu.co*

Highlights

- Density-based solver *rhoReactingFoam* was validated against experimental and computational data.
- Flame prediction performed via RANS, one step global reaction and PaSR as combustion model
- Four single step global reactions evaluated.
- *rhoReactingFoam* provides good agreement with available data for the reaction kinetics considered
- *rhoReactingFoam* is capable to predict small diffusion flames at low-moderate Re.

1. Introduction

One of the most basic structure in combustion is a flame, widely used as heating mechanism in industry equipment like boilers and furnaces. However, even for the simplest geometries, its nature of turbulent combustion and flame instability downstream represents a complex process cannot be treated analytically but numerical models widely validated with experimental data.

In this work, experimental data from the literature of SANDIA D flame [1] was used to validate the numerical model of density-based thermodynamics package compressible reacting flow solver *rhoReactingFoam*, implemented in OpenFOAM package. Numerical model implemented involves Reynolds Averaged Navier-Stokes equations and k-ε for turbulence modeling, Partially Stirred reactor (PaSR) for chemistry-turbulence interaction with a single-step global reaction considered [2]. Finally, the *rhoReactingFoam* results for flame temperature and species were compared with experimental data [1] and previous computational studies widely developed by Lysenko and given in [3].

2. Methods

The Sandia flame D [1], is a piloted free non-premixed methane-air burner in which the flame is established between an internal flow of fuel and an external flow of a lean mixture of methane and air. The Main fuel jet is composed of 25% methane and 75% air by volume with a Reynolds number at the burner exit of 22400. The pilot is a lean mixture ($\varphi = 0.77$) of methane and air.

Numerical implementation in *rhoReactingFoam* involves an axisymmetric domain, spatial discretization of first/second order TVD schemes for advection and second order central differences for diffusion terms. Also, a stabilized local time-step (STLS) and Rosenbrook23 schemes for temporal

discretization were employed for transport equations and species reaction rates respectively. Convergence criteria were 10^{-6} and 10^{-10} for transport quantities and reaction rate respectively.

3. Results and discussion

The Figure 1 shows results for mean temperature and methane mass fractions at flame centerline of this study for the global reaction that best fits the experimental data given [1] and also the results given by Lysenko in [3] which used the Eddy Dissipation Concept (EDC) as chemistry-turbulence interaction, one-step global reaction mechanism and Large Eddy Simulation (LES) for turbulence modelling. Results show that *rhoReactingFoam* reproduces the dynamics of the flame as [3], but in reasonable agreement with the experimental data due to the restriction of the limited reaction kinetics simulated which involves only a one step global reaction.

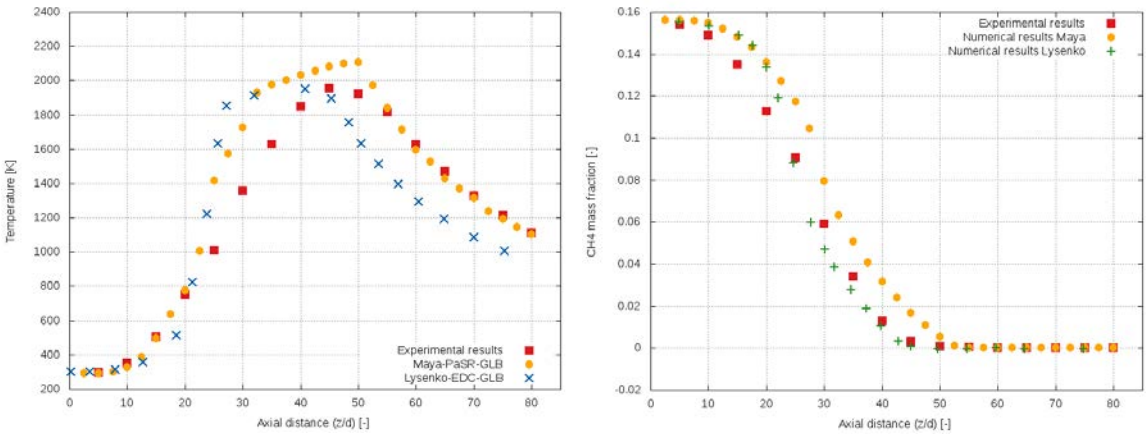

Figure 1. Mean flame temperature (left), and methane mass fraction (right) at centerline. This study: One step global reaction A=6.7x10^{12}, E_a=48.4, a=0.2, b=1.3. See Table II [2].

4. Conclusions

Overall agreement between the simulated results, computational ones from [3] and the experimental data given [1], validate the *rhoReactingFoam* solver for small methane diffusion flames. The coupling of RANS k-ε, PaSR model with single-step reaction demonstrates to provide reliable results as same as [3] for axial temperature with some over prediction of peak temperature but with better performance at flame positions downstream from that point. Also, the most relevant discrepancy is the reactant mixing prediction mainly due to turbulence formulation but in agreement with other studies and solvers. Finally, further research involves the validation and testing of *rhoReactingFoam* with GRI detailed chemistry.

UV/Vis Computed Tomography based 3D Concentration Measurement in Bubble Columns

Jajnabalkya Guhathakurta[1], Günter Rinke[2], Manfred Kraut[2], Sven Simon[1]

1 Institute for Parallel and Distributed Systems (IPVS), Department of Parallel Systems, Universitätsstr. 38, 70569 Stuttgart; 2 Institute for Micro Process Engineering (IMVT), Karlsruhe Institute of Technology, Hermann-von-Helmholtz-Platz 1, 76344 Eggenstein-Leopoldshafen, Germany

**Corresponding author: jajnabalkya.guhathakurta@ipvs.uni-stuttgart.de*

Highlights

- In-situ concentration measurement in bubble columns.
- Measurement based on UV/VIS computed tomography.
- High spatial and temporal resolution.
- Selectivity measurement for Fe(edta)NO system.

1. Introduction

Bubble columns play a crucial role in the chemical industry for two phase systems and are primarily relevant for reactions like oxidation, hydrogenation, alkylation etc. However, a realistic description and prediction of the reaction kinetics and mass transfer are still a major bottleneck in industrially relevant reactive bubble columns. Furthermore, localized concentration measurement are difficult to achieve due to the fast reactions and reduced access. This work aims at developing a spatially and temporally resolved 3D concentration measurement technique in reactive bubble columns using UV/Vis computed tomography.

Another important challenge for chemical and process engineers is determining the selectivity in a two phase reaction system. This is considered as a primary design goal in our measurement technique. The system utilizes multiple wavelengths and fast switching light sources to simultaneously and separately measure the concentration of both the products in a competitive consecutive reaction and deduce the selectivity of the reaction from it.

2. Experimental Setup

The developed UV/Vis computed tomography system accumulates absorption projections from different angles around the bubble column (Blue circle in Fig. 1 middle). These directional absorption projections are then fed into an iterative reconstruction algorithm to obtain a 2D concentration field perpendicular to the direction of flow. The measurement technique can be applied to any chemical system having distinct peak for products in the absorption spectrum e.g. Fe(edta)NO system represented by the spectrum in Fig 1 (left). In this system one wavelength (472 nm) is used for measuring the first product P, another wavelength (696 nm) is used for measuring the consecutive product S and a reference wavelength (540 nm) is used at the isosbestic point. Projection data from all the wavelengths are captured within 1 ms and the process is repeated to get high temporal resolution of the 2D concentration field one after the other.

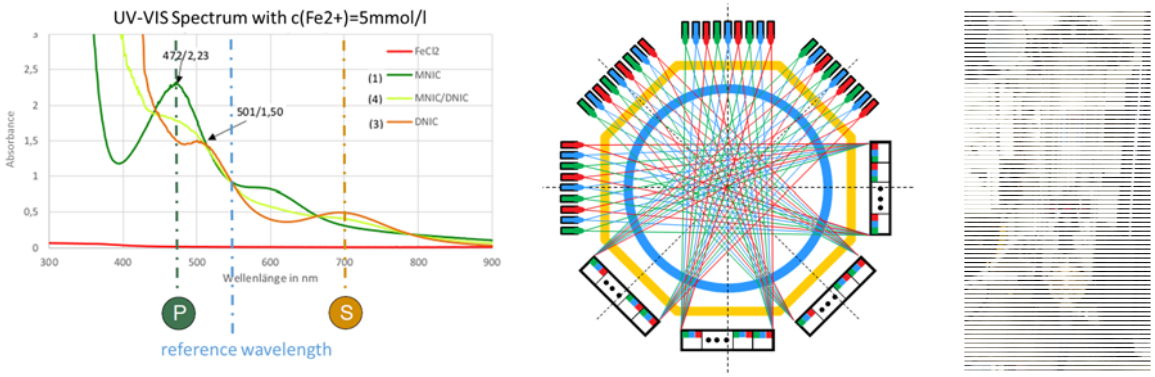

Figure 1. (left) UV/Vis spectrum for Fe(EDTA)NO system [1], (middle) cross section of 75mm diameter bubble column with octagonal refractive index matching mantle showing directional projections, (right) actual bubble column

3. Results and discussion

The setup was optically simulated with Zeemax ray tracing software in order to verify the setup (Fig. 2 left). A collimated laser beam directed by a polygon scanner meets a micro cylindrical lens array which generates the fan beam that is made to travel through the bubble column. The absorption of this fan beam is captured by line sensors on the other end to get the directional projection of the corresponding product. These projections are fed to an iterative reconstruction algorithm uses total variation which performs the best in case of extremely low number of projections as needed by our setup. The functionality of algorithm is verified in simulation where a simulated concentration field in a bubble column is used and the reconstructed field is compared with the original data (Fig 2. right). It can be seen from the cross section that the reconstructed data plot (orange) approximately follows the original data.

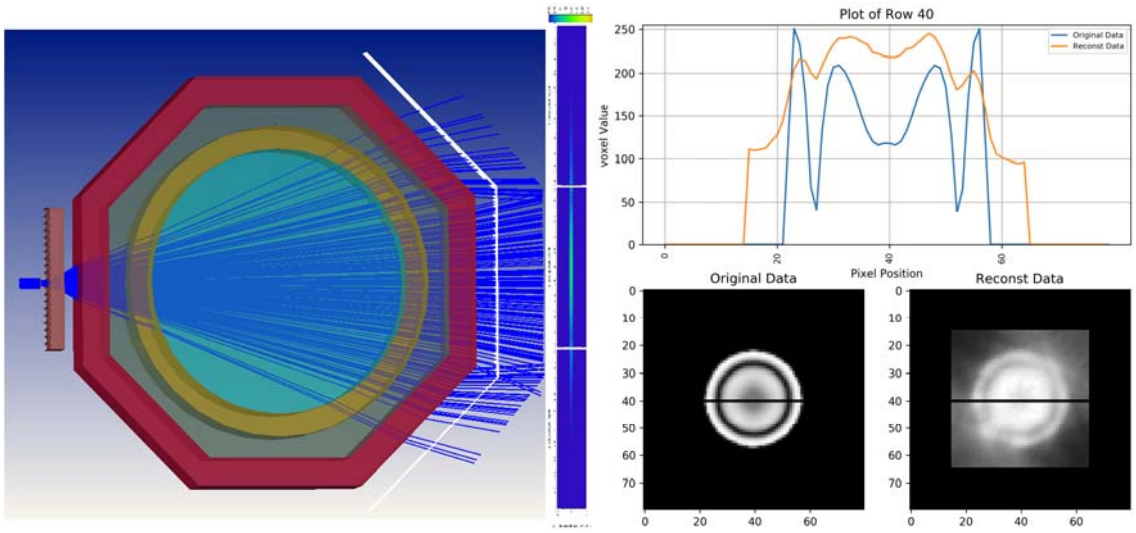

Figure 2. (left) Zeemax ray tracing simulation for each projection [1], (middle) Reconstructed concentration field on simulation data in bubble columns.

4. Conclusions

A novel technique to measure 3D concentrations in bubble columns has been proposed in this work based on UV/Vis computed tomography. The experimental setup along with the iterative reconstruction results and simulations have been presented. Obviously the reconstructed CT data correspond to the ground truth sufficiently with respect to the considered cases.

The Challenge of Continuous Multiphase Flow For Heterogeneously Catalyzed Reactions with Liquid-Liquid Extraction.

Annika Grafschafter[1*], Matthäus Siebenhofer[1]

1 Graz University of Technology, Institute of Chemical Engineering and Environmental Technology, Inffeldgasse 25C/II, 8010 Graz, Austria

**a.grafschafter@tugraz.at*

Highlights

- Successfully implemented continuous multiphase flow.
- Heterogeneously catalyzed reactions with liquid-liquid extraction.
- Hydrodynamic investigation.

1. Introduction

The economic isolation of constituents from dilute aqueous effluents, as can arise in downstream processing of the biobased industry, may be achieved by the combination of reactive separations (e.g. esterification) with liquid-liquid extraction. By simultaneous extraction of the target product with a suitable solvent, equilibrium composition will shift and conversion can be enhanced. Slow chemical reactions, such as esterification reactions, require catalytic acceleration. For continuous operation, heterogeneous catalysts are very suitable since they are simple to separate via sedimentation. The implementation of continuous heterogeneously catalysed reactions combined with liquid-liquid extraction requires adequate apparatus design. Although different equipment is available on the market, equipment design and optimization is still a challenge, especially when targeting continuous multiphase flow. The Taylor-Couette Disc Contactor (TCDC) [1], a hybrid of the Rotating Disc Contactor (RDC) and the Taylor-Couette Reactor (TCR) satisfies the requirements for intensive continuous multiphase operation. The design of internals provides flexible operation under harsh operation conditions. The design is similar to the RDC, but with increased shaft diameter and without stator rings, whereby dead zones for accumulation of solid catalysts can be avoided. At convenient operation conditions, the shaft and rotor discs of the TCDC induce banded flow pattern, providing appropriate mixing of the liquid phases and the solid phase, and providing sufficient residence time for the solid catalysts.

2. Methods

Continuous liquid-liquid-solid flow has been implemented in a TCDC with 50 mm column diameter and 700 mm active mixing height. For the hydrodynamic investigation, ShellSol-T was used as solvent phase, deionized water as continuous phase and Amberlyst15® as solid phase. The hydrodynamic parameters dispersed phase holdup, solid phase holdup, mean droplet size as well as the on-set behavior of appropriate three phase operation have been investigated for varying rate of rotation (0 – 1100 rpm), hydraulic load (5-15 $m^3\ m^{-2}h^{-1}$) and mass load of the catalyst. Since the

continuous phase of this system is the driving force for appropriate mixing behavior, single phase CFD simulations of the continuous phase were conducted and evaluated.

3. Results and discussion

Beyond a critical rotational speed, the vorticity of the continuous phase overcomes sedimentation force of the dispersed phase and the solid phase and ensure intensive phase contact in the single compartment. The solid phase is dragged by the toroidal vortexes, and even in the presence of the dispersed phase the catalyst particles remain within the single compartment for reasonable residence time. The catalyst can easily be separated at the bottom of the column by sedimentation. Via the Q-criterion (CFD simulations) the vortexes inside the TCDC column can be pictured and the vorticity can be evaluated. Figure 1 depicts the vorticity of the counterrotating vortexes at increasing rate of rotation and varying hydraulic load. The vorticity increase with increasing rate of rotation. The increase of the hydraulic load does (nearly) not affect the vorticity.

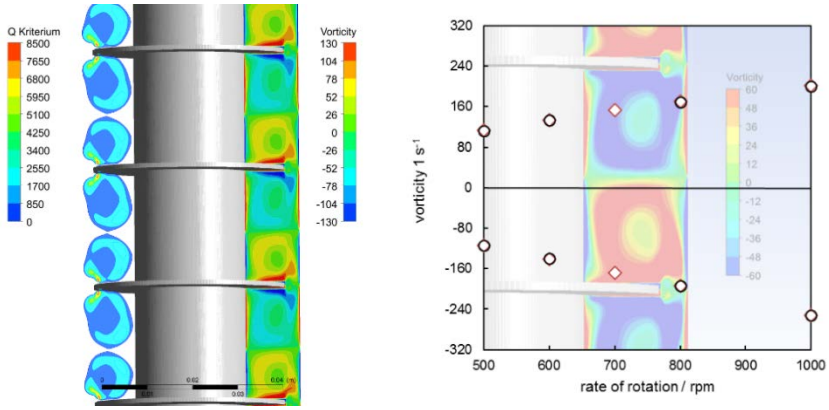

Figure 1. Q-Criterion and vorticity of the toroidal vortexes inside the compartment of a Taylor-Couette Disc Contactor.

4. Summary

The design principle of the TCDC offers intensive phase contact without hydrodynamic dead zones. Continuous multiphase flow was successfully implemented in the TCDC. Hydrodynamic investigations confirm applicability of this column design for intensifying heterogeneously catalyzed reactions combined with liquid-liquid extraction.

Highlights

- Gas solid RTD measurements in millipacked beds show a steep Pe increase for $D/d_p > 4$
- Insertion of fine inert powder in the bed porosity improves Pe, but the effect is not appreciable for very small reactor diameters (~2 mm)
- Reactive performances are improved by the use of inert powder

1. Introduction

Over the decades, fixed bed reactors for catalyst testing have faced a reduction in size and now they commonly have diameters below 1 cm, the limit being the catalyst pellet size (~1-3 mm). The advantages of these reactors are numerous: less catalyst used, less amount of reactant used and of wastes produced, better temperature control, reduced safety risks and easier implementation of parallel reactor systems [1-3]. Those reactors were designed for catalyst screening, so that hydrodynamics was not really an issue as long as the ranking and uncertainty were correct. As those reactors produce a large amount of data, a new question arises: can we use those results to build models for catalyst performance prediction? This work aims at improving our understanding of these small reactors. Do we need to use a hydrodynamic model? When is it interesting to use fine powder to fill the porosity between the catalyst pellets? The results of two experimental campaigns will be presented:

- Measurements of residence time distributions for gas-solid millireactors with reactor (D) to particle (d_p) diameter ratio less than 8, with and without porosity filler;
- Effect of packing on reactive performances.

2. G/S RTD measurements

2.1 Methods

RTD measurements are performed using the concentration step technique, with N_2 as carrier gas and He as tracer. The reactor and particle dimensions are varied between 1-7 mm. The particles are non-porous, in spherical or cylindrical form. The tests are performed with superficial velocities between 0.013-0.06 m/s. A 1D dispersion model is used in order to estimate the void fraction (ε) and the axial dispersion coefficient (D_{ax}) of the reactors.

2.2. Results and discussion

The results of the RTD studies show that, at constant flow rate, it is preferable to work under conditions of $\delta=D/Dp > 4$ (Figure 1). We relate this to the change from structured to random packing that occurs when increasing δ: structured packings offer more potential for channeling

than random beds. Provided that the bed is long enough, the Pe number is sufficient to consider the reactors as ideal (plug flow) for most applications. The addition of inert powder to lower the bed porosity improves the Pe number but the RTD shows an additional contribution. An explanation can be the presence of dead volumes in case of the use of a porosity filler. For very small reactor diameters (~2 mm), the improvement is no longer appreciable.

3. Effect of the packing on n-heptane reforming reaction

The effect of the packing is measured by comparing the conversion in reactors with different packings in a 8-parallel reactor system (Avantium FLOWRENCE). The reaction is the n-heptane reforming over chlorinated Pd/Alumina catalyst at 10 barg, T=450-500 °C with conversions in the range of 60-90%. The reactor internal diameters are 2 mm, and they are packed with cylindrical catalyst particles (d_p=1.6 mm). The parameters investigated are the fine powder size and type. N-heptane conversion increases when adding inert powder to the catalytic bed, with even better results for finer and rounder particles (Figure 1). As at this conversion levels the reactor is always ideal, this difference cannot be explained by an improvement of the Pe number, but may be due to a better heat control or a better mass transfer.

4. Conclusions and perspectives

Gas phase RTD measurements indicate that, if long enough, millipacked bed reactors exhibit a pseudo-ideal behavior. The value of D/d_p has an effect probably related to the passage from structured to random beds. This aspect will be further investigated by CFD.

Addition of small spherical powder showed an improvement of the performance of a gas-solid mass transfer limited reaction. Next step is to discriminate between thermal and mass transfer effects.

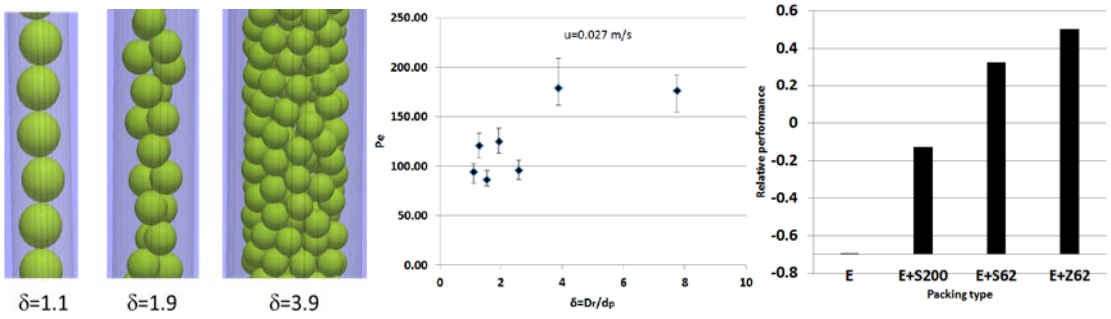

Figure 1. Left: Example of packing. Middle: Effect of δ=D/dp on the Pe number for spheres (L=18.2 cm, u=2.7 cm/s). Right: Relative performance of different packings on n-heptane conversion

Power consumption and mixing dynamics for Newtonian and non-Newtonian across different single-use mini bioreactor configurations

Anne de Lamotte[1], Martina Micheletti[1]

1 Department of Biochemical Engineering, University College London, Gower Street, WC1E 6BT London, UK;

**Corresponding author: a.delamotte@ucl.ac.uk*

Highlights

- Accurate power consumption measurements by the use of a dynamometer
- Detailed mixing dynamics assessment by means of the pH dual colorimetric technique
- Characterization of the impact of rotating speed and viscosity on Newtonian and non-Newtonian fluids
- Evaluation of the influence of baffles and internals on axial- and radial-flow configurations

1. Introduction

The biopharmaceutical manufacturing industry has created a pull for advancing high-throughput, automated technologies for process development and optimisation such as disposable multi-parallel miniature bioreactor platform. Actually, the latter are increasingly used within the industry, not only as screening tools but also as scale-down models. Among the current commercially available small-scale bioreactor systems, the stirred-tank design has again become prevailing. In stirred-tank bioreactors, hydrodynamics governs bulk fluid mixing. The understanding of these two key physical aspects and of their interactions are required within the framework of scale-translation models. The selection of agitation configuration and operating conditions has then to meet two objectives. On the one hand, the influence of process variables on bioreactor performance has to be properly understood. On the other hand, hydrodynamics and mixing, as well as their coupling, need to be assessed in relation to the bioreactor design and scale. In this context, engineering characterisation is required to understand and quantify these multiscale transport phenomena for better bioreactor design. This work aims at gaining a better understanding of the mixing effectiveness within different single-use mini bioreactor configurations for both Newtonian and non-Newtonian fluids.

2. Methods

Measurements are performed in the mini bioreactor systems ambr® 250 (Sartorius Stedim Biotech). The reactor with a working volume of 250 mL has been fitted with either two Rushton turbines (20 mm diameter, 30 mm spacing), or two pitched-blade impellers (26 mm diameter, 30 mm spacing, up- and down-pumping) with or without four equally-spaced baffles. The internals (pH probe and gas sparger) are also used to study their influence on mixing and power characteristics. The working fluids are water and aqueous solutions of glycerol (viscous), sodium alginate (low

shear-thinning) and xanthan gum (highly shear-thinning) of different concentrations. Rheological measurements are carried out using a Kinexus Lab+ rheometer (Malvern Panalytical).

The power draw in the different ambr® 250 configurations is measured by the use of a dynamometer based on a pneumatic bearing allowing rotation without friction. More information about the technique is provided in [1].

The Dual Indicator System for Mixing Time (DISMT) technique, based on a fast acid–base reaction in presence of pH indicators [2], is used to assess the mixing dynamics by using a camera. A description of the DISMT methodology and of the image-processing algorithm used to evaluate the mixing time can be found in [3].

3. Results and discussion

Power consumptions experiments with Newtonian fluids are carried out for providing the common thread of this work, and for characterizing the power curve of shear-thinning fluids within ambr® 250 configurations by means of the Metzner-Otto [4] and Rieger-Novak [5] methods.

The DISMT experiments are used to identify the main structures in the flow within ambr® 250 configurations, and to determine the macro-mixing time, the mixing time of segregated regions in the flow and the rate of reduction in size of the slow mixing regions for fluids with separate rheological behaviour [6].

The influence of Reynolds numbers on power consumption and mixing characteristics of baffled and unbaffled bioreactors is presented for operating conditions corresponding to non-aerated regime (no gas entrainment from the free surface). The impact of impeller type and of internals presence is investigated to assess the functional dependence of the power and mixing numbers on geometrical features under any fluid dynamic regime.

Finally, the mixing and power datasets are combined to determine and compare the mixing effectiveness of the agitation systems in relation with the operating conditions (rotating speed, working fluid).

4. Conclusions

The coupled analysis of power and bulk mixing characteristics of fluids with distinct rheological properties in different single-use mini bioreactor configurations, allows a first step towards a more systematic approach toward scale-down models development. An improved understanding of fluid dynamics and flow properties enables a more adequate application of key engineering parameters, in particular the power input.

Highlights

- Scale-up of oil-in-water DSD and effects of pressure are examined experimentally.
- New approach for prediction and scale-up of jet DSD based on TKE dissipation rate.
- Rise of gas-saturated oil droplets is accelerated by pressure-induced degassing.

1. Introduction

The depletion of readily accessible oil reservoirs in conjunction with the unabated demand for fossil fuels leads to the exploration and production of remote deposits, esp. in deep-sea regions. Such operations at hard-to-reach locations far beyond atmospheric conditions are extremely challenging and associated with elevated risk, which became clear when the Deepwater Horizon drilling rig ignited and sank in 2010 in the Gulf of Mexico, causing one of the largest oil spills in human history. The depiction and prediction of the multiphase plume's behavior under deep-sea conditions and the oil fate is critical for the development of mitigation strategies in case of a subsea blowout. Some of the most important input parameters for accurate oil fate modeling are the ensuing droplet size distribution (DSD), the rise velocity of the present droplets and bubbles plus the physical properties and phase behavior of the involved substances. The highly turbulent flow structure and the multiphase nature of the system as well as the specific deep-sea conditions must be accounted for when experimental facilities are designed or when oil-spill models are developed and tuned[1].

2. Methods

Extensive experimental research on the oil and gas behavior under ambient and in-situ conditions is done at Hamburg University of Technology (TUHH). The DSD of oil-in-water free jets at varying nozzle sizes, measuring positions and exit velocities as well as appropriate scale-up rules for the prediction of the DSD are investigated under ambient conditions. For this purpose, a lab-scale and a pilot-plant-scale experimental plant with direct optical access have been designed, commissioned and used, covering nozzle diameters from 1 mm to 74 mm and volume flow rates from 0.28 to 200 L/min. Particle image velocimetry is applied for the investigation of flow characteristics like the turbulent kinetic energy (TKE) dissipation rate. A colorized white oil (H&R PIONIER 7467) is used as dispersed and DI water as continuous phase. The DSD is determined by means of endoscopic imaging techniques. A high-pressure counter-current flow cell is used in order to simulate the rise

of gas-saturated crude oil droplets (Louisiana Sweet Crude oil, saturated with CH_4, in seawater). Reservoir conditions (~250 bar) and depth-dependent hydrostatic pressures of up to 150 bar, corresponding to the 1,500 m water column of the Deepwater Horizon blowout, can be adjusted. Temperatures range from 4 to 25 °C, also corresponding to the real conditions. The droplet's size, shape and motion is captured by means of high-speed imaging and evaluated over time[1].

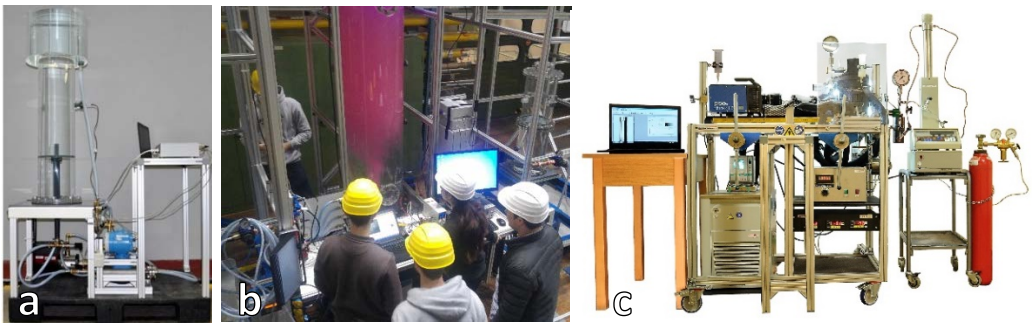

Figure 1. Experimental facilities for the investigation of submarine oil spills at TUHH: a. Lab-scale jet facility with direct optical access and variable nozzle size; b. Oil-in-water jet experiment in the pilot-plant-scale jet facility; c. High-pressure counter-current flow cell for the investigation of single rising live-oil droplets under simulated deep-sea conditions.

3. Results and discussion

The recorded droplet sizes of the oil-in-water jets are approximately log-normally distributed. In collaboration with the University of Western Australia, a new model correlation for the prediction and scale-up of the jet DSD based on the TKE dissipation rate (TDR) and incorporating the recent experimental results as well as older datasets is developed at TUHH. The model correlates the mean diameter with the TDR, which is calculated by means of literature equations, using a power-law function. The results are independent of the nozzle size but scale with the TDR value, which enables scale-up. In contrast to models available in literature, this quite fundamental correlation is capable of accounting for high-pressure effects, like pressure drop at the blowout site and outgassing of dissolved natural gas from the liquid oil. In the drop-rise experiments, gradually decreasing the pressure leads to the formation of gas bubbles inside the initially gas-saturated but purely liquid crude oil droplets. This internal degassing causes a substantial growth of the two-phase particles and a significant decrease of their average density. Both effects lead to an increased buoyancy and therefore a higher rise velocity of the droplets. The enhanced buoyancy of gas-saturated droplets is implemented into the 3D Lagrangian oil fate model by Paris et al. at the University of Miami[2].

4. Conclusions

The presented experimental results and modeling approaches help to understand and predict the fate of the oil masses in case of a subsea blowout. The multiphase nature of the oil and gas jet in question that determines the droplet size distribution as well as pressure-dependent effects like enhanced buoyancy due to degassing are critical for accurate oil fate modeling. This research was made possible by a grant from the Gulf of Mexico Research Initiative, C-IMAGE III.

Experimental investigation of hydrodynamics and mass transfer of viscous non-Newtonian fluids in stirred tanks.

Haider Ali[1], Jannike Solsvik[1]

[1]Department of Chemical Engineering, NTNU-Norwegian University of Science and Technology, Trondheim, Norway

*Corresponding author: jannike.solsvik@ntnu.no

Highlights

- Hydrodynamic and mass transfer of viscous non-Newtonian fluid in a stirred tank.
- Bubble size distribution changes with the height of tank.
- Bubbles size reduces in the stirrer vicinity.
- Rheology of liquids affects the bubble distribution in a stirred tank.

1. Introduction

Stirred tanks massively attract the bioprocess and chemical industries because of their cost-effectiveness. Improved mixing conditions and high heat and mass transfer rates are the prominent characteristics that make stirred tanks suitable for the fluids with complex rheology (non-Newtonian behavior) [1]. A mechanical stirrer enhances the mixing in the stirred tank by breaking the gas bubbles and increasing the turbulence of the liquid. However, the use of highly viscous non-Newtonian fluids significantly reduces the mixing process that consequently affects the performance of a stirred tank [2].

The objective of this study is to experimentally investigate the hydrodynamics and mass transfer characteristics of viscous non-Newtonian fluid in a stirred tank. A more detailed analysis of bubble-liquid mass transfer is obtained in this work because of the combined use of the two types of probes. That is, with the knowledge of the local dissolved concentration of oxygen along with the local bubble size distribution, the overall mass transfer coefficient can be analyzed in further details by splitting it into its components of liquid side mass transfer coefficient and interfacial area. In contrast to previous studies, where an overall bubble size is assumed for the whole tank unit, this study provides detailed information on the bubble size distribution at various local tank positions. Improved knowledge on mass transfer in non-Newtonian liquids is crucial for operation of many fermentations processes. The experiment is first performed to measure the hydrodynamics and mass transfer properties of Newtonian (water) liquid. Then viscous Newtonian (glycerol), and non-Newtonian (Carboxymethylcellulose sodium) fluids will be experimented to examine the effects of fluid rheology. Various gas volumetric flow rates, stirrer speeds, and probe positions are considered to examine their effects on the bubble size distribution, gas holdup, and mass transfer coefficient.

2. Methods

This study used a 15.0 L laboratory scale stirred tank made of plexiglass and with a working volume of 11.0 L. The gas was bubbled in the stirred tank by a ring sparger with 0.06 m diameter. The

sparger consists of 32 holes with a diameter of 0.0005 m. A Rushton turbine stirrer with six blades (0.07 m in diameter) and clearance of 0.045 m was used to prompt stirring in the tank. Dissolved oxygen concentration and bubble size distribution were measured at four different vertical positions (0.055 m apart) of the stirred tank. The gas volumetric flow rate and stirring speed varied from 1.0×10^{-4} to 1.4×10^{-4} m^3/s and 10 to 13.33 1/s respectively. An optical dissolved oxygen probe (InPro 6870i Mettler Toledo, Switzerland) and photo optical probe (VI Kr SOPAT, Germany) were used to measure dissolved oxygen concentration and bubble size distribution. The overall mass transfer coefficient was measured with the dynamic gassing-in method [3]. The rheological properties (apparent viscosity etc.) of the viscous liquids will be measured using rheometry.

3. Results and discussion

Figure 1 shows the bubble size distribution for the different vertical probe positions. The volumetric gas flow rate is 1.0×10^{-4} (m^3/s), stirrer speed is 10 (1/s), and the frame rate of the optical probe is 5 (Hz) for these results. The breaking of the bubble by the stirrer produces significantly small size bubbles in the first position (stirrer vicinity). The size of bubbles starts to increase as they move away from the stirrer (second position) because of the coalescence. The large size bubbles recorded at the third and fourth positions suggest that the bubble coalescence is dominant in these regions. The Sauter mean diameter is 0.95 mm for the first position, 1.78 mm for the second position, 2.15 mm for the third position, and 2.04 mm for the fourth position.

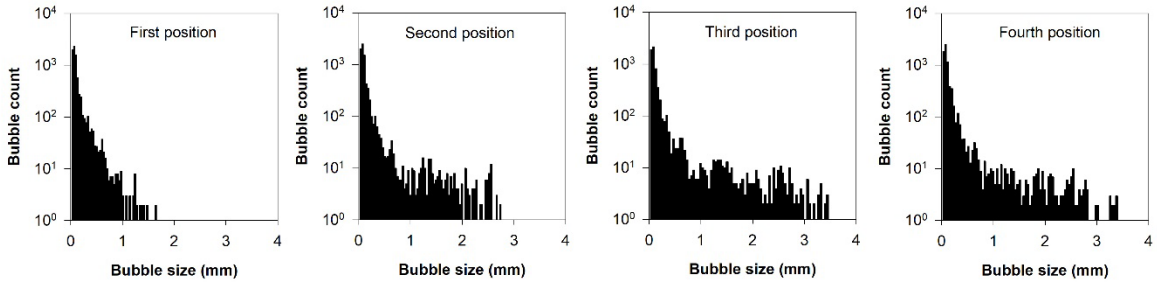

Figure 1. Bubble size distribution for different probe positions.

4. Conclusions

This experimental study investigates the hydrodynamics and mass transfer characteristics of viscous non-Newtonian fluid in a stirred tank. The study uses different gas volumetric flow rates, impeller speeds, and probe or positions to examine their effects on the bubble size distribution, gas holdup, and mass transfer coefficient. Initially, the bubble size distribution in the water was measured at four different probe positions. The coalescence produces large size bubbles in the regions that are quite distant from the stirrer. Use of viscous Newtonian and non-Newtonian fluids will increase the coalescence that consequently affects the bubble distribution in the tank. Therefore, experiments will be carried out to measure hydrodynamics and mass transfer of viscous Newtonian and non-Newtonian fluids.

Highlights

- Mimicking microalgae culture at high concentration using shear thinning liquid phase.
- Identification of flow regimes and their transition.
- Determination of mixing time and gas liquid mass transfer coefficient.
- Optimization of hydrodynamic conditions for higher biomass productivity.

1. Introduction

Bubble column technology is particularly adapted to photosynthetic microorganism culture because the injection of air enriched with CO_2 allows mixing as well as feeding the culture with inorganic carbon. Nevertheless, technological advances are still required to reduce production costs and environmental impacts. In this context, intensification of performances *via* an increase of culture concentration in photosynthetic microorganisms is a promising way to optimize production systems. However, it has been shown that the increase in cell concentration is accompanied by the increase of the viscosity and the modification of the rheological properties of the microalgae suspension [1]. Moreover, to reach high cell concentration, reducing PBR thickness is required to ensure light availability on the whole reactor gap. Confinement and rheological characteristics impact the bubbling effect on hydrodynamics and gas-liquid mass transfer [2]. The objective of this work is to characterize hydrodynamics as well as gas-liquid mass transfer for non-Newtonian liquid phase in a 2D bubble column having gap of 4 mm [2], for different gas injection conditions (sparger size and gas flow rate). For this purpose, non-Newtonian shear thinning solutions are used to mimic the high concentration of *Chlorella vulgaris* cultures at 30-40 g/L. Solutions of Xanthan gum (XG) and Carboxymethyl cellulose (CMC) are used respectively at the concentrations of 1 g/L and 2 g/L. The rheological characterization is performed using the PAAR Physica® MCR500 rheometer and the power law equation is used for modelling the rheological behaviour. Gas sparging is achieved using 15 capillaries which can have 5 different diameters (0.1016, 0.254, 0.508, 0.762 and 1.016 mm) in order to vary the size of the injected bubbles. A wide range of superficial gas velocities is also explored to investigate the effect of sparging on the global hydrodynamics of a non-Newtonian liquid phase in this thin gap bubble column.

2. Methods

Experimentally, the gas phase is characterized locally through the shadowgraphy method using DANTEC DYNAMICS Shadow Strobe, which allows to obtain the size, the shape and the velocity of bubbles. The hydrodynamics of the continuous phase is characterized by Particle image velocimetry (PIV) technique. Secondly, flow regimes and their transitions are investigated by studying gas holdup determined by liquid height or by hydrostatic pressure measurements. Identification of regime transition is obtained from gas holdup using three different methods based on gas retention as a function of superficial gas velocity or swarm velocity method or drift method. The mixing time characterization is carried out using a tracer method which consists in the injection of 2 mL of NaCl Solution at 200 g/L and follow-up the conductivity of the liquid over time until stabilization. Finally, to determine the volumetric mass transfer coefficient, kLa, the classical dynamic gassing-out gassing-in method is employed [2]. The obtained results are compared to those presented in the literature for non-Newtonian solutions in unconfined bubble columns in order to emphasize the confinement effect on hydrodynamics and gas-liquid mass transfer[3].

3. Results and discussion

Figures 1 and 2 present respectively gas holdup and mixing time *vs* the superficial gas velocity for an injection with capillaries of 0.508 mm of diameter. Whatever the nature of the fluid, three flow regimes are observed: homogeneous, transition and heterogeneous regimes. For the three tested liquids, the overall gas holdup increased with the increase of the superficial gas velocity. Besides, at the same superficial gas velocity, the overall gas holdup in non-Newtonian liquids was larger than those in the water [Fig 1]. This result disagrees to one available in the literature ([3][4]and[5]) using unconfined column operating with non-Newtonian fluids. This result could be explained by the effect of the confinement between bubbles and column walls. Indeed, the experiments for an isolated bubble in this column showed that low terminal velocities have been observed in the case of non-Newtonian phase compared to the Newtonian one. Consequently, higher residence time of bubbles is observed with CMC and XG solutions. Comparison between the two non-Newtonian fluids shows that CMC and XG have similar gas hold-ups, certainly due to their similar rheological properties. It could be noted that the regime transitions between the homogeneous and the intermediate regimes appear at lower superficial gas velocity with non-Newtonian fluids due to their coalescence tendency. Higher gas hold-up is obtained in the XG solution than in the CMC, this phenomenon was already observed by [3] which they explained by elastic effects of XG solution.

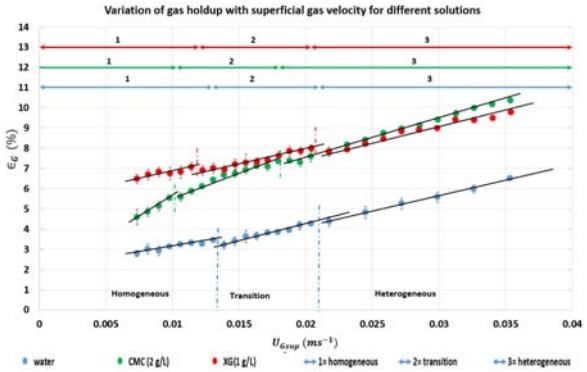

Figure 1. Effect of superficial gas velocity on gas holdup.

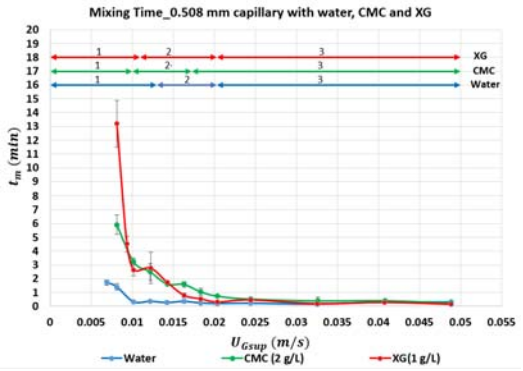

Figure 2. Effect of superficial gas velocity on mixing time

Concerning the mixing time, Fig 2 shows a decrease of this parameter with the increase in the superficial gas velocity. The mixing time in water decreases rapidly during the homogeneous regime ($U_{Gsup} < 0.01$ m.s^{-1}) and then is quite constant for higher values of U_{gsup}. For CMC and XG solutions, the important decrease is observed during the homogeneous and the transition regimes. Increasing the capillary diameter generates large bubbles which leads to the lower mixing times for all solutions. With all capillaries studied, the mixing time in XG solution is higher than in the two other solutions, especially in homogeneous regime.

4. Conclusions

Global hydrodynamics characterization of a thin gap bubble column shows that the gas holdup in non-Newtonian liquid phase is higher than Newtonian one due to the higher residence time. The regime characterization, performed using various methods, shows that regime transitions for non-Newtonian liquids appear at slightly lower superficial gas velocities than the Newtonian one. The mixing time experiments show that mixing in non-Newtonian liquids is quite poor at low gas flowrates, especially during the homogeneous and transition regime with mixing time values up to 10-15 times higher than those observed in the heterogeneous regime. An important increase of the mixing time with the viscosity was also observed. The work for gas liquid mass transfer and experiments with PIV technique are in process to determine the other aspects that can affect hydrodynamics in this thin gap bubble column with non-Newtonian liquid in order to optimize culture conditions for higher biomass productivity.

Highlights

- Introduction of new automation technique for multiphase applications
- General overview of inline techniques for the particle characterization given
- ISO standards are applied to the evaluation and show the advantages of image analysis

1. Introduction

The exact knowledge of drop size distributions (DSD) plays a major role in liquid-liquid extraction, for controlling and optimizing processes and separation efficiency as well as reducing residence times. Many efforts have been made to measure the size of liquid dispersed droplets. The techniques can be divided into those that require a sample to be withdrawn from the vessel, column or pipe and those that take the measurement in situ. The next step forwardc is the control of the fluid particle size in such systems. Therefore, fast information acquisition is needed but difficult to obtain. While many users are confronted with these requirements an adequate measurement technique for all applications is needed but has not yet been developed. A further difficulty handling such dispersed systems is the possible danger of a phase inversion (PI). Does this phenomenon occur spontaneously during a process, it can have fatal consequences for the process and/or equipment.

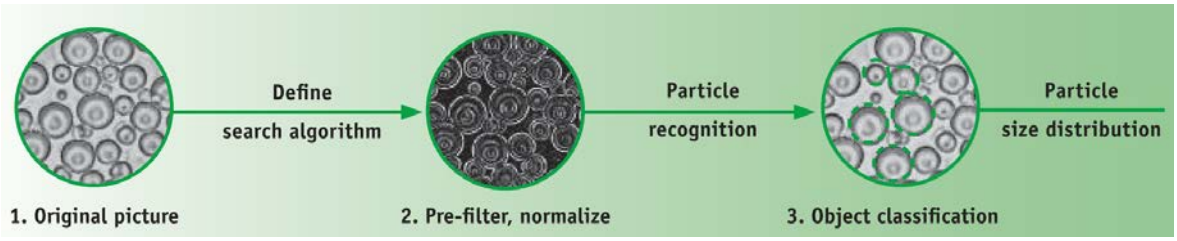

Fig. 1: Photo-optical Measuring Method for Particle Size Distributions

2. Methods

An overview is given for already existing measurement techniques. They are divided into three main groups: sound, laser and photo based techniques. The FBRM® [1], the 2-D ORM® [2] and the PARSUM IPP 30 [3] which all give online and in-situ information together with an in house developed photo optical technique SOPAT-VR® [4, 5] will be discussed in detail. They have been tested for different applications in various multiphase system (liquid-liquid, gas-liquid-liquid, gas-

liquid-liquid-solid). The results achieved by the different measurement techniques are compared with each other. As proposed in literature, image analysis is used as the standard method that all other techniques are compared with. The photo-optical SOPAT measuring technique for particle sizing is capable of acquiring raw data (two-dimensional images) of the dispersed phase (here: droplets) during the process and measure the sizes by means of automated image analysis, see Fig. 1. This study demonstrates the capability of a photo-optical measurement method by taking the example of a separation apparatuses after a mixer.

3. Results and discussion

Fig. 2 exemplarily shows the measured DSDs for the separation process. The experiments showed clearly that the initial droplet size is of major importance for the separation efficiency. The studies, varying volume flow, dispersed phase concentration as well as dispersed phase are shown and its influence determined. Additionally it could not only detect the required DSD, but also was able to distinguish between different dispersed phases, for example disturbing bubbles and furthermore the beginning of PI have been detected and therefore the measurement system could be used as a warning for PI. As the results are available inline and in real time, a closed control loop can be established.

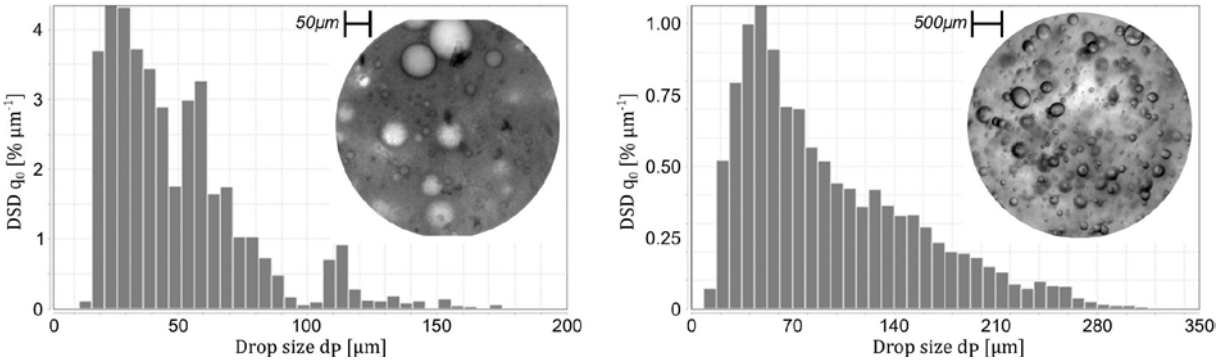

Fig. 1: Measured DSD for w/o (left) and o/w separation process (right) with exemplary photo-optical image data

Highlights

- The fast-moving aggregates were heated by well-characterized multi-diode laser.
- The *in situ* planar aggregate temperature was determine by PLIP technique.
- Averaged particle aggregates temperatures were compared at several fluxes.

1. Introduction

Heat transfer within particle-laden flow strongly influence the process heat flow, energy conversation and the system's reliability of chemical engineering processes [1]. Thus, the understanding of heat transfer in two phase flow and precise temperature measurement of particles are important in improving such process efficiencies. Nowadays, the heat transfer of two-phase flow is still not fully understood because the temperature measurements of suspended particles in the gas flow are extremely difficult. Therefore, planar laser-induced phosphorescence (PLIP) technique has been developed to offer the non-invasive temperature measurement for both static and moving surfaces with higher accuracy [2]. In this work, the temperature measurement of particle aggregates, heated by high radiation flux, has been investigated. PLIP technique has been applied to yield accurate non-intrusive surface temperature of fluidized aggregates. The radiation was supplied by the well-characterized high radiation multi-diode laser system that recently developed at the University of Adelaide [3].

2. Methods

The experiment setup was divided into three parts, which are the high radiation multi-diode laser system to generate high radiation flux, the fluidized bed to provide particle-laden flow, and imaging system for signal collection. $BaMg_2Al_{10}O_{17}$:Eu (BAM) was selected as thermographic phosphor due to its large temperature sensitivity up to 1300 K. The Nd:YAG laser excited phosphorescence emission signals from particles were directed to the imaging system. An imaging splitter transferred two images, which captured at two different wavelengths, into a single ICCD camera. Both images were collected simultaneously with the advantages of minimizing the error during the image processing. The real-time particle aggregates temperature is determined by the emission intensity ratio at two different wavelengths, namely 400 nm and 460 nm.

3. Results and discussion

Single-shot particle aggregates temperature measurement was performed at 7 different heating fluxes. For each flux, 300 images were recorded by the ICCD camera during the heating period. Figure 1 presents the typical example of particle aggregates temperature derivation. Column A and column B are the individual particle aggregates images taken with the 400 ± 20 nm filter and 460 ± 7 nm filter respectively, while column C shows the inferred particle temperature. The final temperature distribution of particle aggregates is obtained by dividing the intensity on two sub-images pixel-by-pixel using MATLAB code.

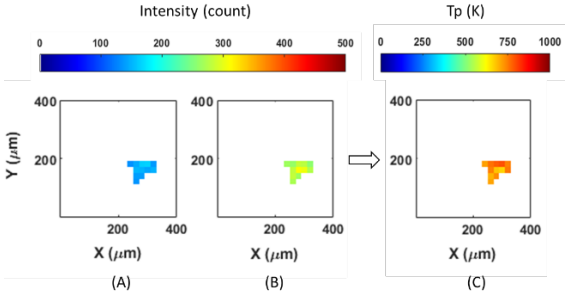

Figure 1: Example of single shot aggregates temperature distribution images deriving from two raw sub-images

Figure 2(a) presents the example of aggregates temperature distribution over 300 images, while Figure 2(b) shows the average aggregates temperature at 7 different fluxes. The average aggregates temperature has the linear increasing trend. As heat flux increasing, the maximum BAM average temperature is achieved more than 700 K when the heat flux at 27.28 MW/m².

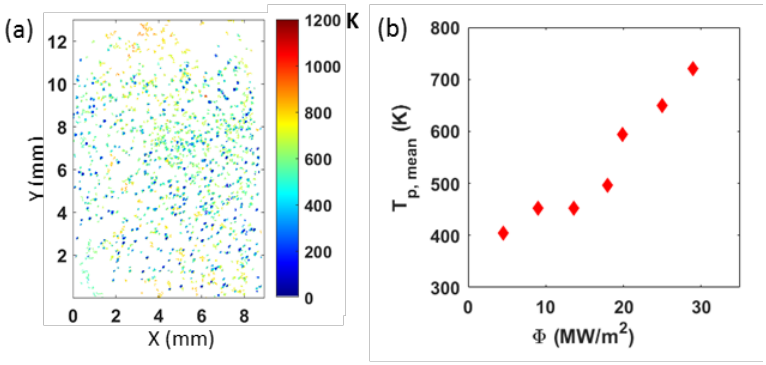

Figure 2: (a) Real particle aggregates temperature distribution in measurement area by overlap particles over 300 images at heating flux of 24.97 MW/m². (b) Mean BAM particle aggregates temperature at various heat fluxes

4. Conclusions

Real-time planar temperature measurement of fluidized BAM aggregates was performed by planar laser induced phosphorescence (PLIP) technique with using a single ICCD camera and imaging split system. Averaged particle aggregates temperatures were compared at several fluxes. At the highest heating flux, the average aggregates temperature was increased to more than 700 K.

Highlights

- Spacer features affect significantly transport phenomena.
- Electrical resistance and deformation can be effectively predicted.
- Results are easily integrated in multi-scale process models.

1. Introduction

In the last years, the scientific community has been exhibited a growing interest towards several separation processes based on membrane technologies. For the development of novel and optimized designs, the implementation of robust and reliable process models is a challenge. An effective modelling strategy, able to provide accurate predictions with a sustainable computational demand, is represented by a multi-scale modelling approach [1]. In a structured separation of scales, numerical simulations analyze in detail transport phenomena at the lowest scale of modelling and provide correlations to the higher scale models, which simulate the whole membrane/channel assembly, unit and plant.

This work presents computational fluid dynamics simulations aimed at characterizing flow and mass/heat transport mechanisms in spacer-filled channels for membrane processes, with particular reference to (reverse) electrodialysis and membrane distillation. Further kinds of numerical simulations were performed in order to assess aspects poorly studied so far, i.e. electrical "shadow" effects of spacers and membrane deformations.

2. Methods

Spacer-filled channels and profiled-membrane channels were simulated by the periodic unit cell approach, i.e. assuming fully developed conditions. The basic set of differential equations includes continuity and Navier-Stokes equations, transport of enthalpy and convective-diffusive transport of solute. Equilibrium, compatibility and constitutive equations were solved in simulations aimed at finding configurations deformed under an imposed load mimicking a trans-membrane pressure. Finally, the Laplace equation for the electric potential was solved in simulations assessing the Ohmic resistance. Grid-sensitivity of results was assessed, in order to present results practically unaffected by the discretization degree. The finite-volume Ansys-CFX code and the finite-element Ansys-Mechanical code were used.

3. Results and discussion

Dimensionless quantities were computed from CFD simulation results, namely Darcy friction factor (*f*), Sherwood number (Sh) and Nusselt number (Nu). Figure 1 reports some typical results for different configurations. It can be observed that woven spacers enhance mass/heat transfer compared to overlapped spacers, but at the expense of larger pressure drops. The *P/H* value has straightforward effects only in the case of woven spacers. SST *k-ω* turbulence model predictions for non-steady flows fairly agree with laminar simulation trends, but direct numerical simulations would be more appropriate for incipient turbulence regimes. Nu and *f* predictions were validated against experimental data and exhibited a good agreement.

Significant effects of membrane deformation were observed: friction and mass transfer coefficients increased in the compressed channel, while they decreased in the expanded channel.

The spacer shadow factor for the Ohmic resistance was found to be close to the reciprocal of the average between porosity and open area, in agreement with experimental findings.

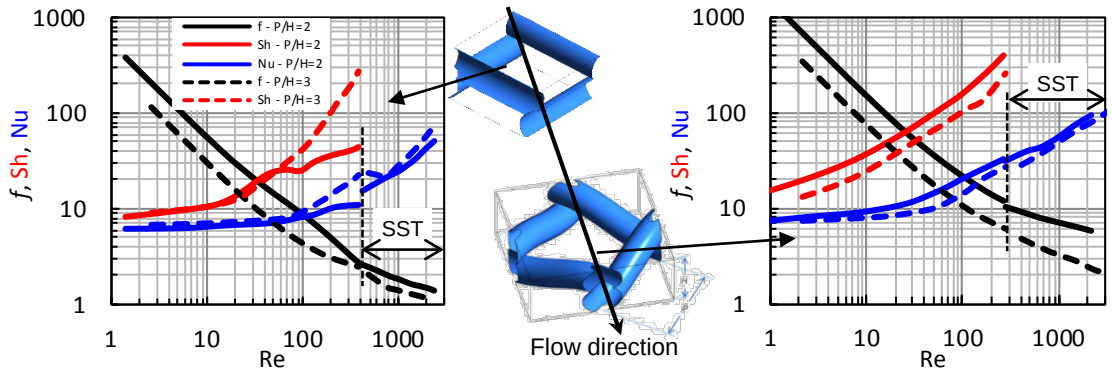

Figure 1. *f*, Sh and Nu in spacer-filled channels as functions of the Reynolds number (Pr=4.33, Sc=600).

4. Conclusions

Simulation tools implementing well-established and validated physical models and numerical methods were presented. CFD predictions showed that spacer features can significantly affect flow and heat/mass transfer characteristics. Novel models showed to be effective in the simulation of aspects poorly investigated so far, such as the mechanical response and the electrical resistance.

The present outcomes provide correlations to integrated process simulators in order to calculate pressure drop, temperature/concentration polarization effects, electrical resistance and fluid-structure interactions. The present numerical simulations represent basic predictive tools for optimization studies and for the development of novel designs and concepts.

Investigating Coarse-Graining Effects on CFD-DEM Simulations of Fluidized and Spouted Bed Reactors

Thomas Eppinger[1], Nico Jurtz[2], Felix Klippel1, Leonard Becker1, Oleh Baran[3], Ravindra Aglave[3], Matthias Kraume[2]

1 Siemens Industry Software GmbH, Nürnberg, Germany; 2 Berlin Institut of Technology, Chair of Chemical & Process Engineering, Berlin, Germany; 3 Siemens PLM, Houston, TX, USA
**Corresponding author: Thomas.eppinger@siemens.com*

Highlights

- Effect of different coarse-graining methods and factors are investigated
- Comparison against experimental data shows good agreement with averaged quantities
- Differences in the dynamic behavior are quantified

1. Introduction

Since its introduction [1], the Discrete Element Method (DEM) has proven to be a valuable method for the analyzing and understanding particulate flows. Supported by the continuously increasing computational power, CFD-DEM simulations have found their way into the chemical and process industry for various applications like solid suspension in mixing vessels, fluidized and spouted beds, granular transport and coating applications in rotary drums [2,3].

The major shortcoming of DEM, however, is its computational cost that increases with the amount of particles involved, their material properties (stiffness) and size. This hinders the application of CFD-DEM simulation to large-scale systems of industrial size. To overcome this shortcoming a coarse grain (CG) model has been described [4]. Using straightforward scaling rules, a group of particles gets replaced by a representative coarse parcel. This effectively reduces the number of particles that need to be processed and subsequently shortens the computational time. On the other hand they introduce a modeling error into the simulation. In this study we are investigating different coarse graining models and quantify the effect on different parameters and their fluctuation like pressure drop and expansion height in a fluidized and spouted bed.

In this work two different contact scaling methods are examined for a fluidized and for a spouted bed reactor. The results are compared against experimental results and against a DEM simulation without coarse graining.

2. Methods

In this investigation the software tool Simcenter STAR-CCM+ was used for the coupled CFD-DEM simulation. The built-in DEM solves for each particle Newton's law of motion in each time step. The particle-particle and particle-wall interaction is taken into account based on Hertz-Mindlin model (spouted bed) or the linear-spring-dashpot model (fluidized bed). Momentum exchange between the background gas phase and the DEM particles is calculated based on Gidaspow drag model and

three different coarse graining (CG) approaches were used: Particle-based CG with l3-scaling, Parcel-based CG with l3-scaling and Parcel-based CG with l2-scaling.

3. Results and discussion

Exemplarily the results for the fluidized bed are shown here, but similar results were also found for the spouted bed. Figure 1 shows a snapshot in time of the different CG methods. In general it can be stated that bed expansion and pressure drop are well predicted for all investigated CG methods, but depending on the CG factor the dynamic of the system cannot be captures which can be seen in Figure 2 as deviations in the RMS values for the respective parameter.

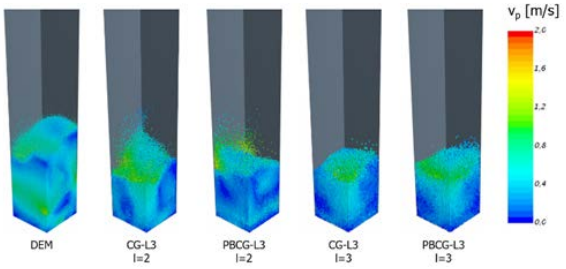

Figure 1. Comparison of the particle dynamics for different CG methods

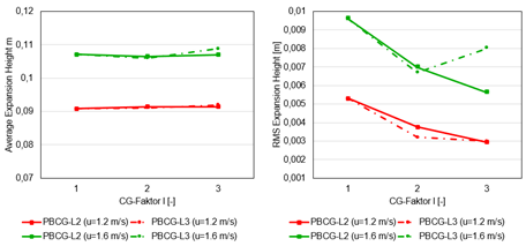

Figure 2: Average and RMS expansion height for different CG methods

4. Conclusions

Coarse-graining is a promising method to increase the number of particles in CFD-DEM simulations and simultaneously reducing the runtime by orders of magnitude. The predictivity is slightly affected in terms of the particle dynamics while overall properties are still predicted accurately in the investigated CG range.

Advection-dominated reactive species transport at fluid interfaces via data-driven Subgrid-scale modeling

Andre Weiner[1], Dennis Hillenbrand[1] , Holger Marschall[1] , Dieter Bothe[1]*

1 Institute for Mathematical Modeling and Analysis, TU Darmstadt

Alarich-Weiss-Straße 10, 64287 Darmstadt

**Corresponding author: bothe@mma.tu-darmstadt.de*

Highlights

- Subgrid-scale modeling for reactive concentration boundary layers
- Data-driven approach for approximate functions
- Significant reduction of mesh resolution and computation time

The transport of chemical species close to the gas-liquid interface of a rising bubble is typically characterized by strong advection along the interface and molecular diffusion normal to it. Consequently thin boundary layers form, which have to be resolved in numerical methods to evaluate local reaction-engineering quantities like enhancement factor, selectivity or yield accurately. In [1,2] we introduced a non-reactive subgrid-scale (SGS) model that mitigates this high-Schmidt-number problem significantly. This model was used successfully in [3] to validate numerical simulations against experimental results of species transport at small rising bubbles. The basic idea is to derive an analytical solution for a substitute problem which describes the main features of an advection-dominated boundary layer. This analytical solution is used to correct diffusive and convective fluxes in interface cells of the numerical simulation.

However, in the general case of reactive boundary layers it is not possible to derive closed-form solutions. Our new approach to extend the SGS modeling for reactive systems is based on a machine-learning algorithm which represents an approximate solution of the substitute problem over a chosen range for characteristic parameters like Peclet or Damkohler numbers. The machine learning algorithm - a multi-layer-perceptron - has adjustable weights which are optimized to reflect the numerical input data. As before, the approximate solution is used to correct the numerical fluxes near the interface in simulations. This approach was validated for the transport of a specie from a rising axisymmetric bubble followed by a first-order decay reaction in [4]. Figure 1 shows the improvement of the species transport via the local Sherwood number profile along the polar angle of the bubble. The flux corrections from the data-driven SGS model enable the representation of the reference profile even for coarse meshes. Additionally, the evaluation of the data-driven SGS model produces almost no computational overhead. This results in a significant reduction of computation time while introducing an error of less than 5% for the overall species transport. Due to the flexibility of this approach it can be adjusted to the required parameter ranges and extended to more complex reaction systems.

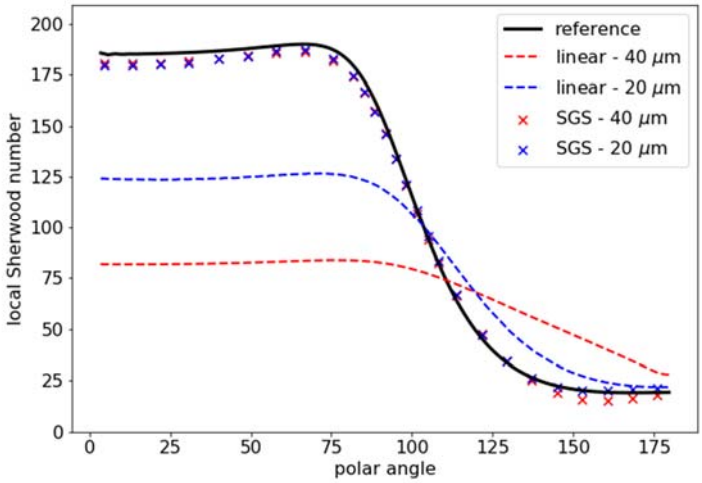

Figure 1. Local Sherwood number profiles for coarse meshes with and without using the SGS model.

Unconventional pressure dependence of Ibuprofen solubility in binary mixture of water and organic solvent

Mirko D'Auria[1], Andreas S. Braeuer[1*]

1 Institute of Thermal-, Environmental-, and Resources' Process Engineering (ITUN), Technische Universität Bergakademie Freiberg (TUBAF), 09599 Freiberg, Germany

**Andreas.Braeuer@tu-freiberg.de*

Highlights

- Solubility of Ibuprofen at elevated pressures
- Hydrogen bond network

1. Introduction

Unexpectedly we found that the solubility of Ibuprofen, a hydrophobic compound, in mixtures of water and organic solvent can increase with increasing pressure. This behaviour can be exploited for particle precipitation strategies that are based on a rapid pressure changes.

We therefore characterized the solubility of ibuprofen in binary mixtures of water and organic solvent (here acetone and acetonitrile) up to 20 MPa. The obtained results are interpreted based intermolecular interactions revealed using Raman spectroscopy and on thermodynamic considerations revealed by measuring the partial molar volumes of the solvents and the dissolved ibuprofen.

This kind of binary mixtures also show an ambiguous behaviour in the hydrogen bond network that changes with temperature and pressure. According to "iceberg theory", water and organic solvent molecules can organise themselves creating regions rich and others poor in water.

2. Setup

For the determination of the solubility data at high pressure, the setup consists of a high pressure variable volume view cell (HPVVVC), where pressure can be fixed by increasing/decreasing the volume and temperature can be adjusted by a heating system.

3. Conclusion

We aim to contribute with this study in the implementation of a precipitation process by pressure variation.

**Corresponding author: travnickovat@icpf.cas.cz*

Highlights

- Binary nucleation of H_2SO_4 and H_2O
- Measuring at Laminar Co-Flow Tube.
- Numerical and analytical models comparison.

1. Introduction

Particle nucleation is one of the important phenomena encountered in both chemical engineering and environmental studies. The Laminar Co-Flow Tube (LCFT) was designed for experimental measurement of binary and ternary nucleation of mixtures of atmospheric aerosols at laboratory conditions, most often H_2SO_4 + H_2O + amines (MEA, TEA)/terpenes (α-pinene, limonene). When nucleating components are entrained co-currently with H_2S0_4 in the axial flow, a clearly defined nucleation zone can be formed in the axial region of the chamber. As a result, the losses of the formed particles on the device walls are minimized. Laminar flow allows mathematical modeling of velocity and partial pressure profiles in the chamber. From these, it is then possible to predict the shape and size of the nucleation zone and subsequently the nucleation rate. Two models were used for mathematical modeling of momentum and mass transfer in the LFDC; 2D axisymmetric CFD model and simplified 1D analytical model. A parametric study was carried out using both models and the influence of the individual simplifications of analytical model on overall behavior of the system was discussed.

2. Methods

The measurement of H_2SO_4 nucleation with water vapor using LCFT is described in detail in publication [1]. The LCFT device consists of two coaxial tubes. A mixture of nitrogen (inert gas) with sulfuric acid is led into the inner tube. A nitrogen mixture with water vapor flows parallel within the inner and outer tube annulus. When laminar profiles are developed, axial flow merges with the annular one. The magnitudes and ratio of flow rates are set, so that the flow remains laminar after opening of the inner tube and both mixtures are in diffusional contact. When the concentrations of H_2SO_4 and water vapors are sufficiently high, in the nucleation zone, stable clusters are formed at a nucleation rate *J*. The nucleated particles grown to detectable size are counted by PSM (Particle Size Magnifier) counter.

To obtain nucleation isotherms, the experimental measurements were supplemented with numerical CFD simulations. 2D axisymmetric CFD model solves Navier-Stokes equations with equation of continuity and component mass balance equations. Simplified analytical 1D model assumes uniform (plug flow) velocity profile and negligible diffusion in axial direction. For nucleation rate modeling, a model of Wyslouzil et al. was used [2]. All results were normalized for relative humidity *Rh* = 0.38.

3. Results and discussion

The resulting nucleation isotherms obtained by experiment and subsequent modeling using the numerical model (v_z=$v_z(r)$) and analytical model with three different choices of plug flow velocities v_z=v_{avg} (average val. of radial laminar vel. profile), v_z=v_{max} (maximum of radial vel. profile in co-flow section), v_z=$v_{i,max}$ (maximum of inner tube radial vel. profile) are clearly illustrated in the figure 1.

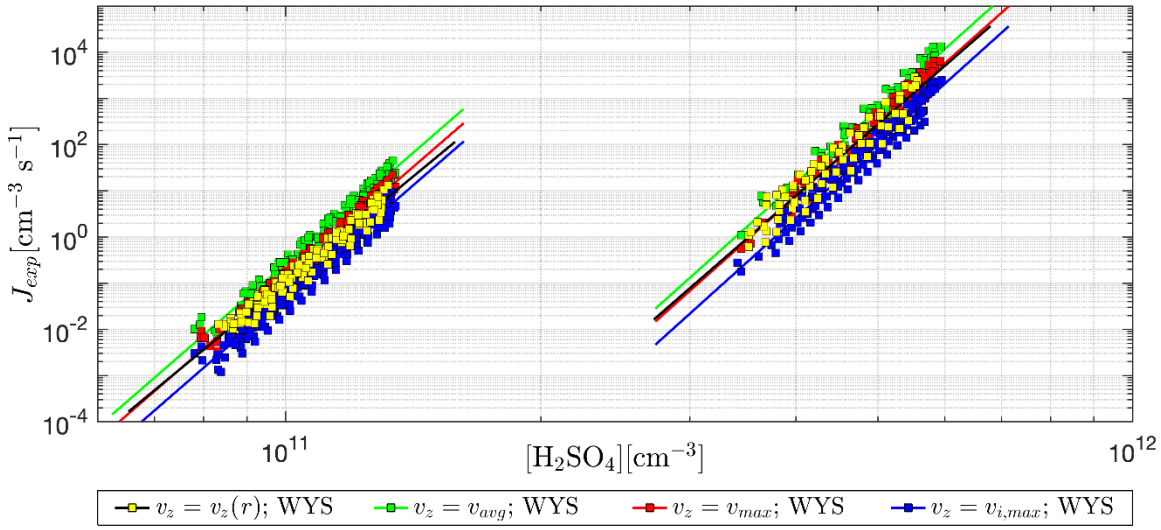

Figure 1. Comparison of nucleation isotherms 15 and 27°C computed by CFD numerical model v_z=$v_z(r)$ and analytical model with different plug flow velocities: v_z=v_{avg}, v_z=v_{max} *and* v_z=$v_{i,max}$.

Deviations in the maximal experimental nucleation velocity are caused by different modeling of gas flow in the region of nucleation zone. For most of our experimental flow rate settings, plug flow rate $v = v_{max}$ is the best choice, when the experimental nucleation rate can be underestimated down to 0.3 times and overestimated up to 2.3 times in comparison to 2D axisymmetric numerical model.

4. Conclusions

By appropriately selecting value of the plug flow rate in the analytical model, it is possible to achieve, that the location and shape of the nucleation zone will be similar and also the resulting nucleation rates will be estimated with sufficient precision. Usage of the analytical model is suitable for this type of nucleation experiments with the advantage of a significant saving the computing time.

Effects of flow structure on mixing related processes.

Jerzy Bałdyga* Michał Kotowicz

1Faculty of Chemical and Process Engineering, Warsaw University of Technology, ul. Waryńskiego 1, 00-645 Warsaw, Poland
** jerzy.baldyga@pw.edu.pl*

Highlights

- Effects of flow structure on mixing, mass transfer and emulsion behavior are considered.
- The rate-of-strain and rate-of-rotation tensors characterize flow structure.
- The invariants of the rate-of-strain and rate-of-rotation tensors are used in modeling.

1. Introduction

Details of micro- and meso-scale flow structures affect the course of many processes of industrial importance. Most often effects of hydrodynamics on processes and products are expressed in terms of such variables like the rate of energy dissipation or the Reynolds number.
Objectives of this work are to characterize the flow structure and show its effect on micromixing in single-phase systems and mass transfer in two-phase systems. Also effects of flow structure on drop breakup and rheolology of dense emulsion will be briefly considered.
A difference in breaking droplets in simple shear and hyperbolic flows is well known. It has been often interpreted and generalized using a simple two-dimensional linear flow approximation [1].

$$\mathbf{S}=\frac{G}{2}\begin{bmatrix}1+\alpha & 0 & 0\\ 0 & -1-\alpha & 0\\ 0 & 0 & 0\end{bmatrix}\quad \mathbf{\Omega}=\frac{G}{2}\begin{bmatrix}0 & 1-\alpha & 0\\ -1+\alpha & 0 & 0\\ 0 & 0 & 0\end{bmatrix} \tag{1}$$

where **S** and **Ω** are the deformation and rotation tensors**,** *G* is the scalar velocity gradient, and *α* determines the flow type: *α* = 0 for simple shear flow, *α* = 1 for plane hyperbolic flow and *α* = -1 for pure rotation.

2. Models for flow structure dependent processes.

In 3D flows instead of eq.(1) one can characterize the flow using the second invariants of the rate-of-strain tensor II_D and the rate-of-rotation tensor II_Ω, ω_i being component of vorticity vector :

$$II_D=-\frac{1}{2}S_{ij}S_{ij}=\frac{1}{2}\left[\left(S_{ii}\right)^2-\left(S_{ii}^2\right)\right]\quad II_\Omega=\frac{1}{2}\Omega_{ij}\Omega_{ij}=\frac{1}{4}\omega_i\omega_i \tag{2}$$

The second invariant II_D characterizes deformation rate and is proportional to the local rate of viscous dissipation of kinetic energy. In turbulence, high values of viscous dissipation are concentrated in sheet-like and ribbon-like structures. II_Ω is proportional to the enstrophy density (enstrophy is the integral of the square of vorticity). In turbulent flows regions of high enstrophy form tube-like structures. Both, deformation and rotation affect micromixing rate [2] and micromixing efficiency [3]. In Figure 1 relative energetic efficiency is presented for the flow defined as elongation in direction 1 and contraction in directions 2 and 3 $\gamma_1'=\alpha'\cdot s=\alpha'\cdot\left(\varepsilon_T/(3\nu)\right)^{1/2}$ and $\gamma_2'=\gamma_2'=-(1/2)\alpha'\cdot s=-(1/2)\alpha'\cdot\left(\varepsilon_T/(3\nu)\right)^{1/2}$ and including effect of Sc; here α' represents effect of reduction of deformation due to rotation effect. In fact α' is similar to the energetic efficiency by Ottino [4].

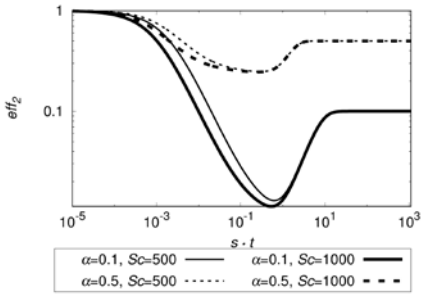

Figure 1. Effect of deformation rate *s* and Schmidt number on relative efficiency of mixing in 3-dimensional flow

In typical models of mass transfer between droplets and continuous phase, the Sherwood number is proportional to $Pe^{1/2}$ with coefficients of proportionality dependent of flow structure. More universal approach, including application of the second invariant, was proposed by Polyanin [5].

$$Sh = \frac{k_L d}{D} = 0.620\left(\frac{1}{K+1}\right)^{1/2} Pe^{1/2}; \quad Pe = \frac{d^2\sqrt{|II_D|}}{D} \tag{3}$$

where *K* represents the viscosity ratio μ_d/μ_c and *D* is the coefficient of molecular diffusion.
However, this approach neglects effects of rotation on mass transfer coefficient. Batchelor [6] has shown that for solid particles at high *Pe* the Sherwood number depends on the ratio of extension rate to rotation rate, s_1/Ω; for small s_1/Ω it affects the Sherwood number for any value of the Péclet number and becomes asymptotically independent of s_1/Ω at high values of this ratio. A real challenge is to generalize this effects by using the second invariants of the rate-of-strain tensor and the rate-of-rotation tensor. At present we can show that for high *Pe* and high II_Ω/II_D the region of closed streamlines around a droplet across which the transfer by molecular diffusion takes place becomes a shell of thickness proportional to $R\cdot\left(II_\Omega/II_D\right)^{1/2}$. Hence, the external mass transfer coefficient can be expressed as $k_L \propto DR^{-1}\cdot\left(II_D/II_\Omega\right)^{1/2}$. As $II_D/II_\Omega \to \infty$ the values to which the mass transfer coefficient tends are $k_L \propto D^{1/2}\left(K+1\right)^{-1/2}\left(II_D\right)^{1/4}$.
Application of both second invariants enables description of drop breakage in 3D laminar flows of emulsions, extension to turbulence and linking to CFD. Rheology of dense emulsions depends on the maximum packing volume fraction that increases with increased deformation of droplets.

3. Conclusion

It has been shown that flow structure affects several chemical engineering processes. A possible way to model these effects is to use the second invariants of the rate-of-strain tensor and the rate-of-rotation tensor. Examples of new results based on proposed approach are presented.

Energy and Chemical Engineering

Impact of variation of rheological properties on pressure drop calculation

Ehsan Farno[1], Nicky Eshtiaghi[1,*]

1 Chemical and Environmental Engineering, School of Engineering, RMIT University, VIC, 3000, Australia

**Corresponding author: nicky.eshtiaghi@rmit.edu.au*

Highlights

- Impact of variation of rheological properties on pressure drop calculation
- Adopted Re3 friction loss model from mineral industries into sewage sludge

1. Introduction

Wastewater treatment is an integral part of the sustainable development of modern cities. Factors such as population growth, water shortage and stricter environmental regulations demand a considerable increase in increasing the capacity of treatment plants as well as improving its efficiency [1].

A large portion of the total energy consumption in wastewater treatment plants is used for pumping wastewater sludge within the treatment processes [2]. Although the energy usage of the sludge transportation systems is critically important, pumping systems are not commonly operating in their best efficiency points. By improving the pumping systems, better energy efficiency of treatment processes can be achieved. Several reasons underlies the inefficient operation of sludge pumping systems. One of them is the variation of sludge rheology which sometimes can be an order of magnitude difference. It is vitally important to identify the impact of rheological variations on the variation in pressure drop of sludge pipeline to be designed. This is even more important for concentrated sludge as it is highly non-Newtonian and, because of that, the pressure drop is more sensitive to the variation of rheological parameters. This paper investigates the impact of variation of sludge rheology on the calculation of pressure drop for highly concentrated sludge pipeline.

2. Methods

Digested sludge was collected at the concertation of about 2% from Eastern Treatment Plant, Melbourne over one year. Sludge was concentrated to 4% and 5.5% using vacuum filtrations process. Samples flow curve was measured using controlled-stress rheometer equipped with a cup-and-bob (with 1 mm gap) and a vane-and-rough cup (with 8 mm gap) geometries for dilute and concentrated sludge, respectively. Flow curve was fitted with the Herschel-Bulkley model using the robust least-squares method of MATLAB.

3. Results and discussion

Figure 1.a depicts the variation in rheological parameters of sludge over the measurement period. And Figure 1.b shows the variation in calculated pressure drop for a typical sludge pipeline resulted from the variation of rheological parameters.

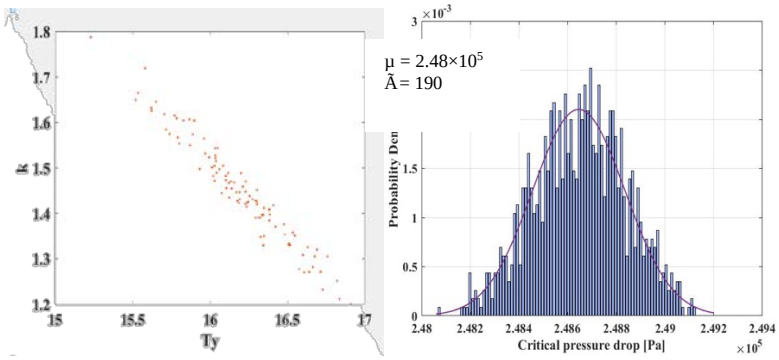

Figure 1. (a) Variation in rheological parameters of sludge (b) variation in calculated pressure drop

Table 1 presents a sensitivity analysis of the pressure drop calculation procedure in respect to variation in the model parameters. As shown in Table 1 [3], pressure drops were mostly correlated to the variation of *k* while variation in τ_H was the least influential factor on the calculated pressure drop.

Table 1. sensitivity analysis of pressure drop calculation procedure

Model parameter	τ_H	*k*	*n*
Sensitivity	*5%*	*60%*	*33%*

Table 2 shows variations of pressure drop as a results of increasing solid concentration. This is almost four times when solid content of sludge increases from 2.3% to 4% and it is doubled for increase of solid content from 4% to 5.5%. Besides, the flow regime will change from turbulent to laminar as Reynolds number drops to below 1600 and 800 for 4% and 5.5% digested sludge, respectively.

Table 2. variation in calculated pressure drop [kPa] for the nominated pipeline

TS	24.6 L/s	40.8 L/s	$Reynolds_3$*
2.3%	263 ±50	263 ±50	8500 - 20000
4%	1041 ±80	1041 ±80	300 - 1600
5.5%	1914 ±100	2034 ±100	150 - 800

4. Conclusions

Results compare the variation in the calculated pressure drop between different sludge concentrations. This study shows that a small variation in rheological parameters of concentrated sludge creates large variations in pressure drop calculation. This variation needs to be considered for the accurate design of sludge pipelines.

Comparison between a Rocking and a Stirred Bioreactor Concerning Particle Stress in a Liquid-Liquid Model System

Robert Panckow[1]*, Chrysoula Bliatsiou[1], Lutz Böhm[1], Michael Muthig[2], Sebastian Maaß[2], Matthias Kraume[1]

1 Chair of Chemical and Process Engineering, Technische Universität Berlin, Fraunhoferstr. 33-36, 10587 Berlin, Germany; 2 SOPAT GmbH, Boyenstraße 41, 10115 Berlin

Highlights

- Mixing concept determines hydro-mechanical stress on particles in bioreactors.
- Liquid-liquid model system substitutes biological system.
- New image analysis by neural networks provides faster and more accurate results.
- Particle analysis tool provides distinction between different disperse phases.

1. Introduction

High mechanical power input to achieve fast heat and mass transfer can damage a present disperse phase, with cells and cell agglomerates being of interest in biotechnology. An efficient mixing system which gives even suspension with gentle stirring and does not generate high shear forces results in a homogeneous culture environment. In this study, fluid-mechanical particle stress is characterized by application of a two-phase model system with liquid disperse phase.

2. Methods

Comparatively, the investigations were carried out in a rocking single-use bioreactor (CELL-tainer® 20L, Celltainer Biotech BV) and in a DN160 stirred tank with torispherical bottom, see **Fig. 1**.

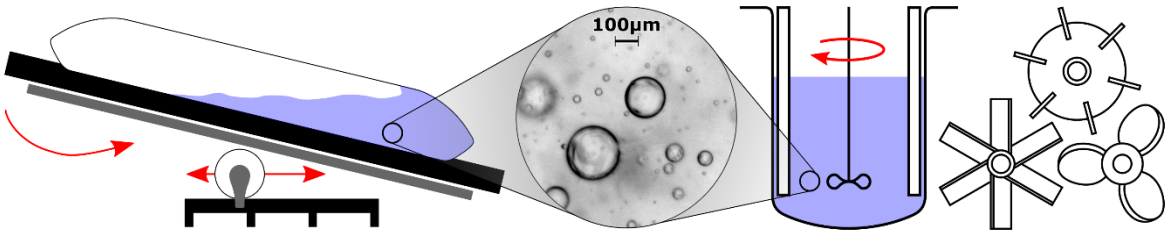

Figure 1. Motion concept of CELL-tainer® 20L (left), recording of drop sizes (middle), DN160 stirred tank with torispherical bottom (right).

The disperse droplet phase consisted of Mobil EAL Arctic 22 refrigerator oil having a density similar to the continuous phase [1]. By variation of working volume V, rotational frequency k and rocking angle φ (CELL-tainer) as well as stirrer geometry and stirrer frequency n (stirred tank), the droplet sizes of the disperse phase were recorded in situ by means of photo-optical particle analysis technology from SOPAT GmbH [2, 3], see **Fig. 1** (middle). Measurement of the two-dimensional raw image data by automated image analysis provided the droplet size distribution. New

implementations of image analysis algorithms based on neural networks yielded faster and more precise size measurements with classification of the detected particles.

The fluid dynamic investigations by particle image velocimetry (PIV) in the stirred vessel and by computational fluid dynamics (CFD) for both reactors support the understanding of the experimentally determined droplet breakage. In the stirred vessel, only the liquid phase was modeled, whereas in the CELL-tainer simulations the volume of fluid (VOF) method was applied to describe the two-phase flow. For both reactors, the RANS-based k-ε turbulence model was used. The velocity vector fields provide the basis for a coordinate transformation towards the flow direction along the streamlines to calculate shear and elongation gradients.

3. Results and discussion

The droplet breakage caused by different wave motion due to various operating points in the CELL-tainer and by the investigated stirrers in the stirred tank was monitored for the model system. The dynamic destruction kinetics were recorded, with the steady-state droplet diameter characterizing the particle stress. Noticeable, the measured drop sizes in the CELL-tainer show higher values as compared to the stirred tank for the investigated range of operating conditions and thus, indicate less particle stress. For the comparison of different stirrer geometries, axial stirrers show higher droplet breakage than radial pumping ones.

4. Conclusions

Due to the high sensitivity of the photo-optical measurement system, a precise differentiation of operating points was possible. The new algorithms could not only detect the desired droplets, but also were able to distinguish between different dispersed phases, for example disturbing bubbles. The dynamic destruction kinetics for different operating points of both reactor types in combination with the particular flow fields give new insights into the transferability of cell cultivation between the two reactor types.

Effect of bubble dynamics and bubble induced turbulence (BIT) on chemically reacting bubbly flows

Manuel Taborda, Martin Sommerfeld

Multiphase Flow Systems, Institute for Process Engineering, Otto-von-Guericke-University Magdeburg; Zeppelinstraße 1, 06130 Halle (Saale), Germany

**Corresponding author: e-mail: manuel.taborda@ovgu.de*

Highlights

- Point-particle Euler/Lagrange method for reacting bubbly flows.
- Tumbling bubble rise model and shape oscillations.
- Sub-grid-scale Turbulence modification modeling.
- Validation for single bubble rise with mass transfer.
- Validation for a laboratory column with chemisorption of CO_2 in NaOH solution.

1. Introduction

Bubble columns as multiphase reactors are commonly used in industry since they yield a high contact area, which affects directly the required mass transfer. Nevertheless, the flow structure and bubble behaviour are very complex so that appropriate modelling in the frame of numerical calculations is still today a challenge, especially when mass transfer and chemical reactions are involved. Bubbles from a certain size show oscillations in the shape and a zig-zag/helical motion, which cannot be captured by classical Lagrangian models anymore. In order to do so, the bubble dynamics should be taking into account not only for the momentum, but also for the mass transfer and chemical reactions.

2. Numerical method and modelling

Based on the Euler/Lagrange approach, numerical predictions of bubble columns were conducted, where all the relevant forces acting on bubbles, such as drag, transversal lift, virtual mass, fluid inertia, wall, Basset and naturally gravity/buoyancy were considered. A stochastic modification of bubble eccentricity and motion angle is used to mimic oscillations (Sommerfeld et al., 2018). The effects of such bubble dynamics on mass transfer were modeled through a dynamic Sherwood number (Montes et al., 1999). Large Eddy Simulation (LES) was used for modeling flow and turbulence of the carrier phase, considering not only the effect of sub-grid-scale (SGS) turbulence on bubble motion (Lipowsky & Sommerfeld, 2007), but also BIT modification by bubbles (Lain et al.; 2002, Sommerfeld, 2001; Sato & Sekoguchi, 1975). SGS turbulence effects were also taken into account through modification of the diffusion coefficient in the species equation. With an analogy to the turbulent dispersion model, SGS variations on the bulk concentration seen by the bubble were also considered.

3. Results and discussion

The model validation was performed by comparing the results with experimental data (hydrodynamic and species transport) present in the Literature (Sommerfeld and Bröder, 2009; Merker et al., 2017; Darmana et al., 2007). The performance of the involved different models, bubble induced turbulence, bubble dynamics, dynamic Sherwood number were tested for these different cases. Good agreement with the experimental observations, not only with regard to the liquid dynamics but also with volume change of single bubbles in time and concentrations of participating species in the bubble column. This was only possible when bubble dynamics in the frame of Euler-Lagrange approach was considered, even with point-particle approximation. The decay of volume from CO_2 single bubbles rising in water were compared with data presented in the literature and good agreement was found. A comparison with experiments of bubble swarms and chemical reactions was also realized. In this case, the predicted decay of pH due to chemisorption of CO_2 in a NaOH solution was satisfactory only when bubble dynamics and enhancement factor were considered.

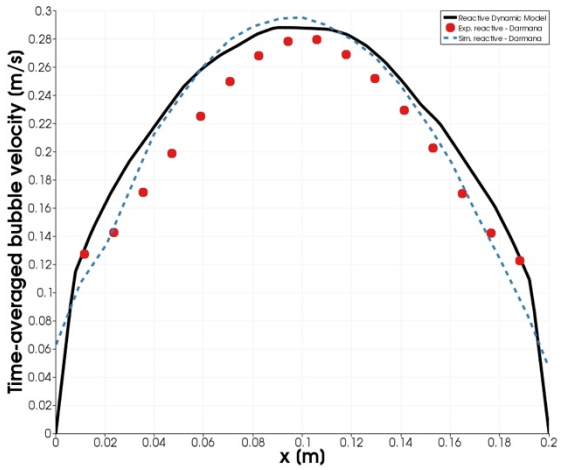

Figure 1. Time-averaged bubble velocity profile at z/H = 0.75.

Highlights

- Vertical slug flow in stagnant and flowing liquids.
- Semi-analytical methods for slug bubble shape determination.
- Effect of inertia, surface tensions, and viscosity on bubble shape and velocity.

1. Introduction

Co-current vertical slug flow is present in numerous fields of applications, among which the transportation of hydrocarbons into pipelines, the promotion of mixing in reactors, the filtration through membranes, or emergency cooling of nuclear reactors are some practical examples. Simplified mechanistic models together with adequate closure laws seem to model satisfactorily vertical slug flow for most industrial purposes. Hence, a prolific number of closure relations have been developed on the terminal slug bubble velocity or the slug void fraction, but few focused on the characterization and the prediction of the slug bubble shape. However, terminal velocity and the shape of the nose are intimately linked, and most closure relations can benefit a better characterization of the slug bubble shape. Semi-analytical (the final analytical set of equations is solved numerically) methods have been reviewed and predictive slug bubble shapes have been computed with respect to flowing liquid velocities and surface tensions. Extended methods to include viscous forces into the predictions have also been studied.

2. Results and discussion

Dumitrescu [5] was one of the first to derive the slug bubble shape and velocity using a couple resolution of the Stokes stream function $\psi(\xi,\eta)$ given by potential flow theory and Bernoulli's equation on the bubble surface. He concluded with an impressive accuracy that the square of the rising velocity U_B of an elongated bubble in a stagnant liquid with negligible surface tension was proportional to the acceleration due to gravity g and the pipe diameter D, leading to a Froude number $Fr = 0.351$.

Ever since, his methodology was extensively used ([4], [9], [3], [1], and [8]) on problems with increasing complexity, taking for instance into account the effects of a flowing liquid ([9], [3], [1], and [8]) and turbulent velocity profiles ([3], and [1]) in terms of Reynolds number, and the effects of surface tension ([9], [1], and [8]) in terms of Eötvös number. These works can be grouped in two resolution methods: the Power Series resolution (PSR) used in [1], [4], [5] and [9], and the Total Derivative method (TDM) used by [3] and [8]. It is also worth mentioning that more recently the viscous potential flow theory was used in [7] and [6] in order to determine the shape and the

velocity of a deformable spherical cap and an ovary ellipsoid respectively. The bubble shape for an air bubble in stagnant water was computed on Fig. 1 using the PSR solution. This result can be extended to different values of surface tensions as shown in Fig. 2 where the resulting velocity is compared to experimental data for different methods of resolution.

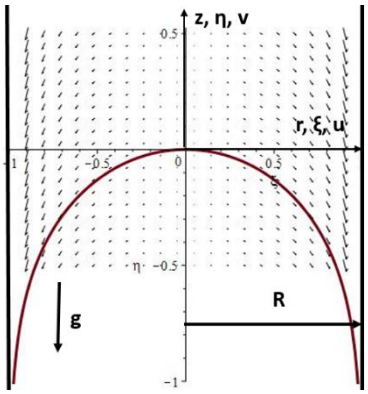

Figure 2. Computed bubble shape and velocity field around it in the moving frame coordinate system.

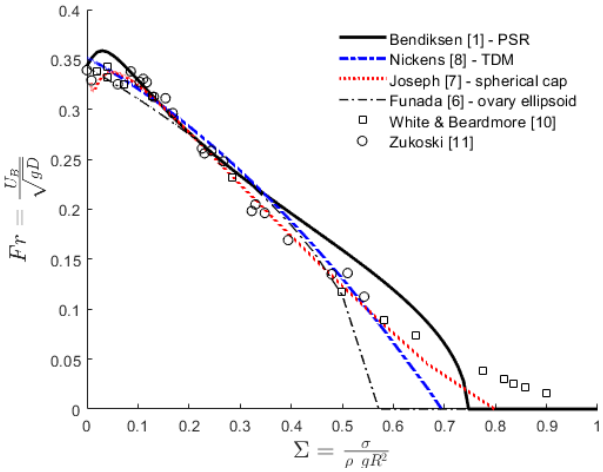

Figure 1. Dimensionless slug bubble velocity in function of surface tensions. Comparison to experimental data.

3. Conclusions and perspectives

The slug bubble shape can be computed using semi-analytical methods and the resulting rising velocity seems to be in agreement with experimental data for small values of surface tensions. For smaller tube diameters, the curvature of the bubble surface and the increasing importance of the liquid film (viscous zone) is in contradiction with potential flow hypothesis and require a specific theory of the kind of Bretherton's [2] in order to accurately predict the film thickness of the developed zone. A new resolution method can thus be found considering both potential flow at the vicinity of the bubble nose and the effects of the draining film at a binding distance $l_{nF}(Eo, Re, Mo)$ of the bubble tip depending on the properties of the system.

**takana@tohoku.ac.jp*

Highlights

- Ionic liquid electrospray characteristics have been clarified by high speed imaging. Ionic liquid electrospray behavior can be categorized into four modes depending on applied voltage and feeding flow rate.
- Ionic liquid electrospray produces nano droplets and it was successfully demonstrated that ionic liquid electrospray enhances CO_2 absorption even at low CO_2 concentration.
- The absorbed amount of CO_2 for 20 minutes increases by 220 % by ionic liquid electrospray.

1. Introduction

Ionic liquids (ILs) are ambient temperature molten salts, which generally consist of a bulky organic cation and organic/inorganic anion. ILs exhibit unique characteristics such as non-volatility, non-flammable, thermal and chemical stability. Moreover, ILs have drawn great attention as a potential CO_2 absorbents. ILs capture CO_2 chemically and reversibly desorb CO_2 by heating.

Since CO_2 chemical absorption occurs at the gas-liquid interface, the absorption rate can be enhanced by increasing the specific surface area. In this study, nano order IL droplets are generated by electrospray with aiming enhanced CO_2 chemisorption. The characteristics of IL electrospray were experimentally evaluated and the effect of applied voltage on the CO_2 absorption performance was discussed with correlating to spray behavior.

2. Methods

Schematic illustration of experimental setup is shown in Fig. 1. Both upper and lower flanges of an acrylic chamber with volume of 50.3 cm^3 has gas inlet and outlet ports of 4 mm in diameter. The CO_2/N_2 gas (1.03% CO_2) and N_2 gas (≥ 99.999%) is introduced in the changer and flows out from the outlet port. CO_2 concentration is monitored by CO_2 analyzer (VAISALA GMP252) at downstream of outlet port. The capillary tube made of a fused silica (ID: 100 µm, OD: 375 µm, GL Sciences) was used as a nozzle. Positive DC high voltage was applied to the capillary nozzle with the counter ring electrode grounded. The electrode gap distance between the center of ring electrode of nozzle tip was set to be 6 mm. 1-ethyl-3-methylimidazolium acetate

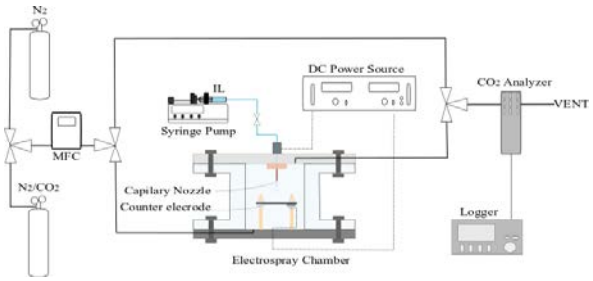

Figure 1. Schematic illustration of experimental setup.

([EMIM][Ac], ≥ 95.0%, SIGMA-ALDRICH) was used in this study as an absorbent. Droplet size distribution was optically measured by aerosol spectrometer (WELAS 2070 PALAS) for the sampling time of 30 seconds. Electro spray behavior was characterized by taking high-speed shadow graph images at the flame rate of 4000 fps (FASTCAM SA-X2, Photron). In the CO_2 absorption experiments, CO_2/N_2 premixed gas was supplied at a constant flow rate of 20 ml/min.

3. Results and discussion

Fig. 2 shows shadow graph images taken by high speed camera. IL spray can be categorized into 4 modes depending on applied voltage and flow rate. The mode I is referred to as "dripping mode" with rather large droplets of ~0.2 mm. The mode Ⅱ generates not only large droplets like mode I but also fine droplets through breakup of the liquid thread extended from the Taylor cone. In mode Ⅲ, ultrafine droplets are continuously generated from the liquid thread tip due to electrostatic repulsion. The typical droplet size distribution of model III is shown in figure 3. The peak diameter of 255 nm is generated in this mode. The mode Ⅳ is observed at a relatively high voltage when corona discharge appears around the Taylor cone. Since ionized gas layer shields electric field at the tip of the ionic liquid thread, larger droplet is primary generated just like mode II followed by finer droplets generation by secondary breakup due to high electric field. In the following experiments, the ionic liquid flow rate was fixed at 2 mL/h.

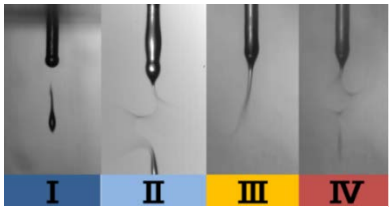

Figure 2. Observed spray modes in ionic liquid electrospray.

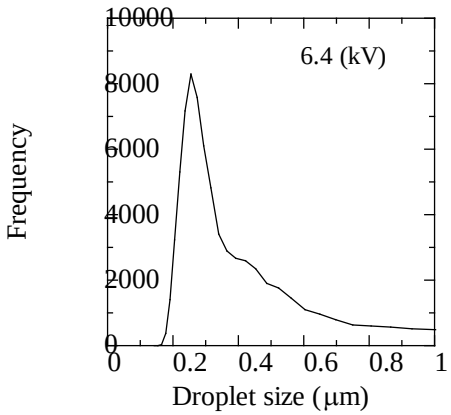

Figure 3. Droplet size distribution in mode III.

Fig. 4 shows the time traces of CO_2 concentration. When 8.0 kV is applied (mode IV), CO_2 concentration rapidly decreases at the initial period. The reaction rate in this case enhanced by approximately 10 times compared to the case without applied voltage. The absorbed amount of CO_2 for 20 minutes also increases by 220 %. When shutting down IL supply and applied voltage, CO_2 concentration recovers. Slower increase in 8.0 kV is because of the attached fine droplets remains on the chamber wall. From this result, it has been clearly shown that atomization of ionic liquid by electrostatic spray enhances the CO_2 absorption even under low CO_2 concentration conditions.

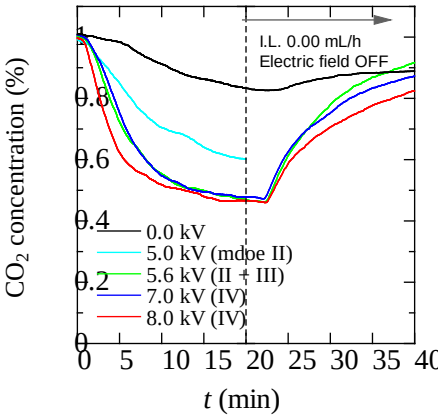

Figure 3. Time traces of CO_2 concentration with various applied

4. Conclusions

The characteristics of IL electrospray was clarified using high-speed imaging and the effect of IL electrospray on CO_2 absorption was shown with correlating to the spray characteristics.

Mixing and its influence on the precipitation of organic nanoparticles from the liquid phase: A Lagrangian perspective

Tobias Schikarski[1]& Holger Trzenschiok[1], Marc Avila[2], Wolfgang Peukert[1*]

1 Institute of Particle Technology, Friedrich-Alexander Universität Erlangen-Nürnberg; 2 Center of Applied Space Technology and Microgravity, Universität Bremen

Highlights

- Precipitated nanoparticles of Ibuprofen down to 25nm
- Precise simulations of liquid mixing in a T-mixer
- Prediction of trend of particle size and shape of PSD with Lagrangian mixing

1. Introduction

Mixing is key for the fast precipitation of organic **[1]** and inorganic **[2]** compounds because it determines the supersaturation build-up, which in turn governs the primary particle formation steps such as nucleation and diffusion-limited growth **[1,2].** Due to the naturally very small diffusivities of liquid mixtures, turbulence is primarily chosen to impose fast and well mixing because of its spatio-temporal randomness and the cascade of various length scales. To accurately model precipitation, turbulent mixing needs to be well captured in simulations.

In our recent study **[3]**, we achieved excellent qualitative agreement in the mixing efficiency of a simple T-mixer between experiments and direct numerical simulations (no turbulence modeling) over a wide range of Reynolds numbers *Re=(100,4000).* Despite the newly gained insights into the mixing process, analysis of the influence of the mixing on the particle size distribution (PSD) of organic nanoparticles, resulting from precipitation experiments at various flow rates, is still missing. In doing so, we study the mixing behavior along Lagrangian trajectories and relate the findings to the experimentally obtained PSDs. It appears that this approach allows to qualitatively predict the trend of the mean particle size as well as the width of the PSD without any precipitation modeling, which is very challenging itself.

2. Methods

A simple T-mixer is used to mix an alkaline aqueous ibuprofen solution with an acidic aqueous Zirconium chloride solution, which triggers the precipitation of Ibuprofen while Zr-ions stabilize the formed particles. The resulting stable nanoparticle suspensions are analyzed with dynamic light scattering to obtain the PSD. Note that the fluid properties of the water-water mixture are not affected by the chemicals as well as the excellent particle stability prevents ripening or aggregation. The numerical approach consists of direct numerical flow simulations of the mixing process solving for the Navier-Stokes (velocity) and the convection-diffusion equation (composition). An empirical-free approach is here applied which does not require any turbulence modeling. Lagrangian trajectories are computed by solving $\frac{\partial x_i}{\partial t} = \boldsymbol{u_i}$, where x_i and $\boldsymbol{u_i}$ are the

position and velocity vector of the i^{th} trajectory, respectively. Details on the mixing and precipitation experiments as well as on the flow simulations can be found in **[3,4]**, respectively.

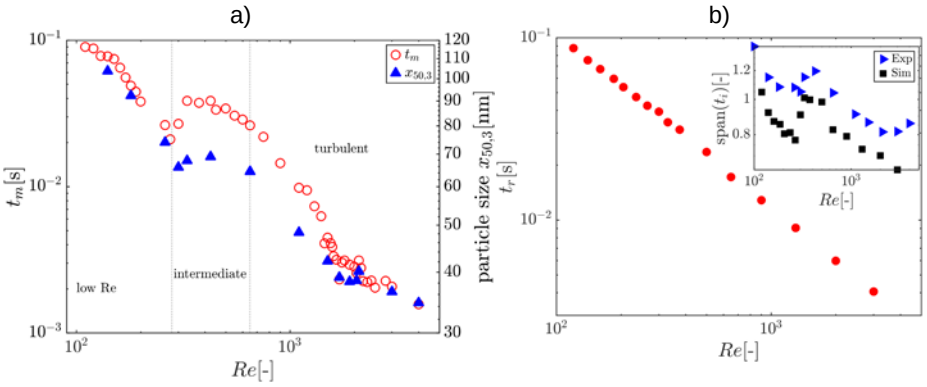

Figure 1. (a) Experimentally measured and computationally estimated mixing time t_m (left y-axis) and median particle size $x_{50,3}$ (right y-axis) as a function of Reynolds number Re. (b) Mean residence time t_r as a function of Reynolds number Re. The inset compares the width of PSD to that of the RTD.

3. Results and discussion

The supersaturation is the thermodynamic driving force of precipitation, which is determined by the rate the two fluids are brought in contact with each other. Thus, the primary particle formation steps nucleation and growth are mixing controlled under the assumption of fast chemical reactions, and the outcome should reflect the mixing efficiency when a sufficient stabilization is applied. This prevailing view is substantiated in Fig. 1a), which depicts a nearly perfect alignment of the experimentally determined mixing efficiency t_m by the Villermaux-Dushman reaction **[3]** with the median particle size $x_{50,3}$ as Reynolds number increases.

In the chemical engineering community, it is common to relate the reaction outcome with the residence time and its distribution. Having a large number of Lagrangian trajectories, the residence time distribution (RTD) can be precisely calculated by simulations. Fig. 1b) shows the mean residence time t_r as a function of the Reynolds number. It turns out that the qualitative trend of the mixing efficiency and likewise of the median particle size induced by alteration of flow structures are not featured by the mean residence time. However, comparing the widths of PSDs with these of RTDs, the qualitative trend is very well captured. This finding suggests that the shape of the PSD is determined by the spatial distribution of large-scale flow structures while the trend of the mean particle size depends primarily on local changes of the fluid composition.

4. Conclusions

In the talk, we will detail the experimental and numerical findings of the comparative study of the precipitation and Lagrangian mixing, respectively. In particular, we will demonstrate how to analyze the fluid composition to predict the qualitative trend of the median particle size. Furthermore, we will address the influence of inflow condition and different mixing fluids.

Highlights

- Detailed experiments on slurry bubble columns hydrodynamics
- Flow regimes in slurry bubble column and their transitions: effect of liquid level and solid particles concentration
- Modelling slurry bubble columns hydrodynamics under HoR, TrR, HeR and PHeR

1. Introduction

Bubble columns and sparged gas-liquid systems have wide application in chemical industry and in biotechnology, being slurry bubble column (SBC) is a special case of three-phase gas-liquid-solid. In most applications, SBC are operated under pure heterogeneous hydrodynamic regime (non-uniform, churn turbulent). However, operation of slurry bubble columns (SBC) in homogeneous regime (uniform, laminar) may be preferred in some cases like in the intensification of catalytic reactors using special distributors [1] or to secure low level of shear stresses in some bioapplications [2]. Most of the research on SBC is however dedicated to pure heterogeneous regime (PHeR) and very little attention has been paid to HoR. In the present contribution we will present a systematic study of the hydrodynamic behavior of SBC equipped with “fine sparger”, able to give homogeneous and heterogeneous regime and transition between them.

2. Methods

This experimental study focused on the flow regimes and gas holdup behavior in a lab-scale slurry bubble column (vertical plexiglass cylinder, diameter 0.14 m, total height 2 m). The gas distributor was a fine perforated brass plate (orifices with 0.5 mm diameter, free plate area 0.19 %), producing both homogeneous (HoR) and heterogeneous (HeR) flow regimes, and the transition between them (TrR). The three-phase gas-liquid-solid mixture was composed of local air, tap water and fine porous silica particles (size 100 µm). The gas holdup e was measured by bed expansion method, using free layer height evaluated visually or by digital image analysis. Three experimental parameters were tested: gas input q, initial slurry layer height H and concentration of solid particles c.

3. Results and discussion

The gas holdup e depends on the gas input q, layer height H and solid content c. From the holdup data measured, flow regimes were identified and the transition points were determined. The reference system for our study is the two-phase system c = 0 % and 0.8 m layer height, presented

in Fig 1 (a). In this system, the bubble column gives three regimes with two transition points, depending on the gas input q. Increasing the layer height and the solid load reduces the gas holdup and destabilizes HoR. At low solid load (c < 3%) all three regimes exist, depending on q. At solid load higher than c ≥ 3% only one regime exists, pure heterogeneous regime. The main findings are resumed in the flow regime map in Fig. 1 (b). Existing model equations, derived for two phase systems [3], were adapted to take in consideration the presence and concentration of the third phase (suspended particles). The parameters of the models have physically meaningful parameters such as terminal velocity or factor of flow non-uniformity and they can be proved by auxiliary visualization experiments.

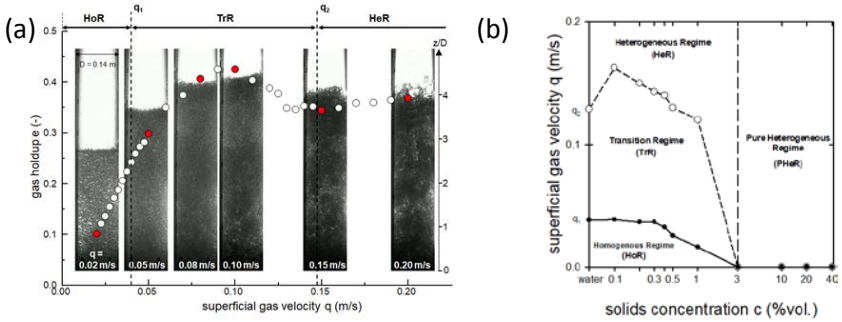

Figure 1. (a) Identification of flow regimes (HoR, TrR, HeR) and critical points (q1 and q2) of flow transition, based on images of bubble column and gas holdup data; (b) Flow regime map for slurry bubble column (SBC).

4. Conclusions

The present study is based on visualization experiments, for determination of gas holdup and flow regimes, and intends to improve our understanding of the dynamics of slurry bubble columns generated by “fine spargers”. The main result of the study is a flow regime map with three parameters, q, H and c.

Integrated Biofilm Reactor-Separator Using a Rotating Spiral Channel

Jordan MacInnes and Esther Karunakaran

Chemical and Biological Engineering, University of Sheffield, Mappin Street, Sheffield S1 3JD

**Corresponding author: j.m.macinnes@sheffield.ac.uk*

Highlights

- Rotating spiral channel controls liquid-liquid contact between media and solvent
- Allows continuous control of nutrient and product concentration
- Preliminary result will be presented to demonstrate feasibility

1. Introduction

Industrial biotechnology aims to use microorganisms to transform one chemical species to another. Engineering systems to control the supply of nutrient species and the removal of product species must optimise production rate per cost. For continuous processing by biofilms - an aggregate of microorganisms attached to an abiotic surface[1] - a surface must be provided with access to a flow of aqueous media to both sustain the biofilm and remove waste. The aqueous flow should be even over the biofilm, have a thickness that allows all of the media to be accessed and have a flow rate that is suited to the biofilm production rate. Indeed, the media supply may be used to optimise production conditions. It may also be helpful to bring a second, immiscible, liquid into contact with the aqueous phase to help control conditions in the medium, not least to separate the product species.

A rotating spiral channel allows such an arrangement of biofilm, aqueous media and an immiscible solvent liquid. The spiral channel rotating around its axis segregates the two fluid phases into parallel-flowing layers of adjustable flow rate and interface position. Fig. 1a shows a schematic of a typical cross-section of the channel. The biofilm is shown on the left hand side wall, stabilised there by the strong radial acceleration ($r\Omega^2$) and in contact with the denser aqueous media, which in turn is in contact with an organic solvent. The media and solvent are flowing in the direction perpendicular to the section, either co-currently or counter-currently.

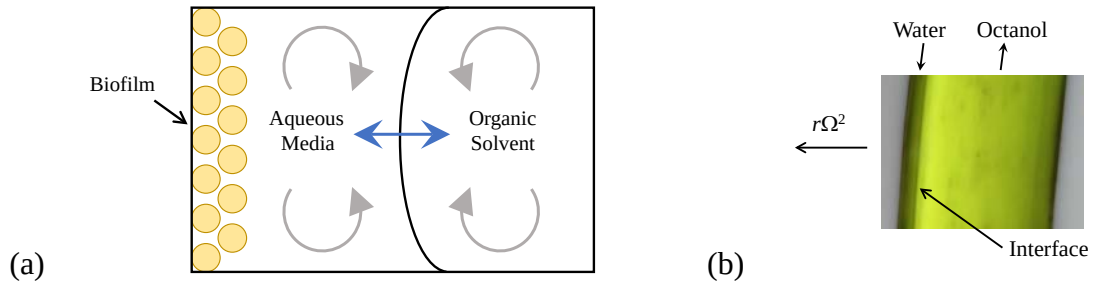

Figure 1. (a) Channel section with biofilm (on the left), aqueous media and solvent. Grey arrows indicate the secondary flow[5] (from centrifugal and Coriolis accelerations) that assist species transfer. (b) Photograph taken from below of water and octanol flowing counter-currently in a rotating spiral channel.

2. Background

Rotating spiral channels allow contacting of two immiscible fluids at the optimum flow rate ratio of the two phases and ratio of the thicknesses of the two fluid layers[2]. Mass transfer coefficients that are orders of magnitude greater than those with conventional contacting methods have been demonstrated[3]. While that work considered gas-liquid contacting, ideal theory[4] predicting interface position and flow rates in relation to fluid properties, rotation rate, pressure gradient and channel size applies equally to liquid-liquid and gas-liquid flows. Indeed, a number of informal tests with the same apparatus used for the gas-liquid work[2,3] confirm it handles liquid-liquid contacting equally well. Fig. 1b shows an image from a test with water and octanol contacting counter-currently. The relatively high viscosity of the octanol means it occupies the majority of the channel cross section for the conditions of the test. This is predicted by the model which also shows that the interface could be moved to other positions by suitable choices for pressure gradient and rotation rate, while maintaining correct solvent flow rate, e.g. that to fully remove the product.

3. Concentration control

Product concentration will vary with position (z) along the channel both as it accumulates from biofilm production and as the product transfers to the solvent. Co-current flow of the solvent results in a steadily increasing product concentration (C) along the channel (Fig. 2a). By contrast, with counter-current flow of the solvent phase the concentration in the aqueous phase first increases rapidly as product is gained from the loaded solvent and then decreases as pure inlet solvent is encountered (Fig. 2b). Consequently, the biofilm media will have a more uniform bulk concentration. Increasing solvent flow rate is expected to reduce product concentration levels in the aqueous phase; decreasing channel size is expected to increase concentration uniformity. Thus, considerable control of product concentration in the biofilm environment should be possible.

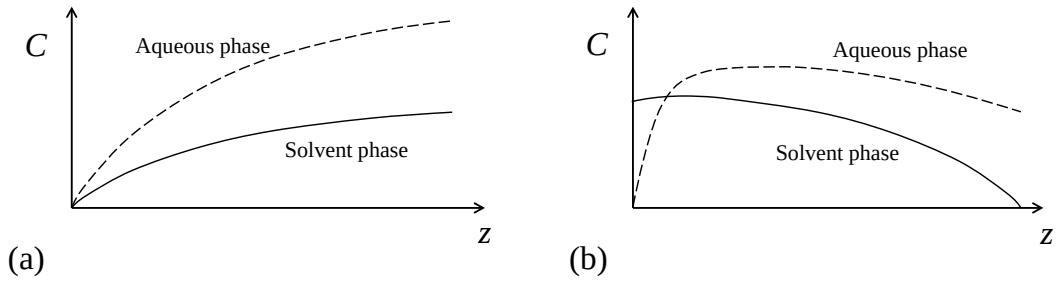

Figure 2. Product concentration profiles along the channel for (a) co-current and (b) counter-current flow of solvent.

4. Conclusions

An existing and proven apparatus[2.3] will be used to produce continuous biofilm processing in a rotating spiral channel with simultaneous product extraction into a counter-flowing solvent stream. A preliminary assessment will be presented at the congress.

Numerical simulation of a high-shear cone mill mixer for food emulsions production

Antonio Buffo[1], Marco Ferrari[1], Gianluca Boccardo[1], Daniele Marchisio[1]

1 Department of Applied Science and Technology, Politecnico di Torino, Torino, Italy

**Corresponding author: antonio.buffo@polito.it*

Highlights

- A CFD analysis of a cone-mill mixer for food emulsions production is carried out
- Development of an open simulation platform for a modelling marketplace
- Qualitative analysis of the result sees a match with experimental data

1. Introduction

Mayonnaise belongs to the family of high disperse phase liquid-liquid emulsions and the prediction of the final droplet size distribution is crucial for determining the properties of the final product, such as structure, stability over time, taste and color. The production of mayonnaise is a typical mixing process, in which the ingredients (i.e. egg yolk, vinegar, oil and water) are first brought together and mixed in large stirred vessels at moderate rotational speed. Then the formed emulsion is finally fluxed into a high-shear mixer, where the droplets undergo breakage until the final size distribution is reached; this last step is crucial to fine tune the droplet size distribution, in order to have a final product with the desired features. In this work, we aim to simulate the last step of the production process by means of a Computational Fluid Dynamics approach coupled with a Population Balance Model (CFD-PBM) [1], to properly describe both the non-Newtonian dynamics of the emulsion and the evolution of the droplet size distribution. This methodology is eventually validated with experimental data available in the literature [2,3]. This work focuses on the macroscale of a more complex multiscale simulation, where the interfacial properties and the rheology of the emulsion are also predicted using a numerical approach. This particular workflow will be useful to develop an open simulation platform for generic multiscale and multiphysics simulations, where the computational codes aiming at different parts of the physics are linked and coupled. This will be the main component of a marketplace for modelling of materials and chemical processes.

2. Methods

A schematic representation of the investigated high-shear mixer, i.e. a cone mill mixer, is reported in Fig. 1. As it can be seen, it is constituted of a solid conical frustum rotor inside of a slightly larger stator of the same shape, forming a small gap in which the emulsion flows (moving from the lowest radii section to the largest) and experiences high-shear rates.

From a computational point of view, this geometry was preliminarily reproduced using a two-dimensional grid, exploiting the intrinsic symmetry of this system. The fluid was considered as a

shear thinning pseudo single phase, with an apparent viscosity evaluated through a power law model fitted with experiments [2]. However, the feasibility of more sophisticated approaches (such as three-dimensional simulations and two-phase models) will be evaluated in the future. The simulations are carried out with the open source CFD code OpenFOAM (version 6.0).

3. Results and discussion

As expected, the preliminary simulations show a high velocity gradient due to the high rotational speed, in particular the highest velocity corresponds to the tip velocity of the rotor: this can be seen in Fig. 2. Another interesting result is reported in Fig. 3, where the axial velocity profile at the middle section is reported: as it can be seen the emulsion flows in the downward direction but there is a small backflow close to the stationary wall, which is evidence of the presence of recirculation patterns typical of these systems. A qualitative analysis shows good agreement with the experimental data.

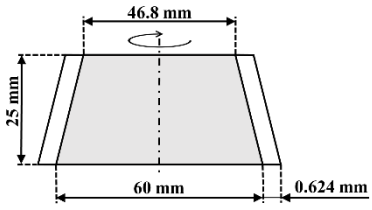

Figure 1. Sketch of the cone mill mixer.

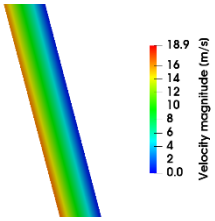

Figure 2. Contour plot of velocity magnitude magnified around the central part of the mixer

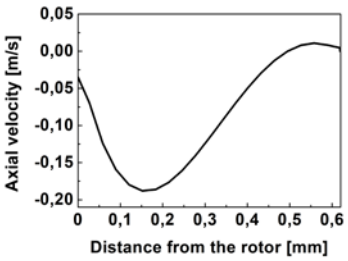

Figure 3. Axial velocity profile at the middle section

4. Conclusions

The first results regarding the fluid dynamics description of the cone mill are promising, as the behavior of the high-shear mixer is properly reproduced. The next step will be the solution of the Population Balance Equation (PBE), in order to account for the droplet breakage induced by the high-shear rates inside the mixer. This will be useful to predict the final droplet size distribution by using a fully-predictive approach.

Highlights

- Mixing of two parallel vertical bubbly flows of various superficial liquid/gas velocity
- Bubble image velocimetry approach to study mixing patterns
- Gas fraction and bubble velocity measurements using optical fiber probes

1. Introduction

Gas liquid contacting is one of the most important operations in the chemical and biochemical industry. Aerated vessels offer a high degree of mixing, heat and mass transfer, while local shear rates are relatively low. Computational Fluid Dynamics are widely used to assist in the design of new (bio)-reactors. The on-going development of these numerical models, often on the basis of a single bubble size, requires precise experimental data for validation purposes. We present experiments on the mixing pattern of two parallel bubbly flows with an almost uniform (initial) bubble size distribution.[1] We studied mixing patterns of both a uniformly and non-uniformly aerated rectangular flow channel, with and without vertical liquid co-flow.

2. Methods

Fig. 1 shows a sketch of the bubbly flow channel. Two separate parallel bubbly streams (Left and Right) are mixed in a rectangular flow channel after the trailing edge of the splitter plate. The superficial gas and liquid velocities, for each of the inlet compartments, is in the range 0.5-6.25 and 0-50 cm/s, respectively. Large uniform bubbles, 4-8 mm in diameter, are formed by needle spargers[2] to yield an overall void fraction in the range 2 - 25 %. We studied the mixing pattern

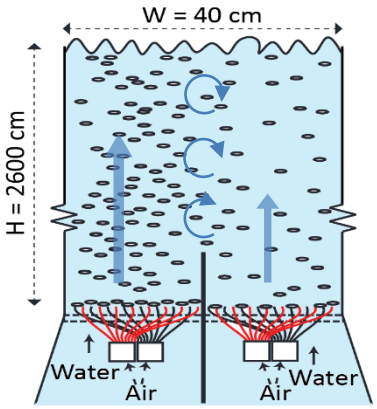

Figure 1. Sketch (not on scale) of the mixing of two parallel bubbly flows with different superficial liquid/gas velocities.

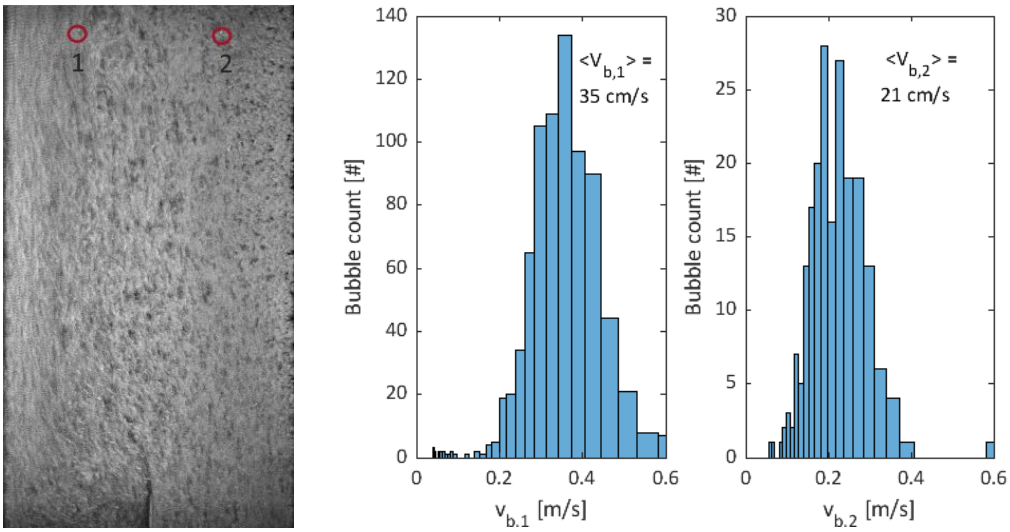

Figure 2. Left: Visualization of bubble streaks. Higher superficial gas velocity on the left size of the column. Bubble probe positions are denoted with a circle. Right: bubble velocity histograms of both monitoring points.

downstream the trailing edge of the splitter plate as a function of the inlet superficial gas and liquid velocities using dual-tip optical fiber probes (local void fraction, bubble velocities and bubble chord lengths), Bubble Image Velocimetry (macroscale mixing pattern) and Laser Doppler Velocimetry (local liquid velocities and turbulence levels).

3. Results and discussion

Fig. 2 (left) shows bubble streaks of an in-homogeneously aerated column (no liquid co-flow). The inlet superficial gas velocities on the left and right side of the column are 1.38 and 1.12 cm/s respectively. A recursive image correlation technique is adopted to calculate the displacement of bubble parcels to obtain local gas velocities for a range of operating conditions. Large self-organizing flow structures arise as a function of the difference in both (left, right) inlet conditions.

Bubble probes are installed in the flow channel as denoted in Fig. 2 by point 1 (left) and point 2 (right) and the measured time-averaged gas fraction (500 s) for both probes is 5.7 and 4.5 % respectively. The right side of Fig. 2 shows the bubble velocity distributions. For the case shown, we observe normally distributed bubble velocities of 35±10 cm/s on the left and 21±6 cm/s on the right, while the bubble chord length distributions are almost identical for both probes. For larger differences in superficial gas velocities between both inlets (left, right), local bubble velocities may start to deviate significantly from vertically up, due to entrainment in a self-organized vortex, and bubble velocity measurements of a dual-tip bubble probe then are subjected to a large measurement uncertainty.

4. Conclusions

We studied mixing patterns of two parallel bubbly flows using a novel bubble image velocimetry approach and dual-tip optical fiber probes. Precise data are obtained on spatial distributions of the local gas fraction, chord lengths and gas velocities with the view of validating CFD simulations.

Highlights

- 0D Population Balance Equation model.
- Breakage and Coalescence kernels formulation.
- Second order structure function accounting for the entire turbulence spectrum.

1. Introduction

Liquid-liquid extraction is a common unit operation in the chemical, food, pharmaceutical and nuclear industries. In order to optimize and control this operation, the knowledge of the droplet size distribution or the Sauter mean diameter is needed. These two properties could be determined through the Population Balance Equation (PBE), whose accurate solution depends on the modeling of its source terms, *i.e*. the breakage and coalescence kernels. The kernels are of fundamental importance since they express the number of droplets breaking or coalescing per unit time. In the case of turbulent dispersions, these models generally assume the droplets to have dimension in the inertial subrange of turbulence, where the Kolmogorov theory applies. Therefore, shear stresses and characteristic times are expressed in agreement with the results of this theory. However, since in a solvent extraction process the droplet diameter varies from microns to millimeters, many droplets will have dimension in other turbulence ranges (Dissipation, Energy-containing). Therefore, general breakage and coalescence models that account for the entire spectrum of turbulence are proposed and experimentally validated.

2. Methods

Coulaloglou and Tavlarides proposed breakage and coalescence kernels considering the droplet to have dimension in the inertial subrange of turbulence. In this work, these models are extended to the entire turbulence spectrum implementing the second-order structure function (SOF) proposed by Davidson [1]:

$$\langle[\Delta u(r)]^2\rangle \approx \frac{4}{3}\int_0^\infty E(\kappa)\left\{1-3\left[\frac{sin(\kappa r)}{(\kappa r)^3}-\frac{cos(\kappa r)}{(\kappa r)^2}\right]\right\}d\kappa$$

The Pope energy spectrum $E(\kappa)$ [2] is considered, since it accounts for the eddy energy distribution in the entire turbulence spectrum. This model depends on the continuous phase viscosity and the turbulent dissipation rate ε. This latter is usually not uniform in the liquid-liquid contactor. Therefore, in the employed 0D PBE model, the ε inhomogenenities were considered through a probability density function obtained from CFD simulation [3]. Finally, the proposed kernels were tested on turbulent liquid-liquid dispersion experiments performed in a stirred tank of 1L volume equipped with a Mixel-TT impeller. Distilled water was used as the dispersed phase, while the continuous phase consisted of a mixture of Isane 175 (1.2 cP) and Marcol 82 (12 cP). The experiments were carried out at varying impeller rotation speeds (600-700-800rpm), dispersed phase volume fractions (1-2%) and continuous phase viscosities (1.2 – 4.1 cP).

3. Results and discussion

The results of the general model (Fig. 1, green) were compared to the ones of the previous model (dashed blue) based on the inertial subrange assumption [3]. At 1.2 cP (pure Isane, left), both models were able to predict the time evolution of the Sauter mean diameter. At 2.4 cP (Isane 70%-Marcol 30%, centre) and 4.1 cP (Isane 70%-Marcol 30%, right), while the simulations based on the general model are in good agreement with the experimental data, the original model underestimate the Sauter mean diameter. Indeed, at higher viscosities, the inertial subrange of turbulence is reduced and most of the droplets have dimension in the Dissipation subrange. In this subrange, the dampening effect of the continuous phase viscosity on the eddy turbulent kinetic energy is more and more important approaching the Kolmogorov scale. Therefore, the model based on the inertial subrange assumption, which do not account for the continuous phase viscosity effects, overestimates the turbulent kinetic energy of the eddies and consecutively the breakup rate.

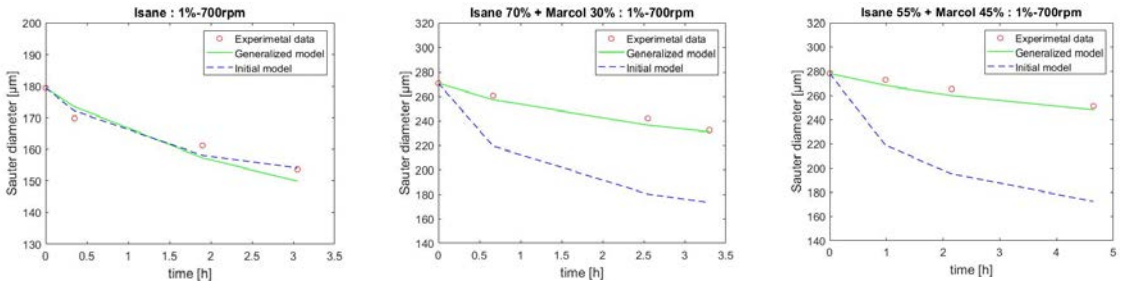

Figure 1. Caption. [Calibri 9].

4. Conclusions

In this work, general breakage and coalescence kernels, accounting for the entire spectrum of turbulence, are proposed. The new model is based on a refined second-order structure function and an energy spectrum considering all the domains of turbulence. The model shows good agreement with experimental data measured in liquid-liquid dispersions at increasing viscosity.

Hydraulic Characterization of Water-Air Flows in Cooling-Tower Packing.

Nicolas Jourdan[1,2], Mohamed Kanniche[1], Thibaut Neveux[1], Olivier Potier[2]

1 EDF R&D, EDF Lab Chatou, 6 quai Watier 78400 CHATOU FRANCE

Highlights

- Study of wet-cooling tower packing hydrodynamics
- Experimental characterization of falling water films: thickness and instabilities
- Benchmark of CFD approaches for simulations of water films

1. Introduction

Industrial wet-cooling towers are used in various industrial fields such as power plants, refineries or chemical plants. These cooling towers are filled with packing to increase heat and mass transfer between hot water and counter-current air flow [1]. Despite numerous investigations of heat transfer performances and pressure losses [2], hydraulic characteristics such as wetting ratios or water film thicknesses –prerequisite for study of fouling phenomena– are yet to be determined. This study aims at presenting both experimental and numerical characterization of packing hydrodynamics using a dedicated pilot-plant and CFD simulations.

2. Methods

To obtain local information on the flow characteristics along the cooling tower packing, a small scale transparent cooling tower pilot-plant was designed and built, with attention put on the representativeness of water and air distributions. Falling films along the packing channels are observed using a fast camera system tangent to the packing surface. The transparent walls allow the visualization all around the packing structure on different spots. The water film is isolated by subtracting images with and without water with the help of a specific program and Matlab Image Analysis toolbox. The global characterization of the packing is obtained by a statistical analysis film thickness over time and location in the various flow conditions (liquid load, air flow rate, temperature and humidity).

In the same time, CFD simulations are performed on simplified geometry, taken from literature [3], in order to investigate the ability of different CFD approaches to predict correctly falling water films along vertical surfaces.

3. Results and discussion

With the experimental apparatus, data on the flow characteristics are obtained and particularly on water films thickness. One example of post-treatment is shown on Figure 1. From the videos, two phenomena are observed: the wavy film instabilities that came from the flow regime and drops falling along the wall significantly increasing the film thickness. Film thickness evolution is one main parameter influencing fooling phenomena such as kinetics of calcium carbonate precipitation and biofilm development. The wavy film instabilities are estimated by plotting the film thickness over time and processing data with a harmonic analysis using Matlab.

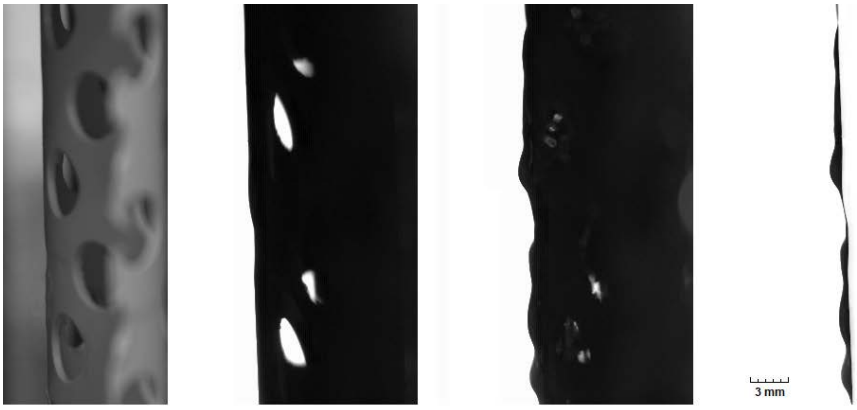

Figure 1. (a) Picture of packing. (b) Reference dry frame. (c) Picture of wetted packing. (d) Subtracted frames to obtain the resulting water film

CFD simulations were performed with two different approaches: Eulerian-Eulerian two-phase model with interface tracking using NEPTUNE_CFD software [4] and VOF method using OpenFOAM software. First results showed that the VOF method is more suitable for falling film simulations because it takes into account the contact angle with the wall for better prediction of wettability, near-wall velocity profiles and shear-stress that influence fouling phenomena (Figure 2).

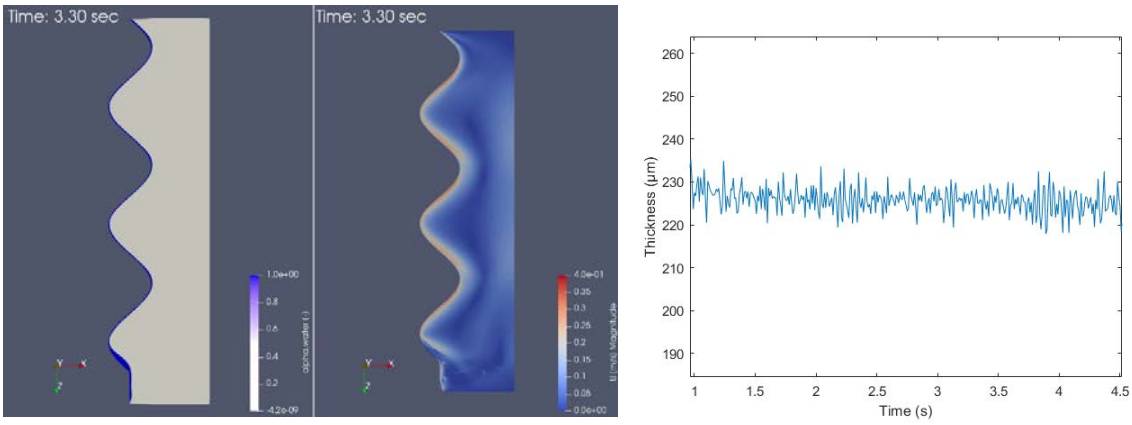

Figure 2. VOF simulations results (a) Water phase rate and air velocity (b) Water film thickness (z=13mm)

4. Conclusions

The experimental setup allows the characterization of falling water on cooling tower packing surface. The water films thickness and their variations were pointed out and the instabilities characteristics were estimated to better understand the phenomena that depend on hydrodynamics. The CFD simulation is promising methods to complete experimental data towards predictive results. These two approaches are complementary to model phenomena of interest such as mass transfer, heat transfer or chemical reactions.

Single Drop Rising and Salt Effects in Low Interfacial Tension System.

Jiyizhe Zhang[1], Yundong Wang[1], Geoffrey W Stevens[2] , Weiyang Fei[1]

1 The State Key Laboratory of Chemical Engineering, Department of Chemical Engineering, Tsinghua University, Beijing 100084, China , 2 Department of Chemical and Biomolecular Engineering, The University of Melbourne, Parkville, Victoria 3010, Australia

Highlights

- Terminal velocities were evaluated for the low interfacial tension system.
- By plotting d_e-v_t-Re in a three dimensional way, application range of implicit correlation can be observed apparently.
- Influences caused by salt addition was investigated.

1. Introduction

Liquid-liquid extraction plays an important role in petrochemical, pharmaceutical, hydrometallurgical, as well as post-processing in nuclear industry. Single drop rising is one of the most fundamental behaviors which influences the terminal velocity and affects mass transfer rate ultimately. However, the motion of droplet is sensitive to contaminations, like salt ions, surfactants or solid particles, which are usually unavoidable in industrial operations. In general, drop terminal velocities can be predicted in three ways [1]: explicit correlations and models in the form of $v_t=f(d_e)$, implicit correlation of $C_D=f(Re)$ and generalized graphical correlation in terms of Eötvös number, Reynolds number and Morton number. Although different methods have been adopted for calculating terminal velocity, few of them are validated in low interfacial tension system. In addition, contaminations like surfactants have been investigated, but limit work has been done to determine the influence caused by salt ions, e.g. salt concentration and type.

In this study, single drop rising in low interfacial tension system (i.e. butanol-water system) was recorded by high speed camera to obtain terminal velocity. Then the terminal velocities were compared to the predictions by correlations from literature, both explicit and implicit. Furthermore, salt effect was determined by adding different salt with various concentrations into continuous phase.

2. Methods

As proposed by European Federation of Chemical Engineering (EFCE), n-butanol/water was chosen as the standard low interfacial tension system and the two phase were mutually saturated before use. Different type of salts were used, e.g. NaCl, Na_2SO_4, NaAc, NaI, $MgCl_2$, $MgSO_4$, and $AlCl_3$. Droplet rising was accomplished in a lab-scale column and was recorded by high speed camera. Images were analyzed by software ImageJ to derive drop diameter and terminal velocity.

3. Results and discussion

For the low interfacial tension system, correlations for terminal velocity were evaluated both explicitly and implicitly. For implicit correlation given as C_D=f(Re), by plotting d_e-v_t-Re in a three dimensional way, the application range of the correlation can be viewed obviously.

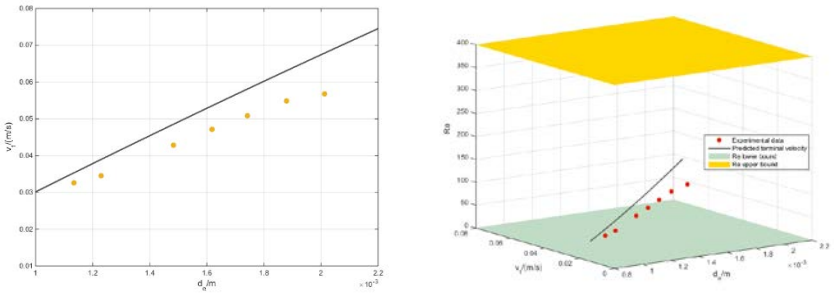

Figure 1. Terminal velocity predicted from Saboni drag coefficient correlation[2]

The addition of salt changes the physical properties of the system and influences the hydrodynamic behaviors of droplet consequently. From a general view in Figure2, the terminal velocity increases with concentration. When the concentration is low, the increase of terminal velocity is not obvious. In this case, ions absorb at the interface and slightly decreases the interfacial tension. However, as the concentration increase further, the increase of terminal velocity becomes apparent. This is because the interface becomes saturated and subsequently addition of salt increases the bulk concentration as well as density.

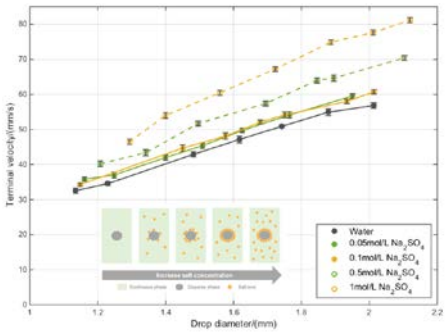

Figure 2. Influence of Na_2SO_4 concentration on terminal velocity

4. Conclusions

Terminal velocities for n-butanol drop rising in water as well as in salt solution have been investigated experimentally. Various explicit and implicit correlations for terminal velocities were evaluated. For the implicit correlations, the application range was considered carefully by plotting d_e-v_t-Re in a three dimensional way. Influence of ions showed that physical properties change caused by salt addition should be analyzed at the same time.

Engineering Method for Calculating of an Axial Valve Separator with an External Location of the Locking Part.

Anna Kapranova[1], Sergey Neklyudov[2], Anton Lebedev[1], Alexander Meltser[2], Dmitriy Voronin[2]

1 Yaroslavl State Technical University, Moskovsky Prospect, 88, Yaroslavl, 150023, Russia; 2 JSC «Regulyator», Gagarin Street, 68a, Yaroslavl, 150023, Russia

Highlights

- Proposed a block diagram of the calculation of the axial valve separator.
- The required valve flow capacity is taken into account.
- The results of stochastic modeling of the hydrodynamic cavitation are the basis.
- An example of the calculation of the axial valve separator is made.

1. Introduction

Improving engineering methods for calculating valves is a pressing issue in the field of pipeline fittings design. The task of reducing the intensity of cavitation effects in the flow part of the valve can be successfully solved by throttling fluid flows. Axial valves provide a straight-line flow of fluid with minimal resistance when opened. The design of the axial valve proposed by the authors [1] assumes a coaxial arrangement of the separator and the movable external locking member, which have the form of hollow cylindrical shells (fig. 1). Thus, the throttle round holes of the fixed separator overlap when the cylindrical shell obeys along its outer surface. This shell can be set in motion as a rack and a crank mechanism.

2. Methods

The purpose of the work is to develop a scientifically based method for calculating the effective ranges of the design parameters of the throttle part of the axial valve. Earlier, the authors used the stochastic approach with the equilibrium representation of the states of the energetically closed macrosystem [2] within the framework of the Ornstein-Uhlenbeck random process [3] to form the model of the bubble formation process in the separator at the initial stage of hydrodynamic cavitation. The proposed stochastic models [4-8] allowed us to obtain differential distribution functions of the number of cavitation bubbles formed during the initial stage of the evolution of hydrodynamic cavitation, according to their size [4-6] and the degree of opening of the axial valve [7, 8]. The expression obtained using this model [4] for calculating the average over the ensemble of the diameter D_{sb} for the macrosystem of cavitation bubbles [5, 6] takes into account the physical and mechanical properties of the working medium, as well as the main design and operating parameters of the axial valve. Another model [7, 8] made it possible to establish a connection between the critical value of the Reynolds number Re_{cr} in the case of a complete opening of the valve and its design parameters. So, these expressions for D_{sb} [5, 6] and Re_{cr} based on [7, 8], as well

as the obtained expressions for the energy parameter of the stochastic model [8] and the hydraulic resistance coefficient [9] are used in the proposed engineering method.

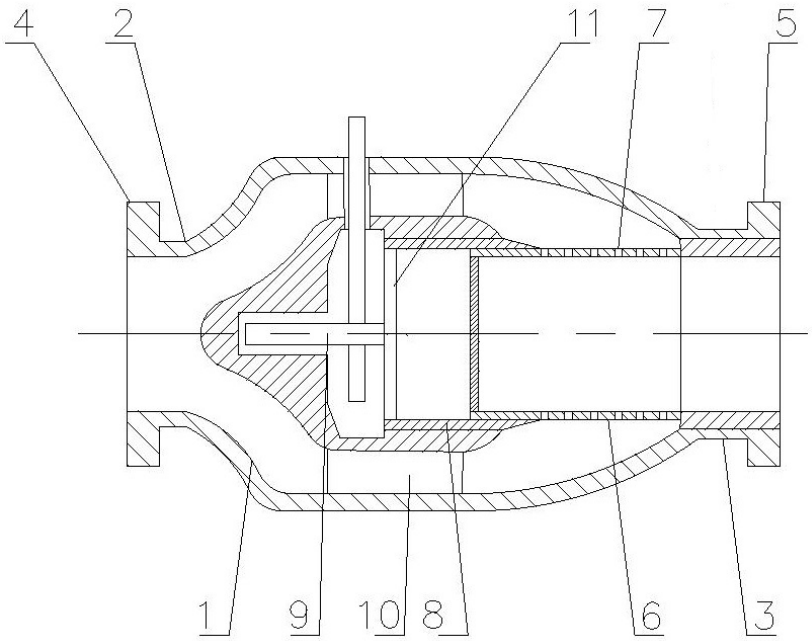

Figure 1. Schematic diagram of an axial valve with an external positioning of the locking member:

1 - outer case, 2 and 3 - inlet and outlet nozzles, 4 and 5 - flanges, 6 - separator, 7 - throttle holes, 8 - cylindrical conical, 9 - rack and pinion mechanism, 10 - cavity of the inner housing, 11 - radial partitions

3. Results and discussion

The proposed block diagram (fig. 2, 3) consists of 25 main blocks for calculating 13 effective values of the design parameters of an axial valve separator. For example, the required parameters include: diameter of round throttle holes d_0, arc distance between the holes in one row, distance between rows of these holes, separator thickness, number of holes for one row, number of these rows, diameter of the outlet of the separator, its perforated part length, bevel angle for the cylindrical part of the shell, etc. Specified operating parameters are the maximum attainable fluid flow through the regulating device at a given value of the medium temperature, the minimum pressure drop, the maximum pressure in the center of the bubble, which corresponds to the minimum value of its radius, the saturated vapor pressure of the medium, the velocity of the fluid in the pipeline. The input parameters for the calculation are the maximum attainable flow rate of the medium, the temperature of the medium, the limits of variation of the minimum pressure drop and the velocity of the fluid in the pipeline. The output parameter is the required valve capacity K'_{vy}. The flowchart proposes a phased calculation of various approximations of the desired design parameters depending on the selected intervals for changing the maximum value of the valve throughput. The specified intervals are refined three times (blocks 3, 10, 21), taking into account the required value of capacity K'_{vy} with the choice of safety factors. For the first time, this is done at specified intervals of change in the minimum pressure drop (block 3), in the second - after calculating Re_{cr} based on [7, 8, 10] to determine correction factors for medium viscosity (block 10), in the third - after estimating the hydraulic resistance coefficient ζ_y^* [9] from the condition of minimal D_{sb} value (block 21) [5, 6].

4. Conclusions

According to the performed calculation example, with K'_{vy}=6,0 m^3/h; Re_{cr}=5209,58; ζ_y^*=0,119 obtained rational ranges of changes of the desired parameters, in particular, the average value of d_0 from the specified range is 5.05x10^{-3} m with a separator outlet diameter of 4.19x10^{-2} m and the length of its perforated part 8.21x10^{-2} m. The main practical value of this work is the possibility of reducing the intensity of cavitation in an axial valve when throttling fluid flows, as a result, extending the service life of regulating devices of this type.

CFD-DEM Simulation of The Breakup of Carbon Black Agglomerates in an Internal Mixer.

Graziano Frungieri[1], Gianluca Boccardo[1], Antonio Buffo[1], Daniele Marchisio[1], Marco Vanni[1]

[1] *Dept of Applied Science and Technology, Politecnico di Torino, Corso Duca degli Abruzzi 24, Torino*

Highlights

- Novel approach for modelling the compounding of rubber materials.
- CFD simulation of an internal mixer for rubber compounding.
- Stokesian Dynamics of carbon black agglomerates.

1. Introduction

The compounding of rubber materials frequently requires the incorporation of solid filler particles, in order to enhance the mechanical properties of the final product. Carbon black particles are among the most commonly used; they generally exist in the form of large agglomerates (up to hundreds of micrometers) which, during the mixing process, are broken down into smaller fragments and uniformly distributed into the rubber matrix.
Previous studies have generally focused on the investigation of the flow field in the mixing equipment and only few attempts have been made in the analysis of the breakup behavior of the agglomerates, with most of them adopting severe simplifications on the aggregate morphology and the breakup mechanism [1].
In this work we adopt a numerical approach which couples a computational fluid dynamics (CFD) simulation of the flow field in a typical mixing equipment with detailed Discrete Element Method (DEM) simulations, able to fully count for the agglomerate morphology and to predict accurately the occurrence of breakup.

2. Methods

A 2D section of an actual rubber internal mixer has been used for the current investigation. The flow field inside the mixing equipment is computed using the open-source CFD code Code_Saturne. The rheology of the rubber medium is modelled according to the Bird-Carreau model. At this stage, agglomerates are treated as point particles, whose trajectories are recorded together with the viscous stress experienced during the motion.
This piece of information is used by a DEM code built in the framework of the FTS (force-torque-stresslet) formulation of Stokesian Dynamics [2]. At this stage the disordered structure of the agglomerates is modeled in detail; the DEM is thus able to evaluate the hydrodynamic forces acting on each constituent monomer and to evaluate the internal stress acting on each single intermonomer contact, in terms of normal force, transverse force and bending moment. The occurrence of breakup can be then readily determined by comparing the internal stresses with the single bond resistance.

3. Results and discussion

Figure 1 shows an overview of the simulation results. In the top figure a snapshot of the instantaneous velocity contour plot is reported. As expected, the regions of highest shear are located in the narrow gap between the rotor tip and the chamber wall. The bottom left figure reports the intensity of the hydrodynamic force acting on each single monomer. It is apparent that larger forces act on the most external monomers. On the contrary, inner monomers experience lower hydrodynamic forces because of the screening effect induced by the surrounding ones. However, the most stressed bonds are generally located in the inner parts of the agglomerate (bottom right figure); this is in line with the expectation that the stress induced by the flow field propagates from the peripherical to the internal region of the agglomerate and accumulates in some critical locations. [3]

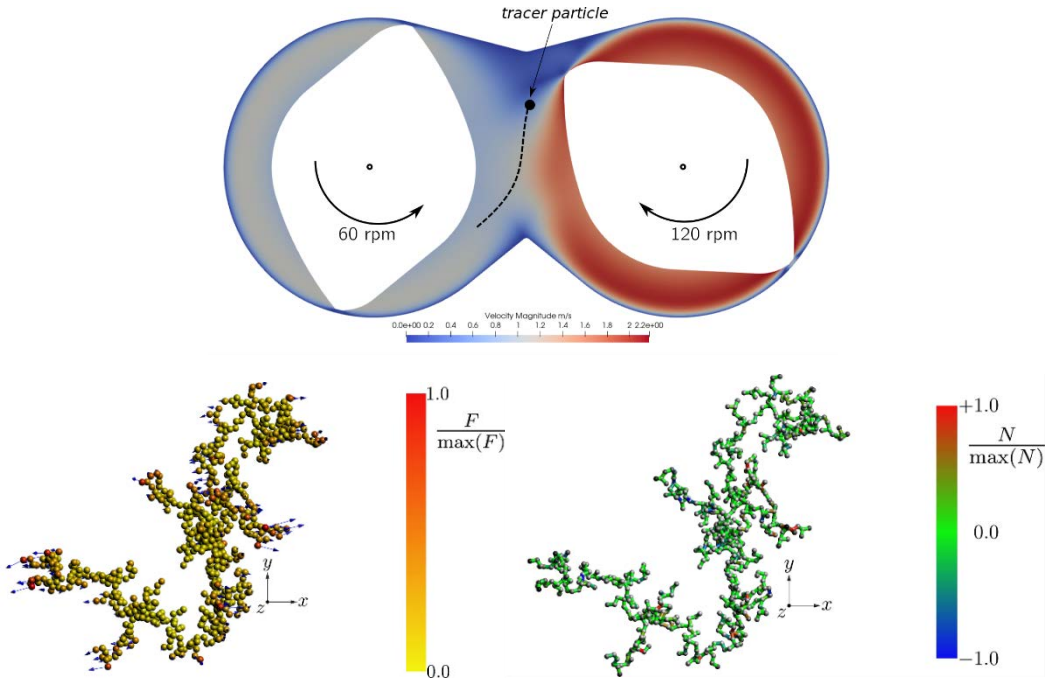

Figure 1. (top) Instantaneous velocity contour plot in a 2D section of an internal mixer. The gap between the rotor tip and the chamber wall is 1 cm wide. (bottom left) Instantaneous hydrodynamic forces acting on a model carbon black agglomerate. The agglomerate has fractal dimension equal to 1.7 and gyration radius equal to 30 micrometers. (bottom right) Instantaneous normal stress acting on the monomer-monomer bonds. Positive values indicate tensile stress.

4. Conclusions

In this work a combined CFD-DEM approach is adopted to investigate the compounding process of rubber composites. Results provide new insights into the breakup mechanism and may be useful for the design and the choice of operative conditions of internal mixers.

The project leading to this application has received funding from the European Union's Horizon 2020 research and innovation programme under grant agreement No 760907.

Intensifying the Re-carbonation Process of Water.

Gabi Altabash[1], Mahmoud Al-Hindi[1], Fouad Azizi[1*]

1 Dept. of Chemical and Petroleum Eng. American University of Beirut, POBox: 1107 2020 Beirut, Lebanon

Highlights

- An attempt to intensify CO_2 absorption in water was undertaken,
- Two different measurements techniques were employed,
- High k_La values were obtained in short residence times at low energy consumption,

1. Introduction

Several reactor types are used for gas-liquid mass transfer operations; however, many of which remain improperly designed because of their complex hydrodynamics. A new type of static mixing element was recently introduced in which woven mesh screens or grids are used to repetitively superimpose an adjustable uniformly distributed turbulence field on the nearly plug flow conditions encountered in high velocity pipe flows. These mixers were found to be very effective at processing multiphase operations [1, 2]. These screens are typically used as a source or sink for turbulence and are characterized by their wire size, mesh opening, and fraction open area. This study therefore aims at employing them to intensify the absorption of CO_2 in RO water without chemical reactions. Its success would allow achieving smaller reactor volumes and introducing various economical and safety enhancements. Faster and more efficient re-carbonation processes can thus be conducted at lower energy consumption and space requirements. In addition, the intensification of these processes will also impact the design of photo-bioreactors by providing CO_2-rich waters for the cell cultures in very short residence times and influence various applications of biogas upgrading.

2. Methods

In order to meet the research objectives, a plug flow reactor design (length = 560 mm and inner diameter = 25 mm), equipped with screen type static mixers was employed to test and quantify the transfer rates of CO_2 into RO water. To analyze the data, the amount of absorbed CO_2 was quantified using two different measurement techniques, namely, pH measurements and another direct measurement technique using a CO_2 analyzer (Anton Paar®, model CarboQC). The method of analysis was that proposed by Kordač and Linek [3]. The experiments were conducted using 8 screen elements placed at 70 mm apart. The total superficial velocity was varied between 1 and 2 m/s while testing for three different gas volume fractions (ϕ = 10, 20, and 30%). Under these conditions, the residence time of the mixture in the mixing section varied between 0.28 and 0.56 s.

3. Results and discussion

The efficiency of the reactor was evaluated from the calculated volumetric mass transfer coefficients, k_La, that were determined from the dissolved concentrations of CO_2 in water. The two

measurement techniques differed by less than 10% when comparing pH measurements to pH values back-calculated from direct CO_2 measurements. Similarly, to many other studies, k_La increased with an increasing U_T and ϕ (cf. Figure 1). It reached a maximum value of 1.01 s^{-1}. These values were obtained at low energy consumption rates. The latter was characterized using the specific energy consumption per unit mass of liquid treated, E_{spm} [1]. This parameter was found to vary between 0.002 and 0.019 kWh/tonne and always decreased with an increase in ϕ because of the subsequent reduction in the total pressure drop. For a detailed comparison with other gas-liquid contactors, the reader is referred to [1]. Furthermore, to better differentiate the effect of changing the screens, it was critical to choose the Reynolds number characteristic length with respect to the screen geometry and not rely on the empty pipe Re (cf. Figure 2).

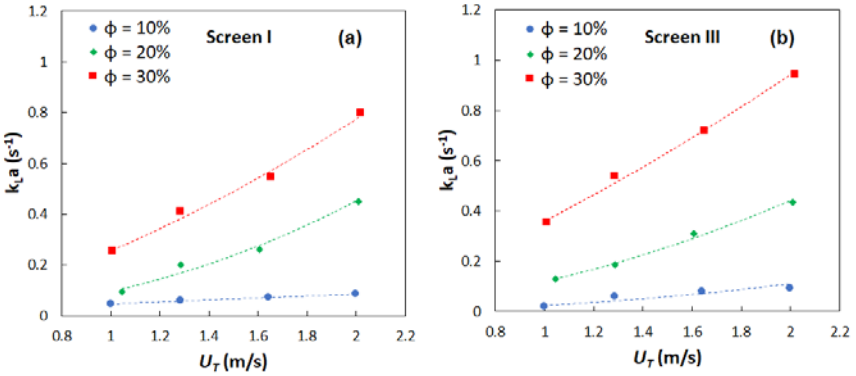

Figure 1. Effect of superficial velocity and gas holdup on the volumetric mass transfer coefficient.

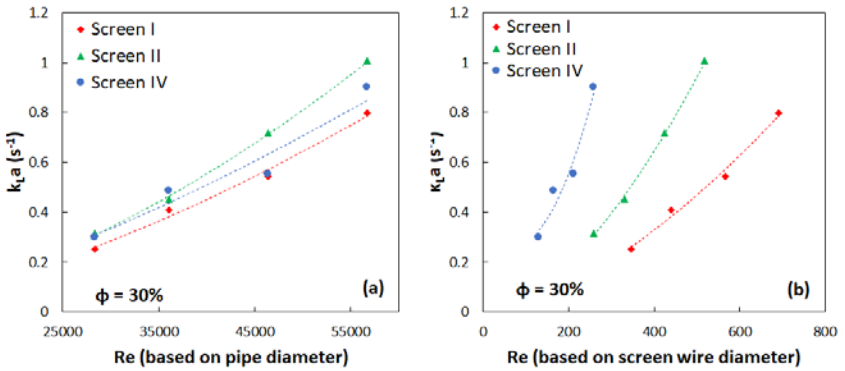

Figure 2. Effect of changing Re characteristic length on interpretation of results.

4. Conclusions

Intensifying CO_2 absorption in RO water was investigated using a tubular reactor equipped with screen-type static mixers. k_La values were affected by screen geometry where higher values were recorded when using screens characterized by small open area, small wire diameter and mesh size. The values obtained in the present work were found to be one to two orders of magnitude higher than conventional gas-liquid contactors such as mechanically agitated tanks and bubble columns and were in the same order of static mixers and advanced flow reactors.

Crystal Growth Simulation in a Continuously Operated Helically Coiled Tube.

Viktoria Wiedmeyer[1], Andreas Voigt[1], Kai Sundmacher[1,2]

1 Otto von Guericke University Magdeburg, Magdeburg, Germany; 2 Max Planck Institute for Dynamics of Complex Technical Systems, Magdeburg, Germany

Highlights

- The crystal size distribution width stays constant in the helically coiled flow tube.
- The crystal product-to-seed ratio attains a saturation level at increasing tube length.
- For a tube length of up to 150 m, the crystal residence time is in the order of minutes.

1. Introduction

Continuous crystallization can be advantageous in continuous process chains when a constant product quality is required. The product quality is influenced by the product crystal size distribution. A narrow size distribution and a low number of additives are often preferred considering downstream steps in the process chain as solid liquid separation. Hence, cooling crystallization is selected. Among the continuous crystallizers, tubes offer narrow residence time ranges and thus narrow product crystal size distributions may be reached through crystal growth. Breakage and abrasion are negligible compared to setups with active mixing. Among the tubes, helically coiled flow tubes (HCTs) have a compact geometry and mixing properties, which are necessary to realize narrow residence time distributions. The potential of this novel crystallization device and a reasonable operation regime regarding residence times and tube lengths are estimated.

2. Methods

A simulation study is carried out for varying flow rates and crystallizer lengths. The model is a coupled population balance equation (PBE) system that is based on experimental results. The system consists of a PBE that is dominated by (1D) growth [1] and (1D) convection along the axis of the HCT and of mass balances for the continuous phase. The partial differential equations are solved by discretization on an equidistant grid of finite volumes using a slope limiter. Numerical diffusion can be adjusted by the number of control volumes to reflect hydrodynamic dispersion and growth rate dispersion. The investigated model substance is univariate potash alum. For this substance, experiments showed that aggregation could be neglected [2]. Further, the model includes experimentally measured size-dependent crystal residence times at two selected laminar fluid velocities of 0.27 m/s and 0.35 m/s [3]. The laminar flow range is selected to realize sufficient residence times at reasonable tube lengths. The inlet temperature was 41 °C. It was assumed that the temperature profile decayed exponentially along the tube to 35 °C while it reached 35.5 °C at a tube length of 10 m.

3. Results and discussion

As expected, the mean product size and mass increase with the tube length. The width of the crystal size distribution stays constant in the simulations due to the size-dependent crystal velocity despite growth rate dispersion. At a length of 25 m, the mean crystal size increased from 80 µm to 119 µm at the low flow rate. At a length of 100 m, it increased only slightly more to 124 µm while the standard deviation of the product crystal distribution was still equal to the initial standard deviation of 15 µm. Similarly, the crystal product-to-seed mass ratio saturates with the tube length in Figure 1. Since the temperature profile is fixed along the HCT, the supersaturation approaches the equilibrium solubility with an increasing tube length and the driving force for crystal growth diminishes. For a tube length of 25 m, the crystals occupy 9 % of the HCT volume at steady state while they occupy 11 % for a tube length of 100 m. For a tube of 25 m length, the crystal residence time is about 8 min while it is about 30 min for 100 m. For the higher fluid flow rate, the residence time is only about 10 min at 100 m. Only for large tube lengths, the product to seed mass ratio is higher than for the low flow rate.

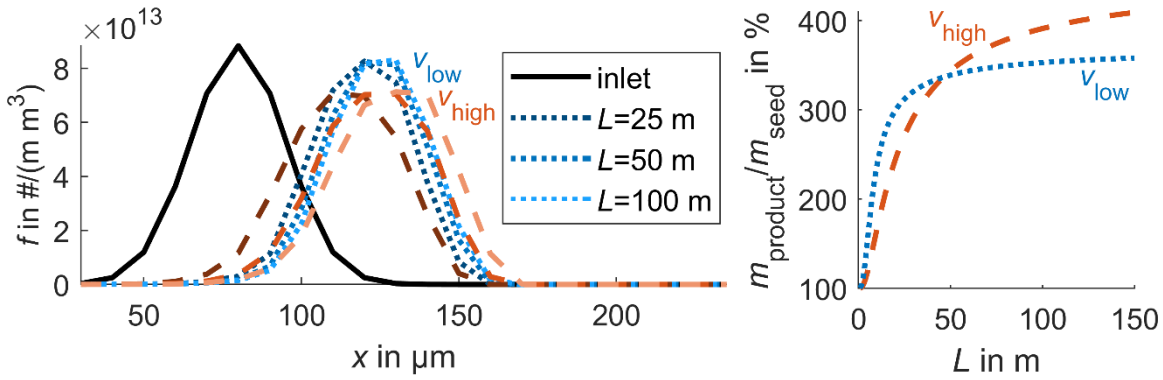

Figure 1. Left: Crystal number distribution per second at steady state in the feed and in the product over crystal size for two laminar flow rates at varying tube length. Right: Ratio of product to seed crystal mass at steady state over tube length for two laminar flow rates under fixed conditions.

4. Conclusion

Continuously operated helically coiled flow tubes can produce narrow crystal size distributions. For a fixed temperature profile, the product to seed mass ratio saturates with the tube length. When the product crystal mass shall be maximized, it depends on the tube length whether low or high flow rates are advantageous assuming that sedimentation is avoided. In this case, a tube of 0.06 m diameter and of up to 25 m length for the low flow rate and up to 100 m length for the high flow rate seems to be reasonable.

Selectivity of gas-liquid reactions in straight and coiled capillaries and CFI

Julia Grühn[1], Norbert Kockmann[1]

1 TU Dortmund University, Biochemical and Chemical Engineering, Laboratory of Equipment Design,

Emil-Figge-Str. 68, 44227 Dortmund, Germany

**Corresponding author: julia.gruehn@tu-dortmund.de*

Highlights

- Deeper understanding of gas-liquid reactions with mass transfer
- Optical measurement technique for mass transfer and selectivity
- Correlations between flow behavior and chemical selectivity

1. Introduction

Two-phase flow and gas-liquid reactions in particular are of great importance in the chemical industry and, therefore, subject of current research since they are often limited by mass transfer or show low selectivity [1]. Investigations of Krieger *et al.* based upon the consecutive oxidation of leuco-indigo carmine [2]. To visualize local gas-liquid mass transfer in capillary plug-flow a colorimetric technique was used there. For studies on selectivity it is essential that the oxidation passes two detectable color changes. Further investigations on flow behavior have shown three relevant flow regimes depending on different operating conditions [2]. Since the selectivity in bio-catalytic reaction systems is an important field in research as well, investigations of bio-catalytic parallel reactions were performed, too**.** Beyond that, suitable reaction systems from the DFG-SPP1740 "Reactive Bubbly Flows" [3] were tested and an optical measuring method was established.

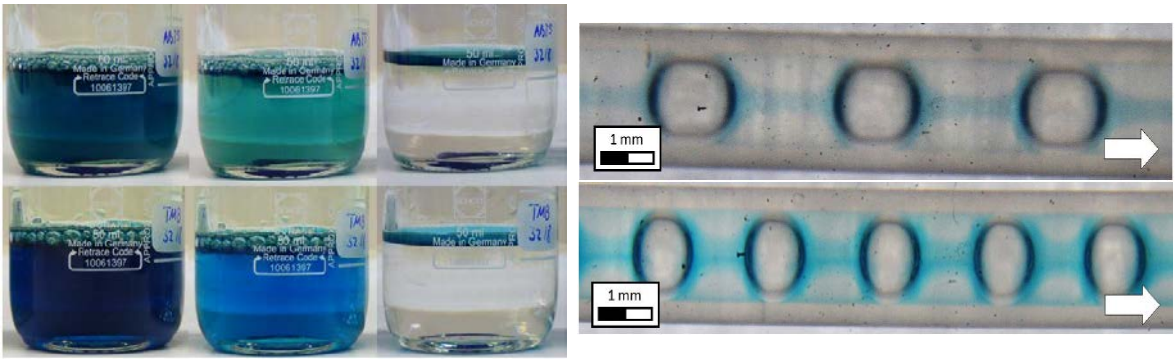

Figure 1. Top left: Enzymatically solution of glucose oxidase and ABTS (2,2´-azino-bis(3-ethylbenzothiazoline-6-sulphonic acid)) as dye. Completely oxidized (l.), 35 s after oxidation (m.), completely reduced (r.). Top right: Gas-liquid capillary flow with the enzymatically solution and ABTS as dye. Bottom left: Enzymatically solution of glucose oxidase and TMB (3,3´,5,5´-Tetramethylbenzidine) as dye. Completely oxidized (l.), 45 s after oxidation (m.), completely reduced (r.). Bottom right: Gas-liquid capillary flow with the enzymatically solution and TMB as dye.

2. Methods

The experiments of the two-phase flow in capillaries were performed according to the approach of Krieger *et al*., in which the flow regime is dominated by Taylor vortices. The experimental setup consists of a straight capillary build of FEP (fluorinated ethylene propylene) with 1.6 mm inner diameter. Furthermore, the experiments were performed in a PMMA box (Poly(methyl-methacrylate)) filled with deionized water [2]. Since FEP and water have nearly the same refractive index, it can be assumed that disturbances caused by deviating refractive indices are negligible. Beyond this, the experimental setup is temperature-adjustable. Building on this, investigations on gas-liquid reactions in coiled capillaries and coiled flow inverters (CFI) follow for suitable bio-catalytic systems as well as for chemical systems from the DFG-SPP1740 “Reactive Bubbly Flows” [3]. For analytical evaluation an optical measurement system is required to avoid flow disturbances. The colorimetric technique used by Krieger *et al*. was adapted to the respective reaction system [2].

3. Results and conclusion

Finally a deeper understanding on selectivity of gas-liquid reactions in general is developed by comparing the experimental results of the consecutive oxidation of leuco-indigo carmine with the bio-catalytic parallel reaction and other reaction systems from the DFG-SPP1740 “Reactive Bubbly Flows”. Furthermore, the studies on the different reactor types (straight capillary, coiled capillary and CFI) provide information about the correlation between flow behavior and selectivity for gas-liquid reactions.

Development of a Novel Atomization Process using Liquid Carbon Dioxide

Clara Lauscher*, Gerhard Schaldach, Markus Thommes

TU Dortmund, Laboratory of Solids Process Engineering, Emil-Figge-Str. 68, 44227 Dortmund, Germany

**Corresponding author: clara.lauscher@tu-dortmund.de*

Highlights

- Fabrication of droplets in the small micrometer range.
- Dispersing a liquid in liquid carbon dioxide.
- Expansion of the CO_2 emulsion.

1. Introduction

Atomization is used in many industrial processes like in spray drying. Unfortunately, atomization is limited regarding small droplet sizes. A new approach to overcome this limitation is to disperse two liquid phases into each other rather spraying a liquid into a gas. Since the droplet size also depends on the continuous phase, using emulsification could be beneficial for achieving the desired size reduction. Indeed, in addition to spraying, there are various methods of emulsification and the milk industry has already proven that it is possible to produce droplets smaller than 1µm. The aim of this study is to investigate the potential to produce an aerosol using emulsification. Therefore, an emulsion of liquid carbon dioxide and a non-miscible liquid will be produced. Afterwards, due to the expansion of the emulsion a fine aerosol will have been prepared.

2. Methods

Based on the idea an aqueous system will be emulsified with liquid carbon dioxide using various emulsification processes. Therefore, a high-pressure emulsification system will be constructed utilizing HPLC equipment. Following, the high-pressure emulsion will be evaporated through a special nozzle.

3. Results and Discussion

As the emulsification system needs to be constructed, first experiments were conducted by using silicon oil (η = 1mPas) instead of liquid carbon dioxide as the continuous phase. Demineralized water is the disperse phase. The disperse phase (water) was pumped through a capillary (d = 0.3mm) with a volume flow rate of 50ml/min leading to a Reynolds number of 3500.

The Reynolds number of the continuous phase was calculated based on the physical properties of the continuous phase and drawn in Ohnesorge/Reynolds diagram (figure 1a). As shown in the diagram, the disintegration regime changes from the Rayleigh regime to second wind induced regime by changing the continuous phase from air to silicon oil. By spraying into air a droplet size of about 570µm can be expected [1]. In case of spraying the water into silicon oil the average droplet diameter ($d_{50,3}$) measured in the preliminary experiment is about 110µm as shown in

figure 1b. The emulsion was analyzed using laser diffraction technique (Malvern Spraytec, Harrenberg, Germany).

In general, the Reynolds number of the continuous phase increases with decreasing viscosity and increasing density. Consequently, dispersing in a liquid phase can cause higher Reynolds numbers and result in smaller droplet sizes.

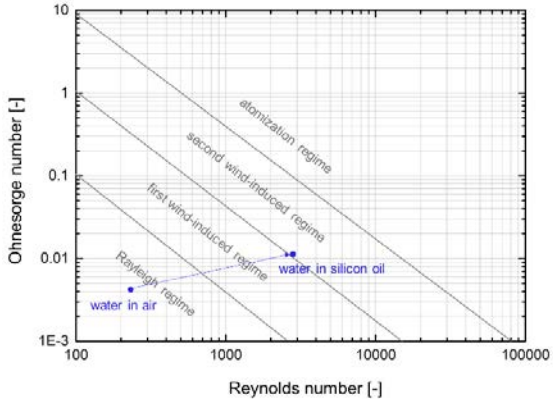

Figure 1a. Ohnesorge/Reynolds diagram for dispersing water in silicon oil versus in air.

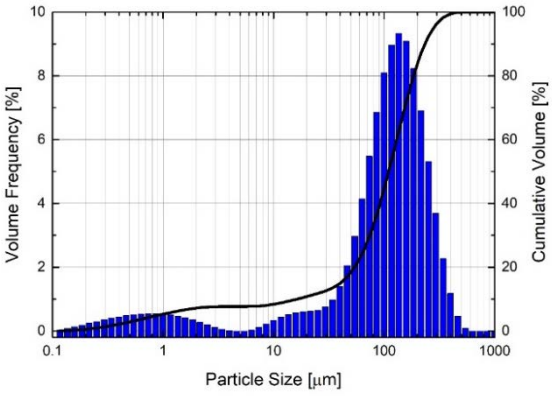

Figure 1b. Particle Size Distribution Dispersing water in silicon oil (η= 1mPas) through a capillary nozzle (d=3mm).

4. Conclusions

The idea to emulsify liquid carbon dioxide seems to be a promising approach to produce fine droplets. The low viscosity will increase the Reynolds number significantly. In addition, liquid carbon dioxide facilitates spraying of the emulsion and is non-toxic. Liquid carbon dioxide vaporizes rapidly as soon as the pressure drops below the saturated vapour pressure and should support the production of even smaller droplets.

The effect of liquid film thickness on the mass transfer of a single catalyst pellet in a scaled down trickle bed reactor

Jonathan White[1], Frans Muller[1], Thomas Chamberlain[1], Richard Bourne[1], Colin Brennan[2], David Taylor[2]

1 Institute of Process Research & Development, University of Leeds, Leeds, LS2 9JT, UK; 2 Syngenta, Jeallot's Hill International Research Centre, Bracknell, Berkshire, RG42 6EY, UK

**Corresponding author: cp15jpw@leeds.ac.uk*

Highlights

- Single pellet trickle bed reactor presented
- Liquid film thickness limits hydrogen diffusion to the catalyst
- Model relating mass transfer rate of hydrogen to liquid flow rate developed

1. Introduction

Heterogeneous hydrogenations are an important class of catalytic reactions, used extensively within the fine chemical, agrichemical and pharmaceutical industries [1]. Though these reactions are often performed in batch due to better understanding of the limiting regimes, continuous hydrogenation has the potential to offer increased economic, safety and quality improvements [2]. Trickle bed reactors (TBR) are an attractive option for continuous manufacturing due to simple operation and lower back mixing enhancing selectivity. However, due to the complex relationship that exists between the kinetics and hydrodynamics, these reactors can be challenging to study at laboratory scale [3]. This article presents a method for scaling a TBR down to the scale of a single catalyst pellet to investigate the effects of liquid film thickness during the reduction of styrene.

2. Methods

A single pellet TBR was developed by immobilizing a 1% Pd/C extrudate within a packed bed of glass beads (shown in Figure 1). A reactor column of similar diameter to the length of the extrudate was used to minimize liquid bypassing. Hydrogen gas and a styrene solution in methanol were passed co-currently through the bed and the styrene conversion was monitored via gas chromatography. Liquid flow rates were chosen based on the liquid holdup within the reactor and corresponded to Reynolds numbers between 1 and 5. The gas flow rate remained constant throughout this study. To examine the extent to which diffusion though the liquid film effects the overall mass transfer rate of hydrogen (MTR_{H2}), hydrogenations were conducted with both hydrogen saturated and unsaturated methanol. To visually investigate the film thickness as liquid trickles over the catalyst, a small number of pellets were glued together to form a stack. Liquid was passed over the stack at various flow rates and filmed using an optical microscope to observe changes in the film thickness.

3. Results and discussion

The film thickness and single pellet TBR results are shown in Figure 1. As confirmed by the pellet stack experiment, at increased liquid flow rates the methanol film on the surface of the catalyst

becomes thicker. When unsaturated, hydrogen must diffuse through this film and the increase in thickness is thought to give rise to the apparent decease in MTR_{H2}. With liquid presaturation the MTR_{H2} increases almost linearly with increasing liquid flow rate. As diffusion through the film is no longer limiting the reaction, increased turbulence is thought to enhance mass transfer and contribute to the observed increase in MTR_{H2}.

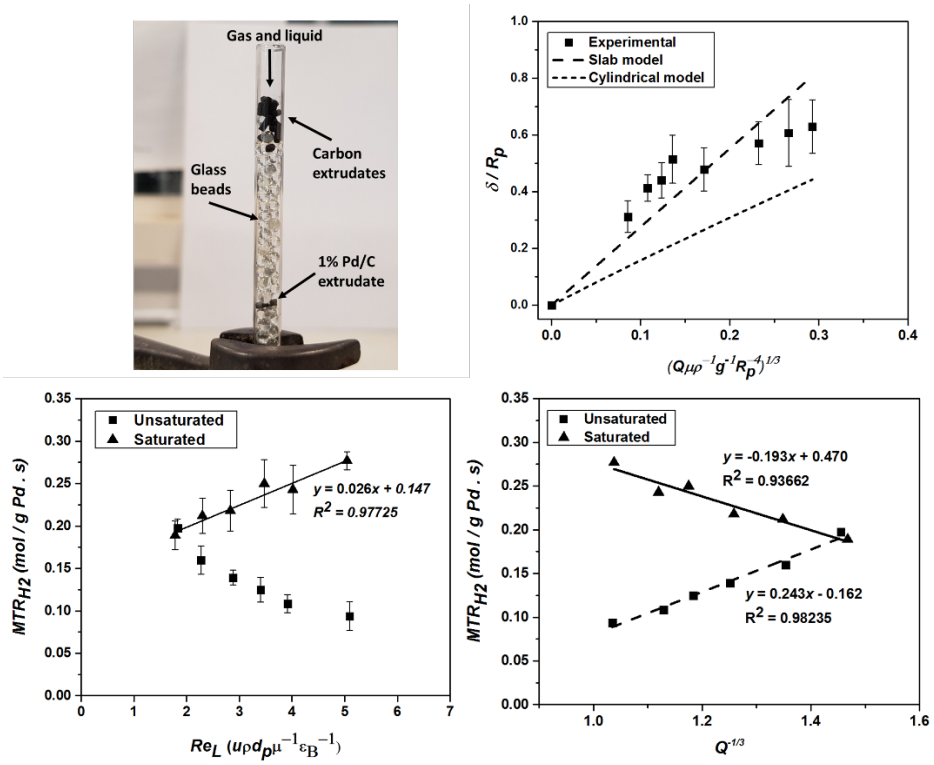

Figure 1. Top left; the single pellet TBR used. Top right; recorded liquid film thickness on the pellet stack at various liquid flow rates. Bottom left; mass transfer rate of hydrogen against different liquid flow rates. Bottom right; correlation between the mass transfer rate of hydrogen and the reciprocal cubic root of liquid flow rate.

The effect of volumetric liquid flow rate on film thickness was modelled and subsequently a relationship between the MTR_{H2} and liquid flow rate was found. This model was shown to fit both the liquid film and single pellet TBR experimental data well.

$$MTR_{H2} = \frac{ADC_{H2,l}}{\delta} \; and \; \delta = \sqrt[3]{\frac{3\mu Q}{\rho g S_A}} \; \therefore MTR_{H2} \propto \frac{1}{\sqrt[3]{Q}}$$

4. Conclusions

A single pellet trickle bed reactor has been used to investigate the liquid film thickness trickling over a catalyst pellet. Increasing the liquid flow rate results in a thicker film and thus exhibits a greater limiting effect due to the increased diffusion distance. A model was developed to describe the relationship between the overall mass transfer rate and the volumetric liquid flow rate.

A computational workflow to study particle transport in porous media: coupling CFD and deep learning

Gianluca Boccardo[1], Agnese Marcato[1], Daniele Marchisio[1]

[1]*Department of Applied Science and Technology, Politecnico di Torino, Torino, Italy;*

**Corresponding author: gianluca.boccardo@polito.it*

Highlights

- CFD simulations of fine filtration in packed beds are performed
- Deep-learning methods are used for feature extraction and parameter identification
- Effectiveness of different machine-learning setups are presented

1. Introduction

The study of particle transport in porous media is of the utmost importance as it touches a wide variety of different fields: from the study of contaminant transport in aquifers to the design of effective packed bed reactors in chemical engineering. One of the difficulties lies in the many parameters characterizing the porous media (which are generally geometric), and whose impact and synergy of action can be impossible to analytically predict. These particularities, which render the problem of particle transport in random media difficult to treat, at the same time make it a prime candidate for machine learning (ML) and specifically deep-learning (DL) approaches. These techniques are particularly suited to extract essential features hidden in data, and are making their way from computer science to "hard sciences", e.g. in chemical engineering [1]. In this work we couple our recent CFD work exploring fluid flow and particle transport and deposition [2] with a variety of different classes of classical and deep neural networks (NNs and DNNs).

2. Methods

The first step was the creation of the geometry: first, randomly arranged distributions of non-overlapping circular elements are generated, then, CFD simulations of fluid flow and particle transport and deposition were performed, using the open-source CFD code OpenFOAM: a snapshot of a simulation can be seen in Fig. 1. One thousand of these fully solved CFD realizations are used for generating the datasets, each differing in a random variation of the defining spatial features: porosity, grain diameter, channel width. Reynolds and Peclet numbers (respectively via the imposed pressure drop and the mass diffusion coefficient) were also randomly varied.

3. Results and discussion

Using the obtained "fully-solved" CFD dataset described earlier, a parameter identification analysis was performed by employing differently built NNs and DNNs (using Matlab Machine Learning Toolbox). First, a single layer NN was used for prediction of permeability and particle deposition efficiency. When a new, random set of parameters (inside the training range) was given to the NN, the result prediction was almost perfect (error <0.5%) as the parity diagrams in Fig. 3 show. Different number of neurons were used, from 10 to 100, with 20 neurons giving the best results: this fits with the expected trade-off between a too coarse prediction with fewer neurons and overfitting with too many. Then, deep-neural networks with different arrangements of 20 neurons in 1-, 2-, and 3-layered fully-connected networks were tested, without appreciable differences in prediction accuracy, showing that for these number of features a simple 1-layer

network suffices. Then, we tested the obtained neural network to make predictions using input data from outside the range where the network was trained: as it is to be expected, the predictions degrade in quality the further the input data is from the training range. Nonetheless, as it can be seen in Fig. 2, reasonable accuracy (<10% error) can still be obtained even when all input parameters are well below (or above) the limits of the data range: this shows the wide range of applicability of this approach.

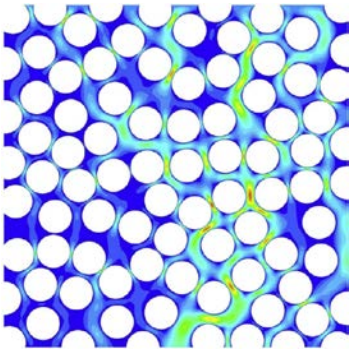

Figure 1. CFD contour plots of velocity magnitude for the 2D random arrangement of circles

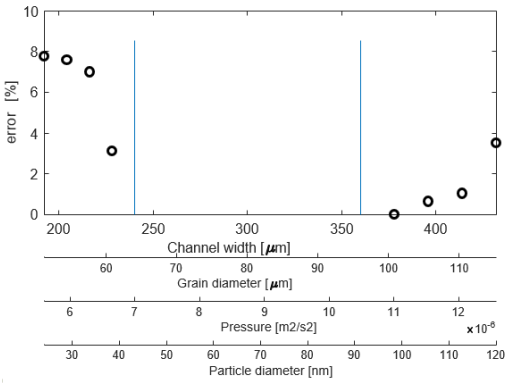

Figure 2. Prediction errors when input data (quantitities on the different scales) is outside the training range of the neural network, indicated by the vertical lines (inside of which error is circa 0%, as seen in Fig. 2).

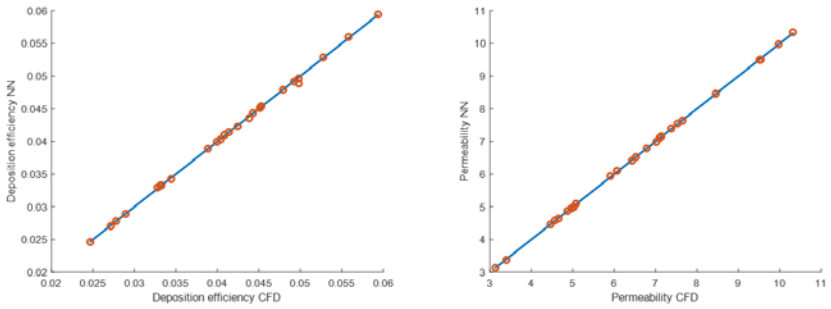

Figure 3. Parity diagrams comparing actual CFD simulations with NN-predicted results.

4. Conclusions

Different types of neural networks are used to predict both fluid dynamic and mass transfer properties in porous media: the results show that this approach is very successful, reducing the cost of property prediction by orders of magnitude (CFD: around 10 minutes, NN: around a second). This allows for fast reactor/filter prototyping, on-line process control (analyzing process response in real time) and makes tightly-coupled multi-scale modelling possible by means of efficient, machine-learning powered, surrogate models for pore-scale transport.

Comparison of Miniaturized Draft Tube Baffle and Coiled Flow Inverter Crystallizer Construction

Mira Schmalenberg*[1], Anna Nocon[1], Felix Buckmann[1], Norbert Kockmann[1]

1 TU Dortmund, Emil-Figge-Straße 68 44227 Dortmund

**Corresponding author: mira.schmalenberg@tu-dortmund.de*

Highlights

- Continuous crystallization for process development
- Comparison of design methods
- Down-scale of a draft tube baffle crystallizer
- Residence time behavior in comparison

1. Introduction

To develop processes as quickly and easily as possible, continuous apparatuses are required even for very small quantities. This is especially valid for crystallization, which is still frequently carried out in batch mode[1].
The procedure for constructing two different cooling crystallizers is to be compared here. A Draft Tube Baffle (DTB) crystallizer as a stirred tank is compared to a Coiled Flow Inverter Crystallizer (CFIC), which belongs to the tube crystallizers. In addition to the different construction methods, the main features of the crystallizers will also be compared.

2. Methods

In order to ensure a homogeneous suspension flow in the CFIC, Hohmann et al. [2] has already developed a flow chart to identify homogenous suspension flow. The CFIC presented here has been developed on the basis of this map[3]. The most important parameter here is the densimetric Froude number based on flow velocity and density difference between fluid and solid.

Regarding the DTB an already known DTB[4] crystallizer has been down scaled from 1100 L to 1 L to allow the same suspension characteristics. With the help of different particles (glass particles and acetylsalicylic acid) and solid weight fractions it is possible to determine an operating range for the DTB. Here the densimetric Froude number is an important parameter, too.

3. Results and discussion

A tube-in-tube CFIC has been designed with an internal process tube diameter d_i of 1.6 mm (Figure 1, left). This was designed for a suspension flow rate of 15 – 20 g·min^{-1}. The CFIC can be varied by identical units so that the coiled tube length (7.8 - 54.6 m) and thus the mean residence time (1 – 7 min) can be varied. The special feature of this crystallizer is the very narrow residence time distribution, which is close to an ideal plug flow. [3]

In contrast, the constructed DTB (Figure 1, right) obviously behaves similarly to the residence time distribution of an ideal continuous stirring vessel. Thus, despite a similar mass flow rate (around 15 g·min^{-1}), significantly longer residence times of about 67 min are possible. This should make it possible to produce much larger crystals than in the CFIC.

The special feature of the DTB is that it has a classifying function. This is induced by the baffles so that fine grain can be removed and a narrower crystal size distribution (CSD) be reached. In this work, the achievable CSD, which should be narrow, of the two crystallizers will be compared although the crystallizers are of two different types.

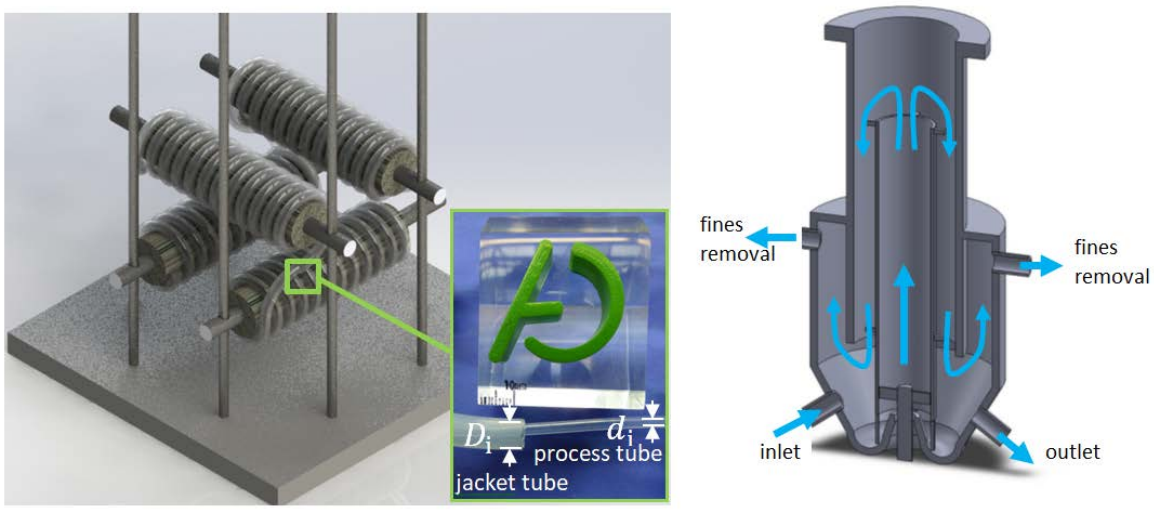

Figure 1. Single CFIC unit with coiled tube length of 7.8 m with tube-in-tube construction of the CFIC (left); Down-scaled DTB prototype with flow direction (right)

4. Conclusions

Two different continuous cooling crystallizers have been designed for small quantities of about 15 g·min^{-1}, where for both a complete homogenous suspension behavior is a design criterion. To characterize the crystallizers, the residence time behavior was compared. This shows that the different apparatuses are suitable for various crystallization tasks.

The German Federal Ministry for Economic Affairs and Energy (BMWi) is acknowledged for funding this research as part of the ENPRO2.0 initiative. (Support code: 03ET1528A)

Power and Flow Characteristics of the in-line Rotor-Stator Ytron ZC1

James M. Mitchell, James C. Bacon, Nabeel Umar#, Chris D. Rielly, N. Gül Özcan-Taskin*
Loughborough University, Dept. of Chemical Engineering, Loughborough, LE11 3TU, UK
#Now at: 3M Derby Road, Loughborough UK

Highlights

- The suction performance of an in-line rotor-stator used for powder incorporation into a liquid, the Ytron ZC1, showed an optimum range of operation avoiding liquid flow into the powder inlet for both 1.5 and 3.0 mm gap heads
- Power characteristics of the Ytron ZC1 were determined and two expressions were obtained for 1.5 and 3.0 mm gap rotor-stator heads
- Results obtained will form the basis for further studies on incorporation and deagglomeration

1. Introduction

Nanoparticles incorporated in novel formulations have been shown to improve product properties or achieve properties and performance that cannot be achieved otherwise. Abrasion-resistant coatings, pharmaceuticals, catalysts, paints and coatings with increased colour brilliance and increased protection from sun creams are examples of such products. Final or intermediate products in the form of nanoparticulate dispersions in a liquid require initially the incorporation of the dry nanoparticle powder into the liquid, which is often performed using a stirred tank[1]. The pre-dispersion formed is then deagglomerated using a power-intensive device, such as a rotor-stator. In this study, the performance of an in-line rotor-stator, Ytron ZC, used for powder incorporation, is assessed in terms of its power and suction characteristics.

2. Experimental

Experiments were conducted using a variable speed Ytron ZC1 operated up to 6,500 rpm in the recirculation loop of a 0.58 m diameter stirred tank equipped with a hydrofoil (Figure 1). The liquid volume was 100 l. The Ytron ZC1 rotor-stator head shown in Figure 2 is available with gap sizes of either 1.5 or 3.0 mm; the stator teeth had a length of 9.19 mm. Power input was determined using a calorimetry technique. The suction performance of the device was determined by making air velocity measurements with an anemometer at the powder inlet.

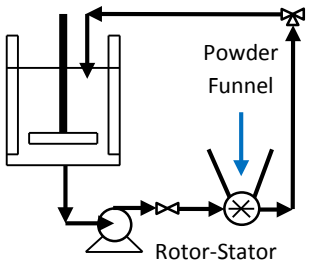

Figure 1. Experimental set up

Figure 2 Ytron ZC mixer head stator, on the left, of diameter 0.089 m and rotor, on the right, of diameter 0.095 m

3. Results and discussions

Figure 3 shows that the liquid flow rate through the rotor-stator is not affected by the rotor speed or teeth gap, which suggests that the Ytron YC1 has negligible pumping action and therefore

requires an external pump.

The liquid flow through the rotor-stator head induces suction from the powder inlet to achieve incorporation when dry powder is added. It can be seen from the air velocity results (Figure 4) that at a given rotor speed, the air velocity increases slightly as the liquid flow rate is increased, then tends to a plateau which corresponds to the optimum operating range.

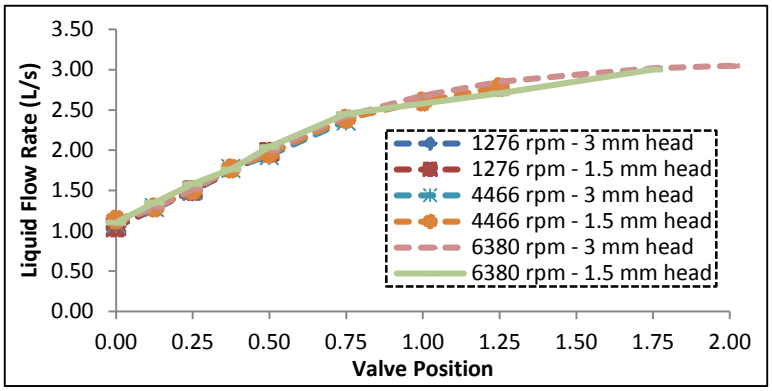

Figure 3 Liquid flow rates for a range of rotor speeds using the Ytron-ZC1

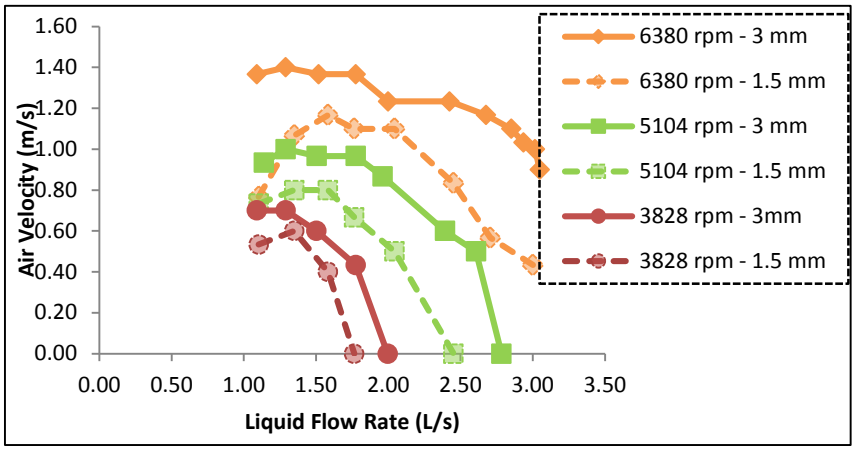

Figure 4 Air velocities over a range of conditions for Ytron-ZC1 and ZC0

Further increases in the liquid flow rate decreases the suction performance (Figure 4). This reduction in suction at high liquid velocities is caused by the flooding of the powder inlet by the liquid, which is highly undesirable as the wetted powder can form clumps and cause blockage. Increasing the rotor speed increased the air velocity, resulting in improved suction performance. The 3.0 mm gap head has a higher suction air velocity and is therefore better suited for powder incorporation.

From the data obtained, the following relationships were obtained in which the values for Po_1 and Po_2 ($P = Po_1 \rho N^3 D^5 + Po_2 \rho N^2 D^2$) were of the same order of magnitude as those reported for other in-line rotor-stators[2]:

$$P = 0.28\rho N^3 D^5 + 13.95\,\rho N^2 D^2 Q \qquad \text{for 3.0 mm head and}$$
$$P = 0.20\rho N^3 D^5 + 15.07\rho N^2 D^2 Q \qquad \text{for 1.5 mm head.}$$

4. Conclusions

The suction performance of an in-line rotor-stator used for powder incorporation, the Ytron ZC1 was determined over a range of rotor speeds and liquid flow rates, which demonstrated that there is an optimum range over which powder incorporation can be achieved. The effect of gap width could be identified. In addition, the study on the power characteristics of the device allowed two relationships to be obtained for the different gap sizes. These will form the basis of further work on incorporation and deagglomeration.

Performances of a Compact Static Mixer for Turbulent Flows in Pipelines

Alessandro Paglianti[1], Francesco Maluta[1], Giuseppina Montante[2]

1 DICAM – Università di Bologna, via Terracini 34, 40131 Bologna, Italy; 2 CHIMIND – Università di Bologna, via Terracini 34, 40131 Bologna, Italy

Highlights

- Good mixing with limited energy requirements is achieved by a very compact static mixer.
- Enhancement of blending is ensured without modification in existing pipelines.
- Effective mixing with limited space requirement helps continuous process intensification.

1. Introduction

Static mixers for turbulent flows are adopted in several industrial operations, ranging from synthesis of pharmaceuticals [1], to mass transfer in bioreactors [2], emulsification [3] and heat transfer [4], just to mention a few examples. In this work, the mixing performances and the energy requirements of a novel static mixer, whose main characteristics with respect to other traditional designs are the easiness of the installation and a very compact geometry, are investigated by Computational Fluid Dynamics (CFD). The validation of the computational results based on the comparison with experimental pressure drops and tracer homogenization data is presented. The investigation can be easily extended to any industrial application, for the preliminary identification of the most effective geometrical and operating conditions for achieving the desired production target.

2. Methods

The velocity flow field, the pressure drops and the pipe length required to achieve the blending of two miscible liquid streams are obtained by the numerical solution of the Reynolds-Averaged conservation equations of mass, momentum and scalar concentration for incompressible, isothermal and steady-state flow of Newtonian liquids. The Reynolds stress and the Reynolds flux terms are modelled using the eddy viscosity and the eddy diffusivity hypotheses, respectively. The computational domain consists of a pipe of diameter, D, equal to 90 mm and length, L, equal to 10×D placed horizontally and equipped with one compact static mixer element of the TWIN-P series designed by Pittaluga s.r.l. It is a very compact static mixer, being its width, W, equal to D/7, consisting of six 45° pitched blades fixed to the external surface of a Venturi section. Blending is ensured by a double-mechanism, due to the combined action of the blades and of the Venturi section, and is particularly suitable for treating streams of very different flowrates. The domain discretization is performed through an unstructured grid consisting of about 4.3×10^6 cells. The grid effect on the mean velocity field, on the turbulent variables and on the degree of homogenization is also considered. The simulations replicate a parallel experimental investigation, considering different flow rates of the main liquid water stream, Q, varying from 4 to 35 m^3/h and a single flow rate of the secondary stream, Q_s, that is an aqueous solution of Rhodamine of 10 L/h. The pressure

drops and tracer concentration data adopted as a benchmark for the simulation results are measured by pressure transducers and Planar Laser Induced Fluorescence (PLIF), respectively, placing the static mixer in a test rig consisting of a 7 m long plexiglass pipe, a storage tank and a centrifugal pump.

3. Results and discussion

The energy requirements and the mixing performances of the TWIN-P static mixer are shown in Figure 1, by means of the parameter K at different water flow rates and of the Coefficient of Variation (CoV) of the Rhodamine concentration along the pipe axis. The K value is defined as:

$$K = \Delta P / \left(\frac{1}{2}\rho V_s^2\right) \tag{1}$$

where ΔP is the absolute pressure difference across the mixer, ρ is the fluid density and V_s is the fluid superficial velocity. The CoV at selected pipe cross sections is calculated as:

$$CoV = \sqrt{\frac{\sum_{i=1}^{N}(C_i - C_{mean})^2}{N-1}} \frac{1}{C_{mean}} \tag{2}$$

where c_i is local Rhodamine concentration at the i-th evaluation point, c_{mean} is the mean concentration on the cross section, N is number of evaluation positions at the cross section.

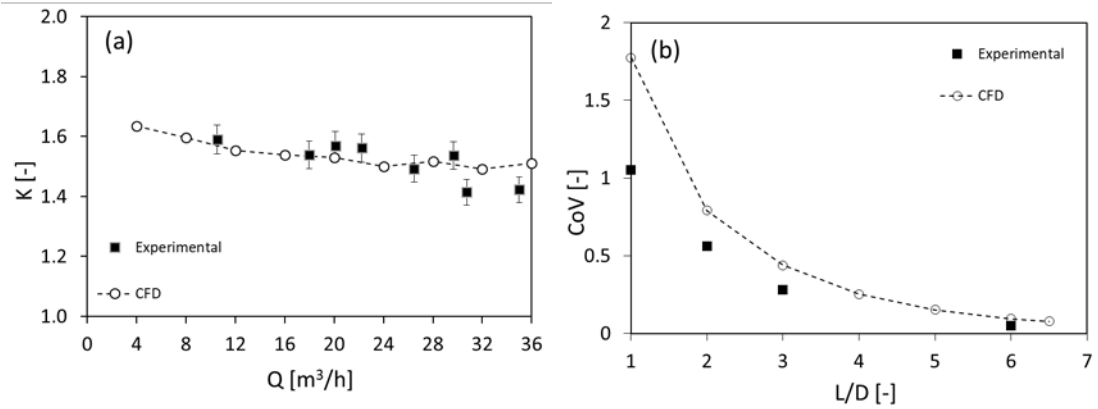

Figure 1. Comparison of CFD and experimental results. (a) K vs Q; (b) CoV at different cross sections downstream the mixer outlet section, Q=20 m³/h.

Based on the experimental data and the comparison with the performances of other static mixers for similar applications[5], the investigated TWIN-P static mixer is found to ensure low pressure drops and good mixing performances. The CFD results fairly agree with the experiments. As a result, the fully predictive three-dimensional CFD modelling approach considered in this work is confirmed an industrially viable and reliable method for turbulent static mixing design and optimization.

CFD Analysis of Direct Contact Condensation (DCC) of Superheated Gas Jets into a Vertically Flowing Liquid Channel.

K N Jayachandran[1], Arnab Roy[2], Parthasarathi Ghosh[1]

1 Cryogenic Engineering Centre, Indian Institute of Technology, Kharagpur, India-721302; 2 Department of Aerospace Engineering, Indian Institute of Technology, Kharagpur, India-721302

**Corresponding author: knjayachandran93@gmail.com*

Highlights

- Two fluid model used for simulation of DCC in R123 gas-liquid flows.
- Mean bubble diameter correlation will be developed for low Jakob (Ja) number liquid flows.
- Numerical model will be validated with experimental data of Zhu *et al.,* [1].

1. Introduction

In a typical staged combustion cycle based LOX/kerosene semi-cryogenic rocket engine, the liquid oxygen booster turbine is driven by the oxidizer-rich combustion products from the pre-burner [2,3]. The turbine driving gas comes in direct contact with the liquid oxygen stream from the booster pump after the booster turbopump exit and gets condensed [4]. Very few studies are reported in the above complicated case of direct contact condensation, which demands further investigation in this area [3]. The purpose of the present study is to understand the GOX-LOX DCC by exploring the DCC of R123 fluid with similar flow (low liquid Ja) and geometry configuration as reported in Zhu *et al.,* [1] by the use of numerical methods.

2. Methods

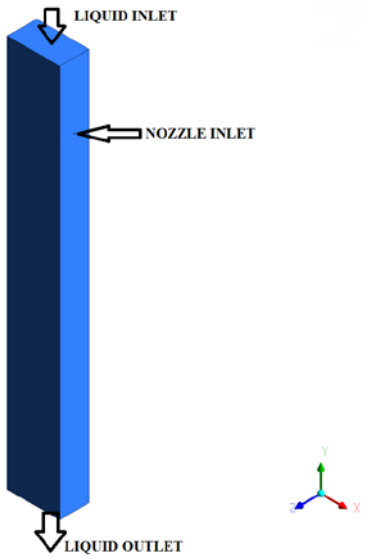

Figure 1. Geometry with gas and liquid boundaries.

Table 1. Boundary conditions.

Parameter	Value
Nozzle inlet mass flow rate (g/s)	1.22
Nozzle inlet temperature (K)	346.98
Liquid inlet velocity (m/s)	1
Liquid inlet temperature (K)	311.98
Domain pressure (MPa)	0.175

A two-fluid model with thermal phase change model for predicting condensation effects has been implemented in the present study using the commercial CFD package ANSYS CFX®. The geometry has been taken from the experimental data of Zhu *et al.,* [1] as shown in Fig. 1. The nozzle has a diameter of 2mm whereas the liquid domain is of dimensions 45mm x 80mm x 600 mm. The boundary conditions are reported in Table 1.

3. Results and discussion

Initially, steady state simulations are performed and the gas volume fraction contours are plotted as shown in Fig. 2. It can be observed that the gas exits through the nozzle and comes in contact with liquid R123. Further, transient simulations have to be performed to understand the dynamic condensation process.

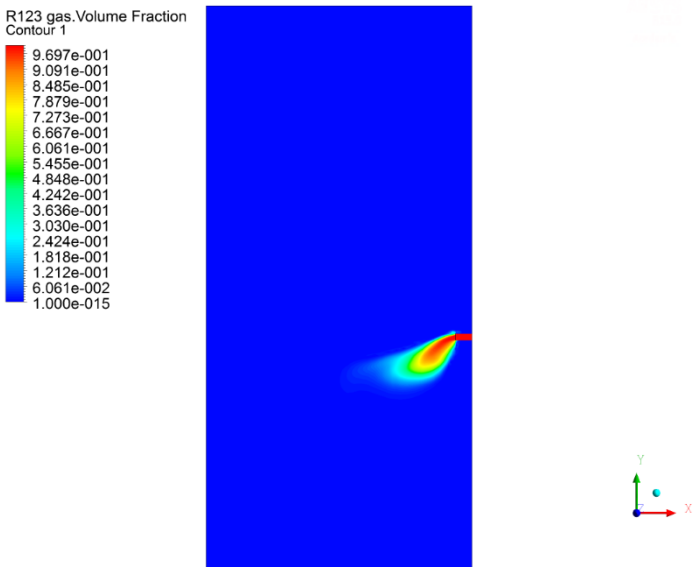

Figure 2. Gas volume fractions after steady state simulations.

4. Conclusions

A two-fluid model used to simulate the DCC of R123 gas-liquid flow. Further, the different sets of experimental data will be simulated to validate the numerical model. It has been observed by the authors in the previous works that the mean bubble diameter correlation by Anglart *et al.,* [5] may not be applicable for all cases of DCC. Hence, based on the simulations, a correlation for mean bubble diameter will be developed.

3 Department of Chemistry, Eurasian National University, 2 Satpaev st., 010008 Astana, Kazakhstan

**Corresponding author: cecile.lemaitre@univ-lorraine.fr*

Highlights

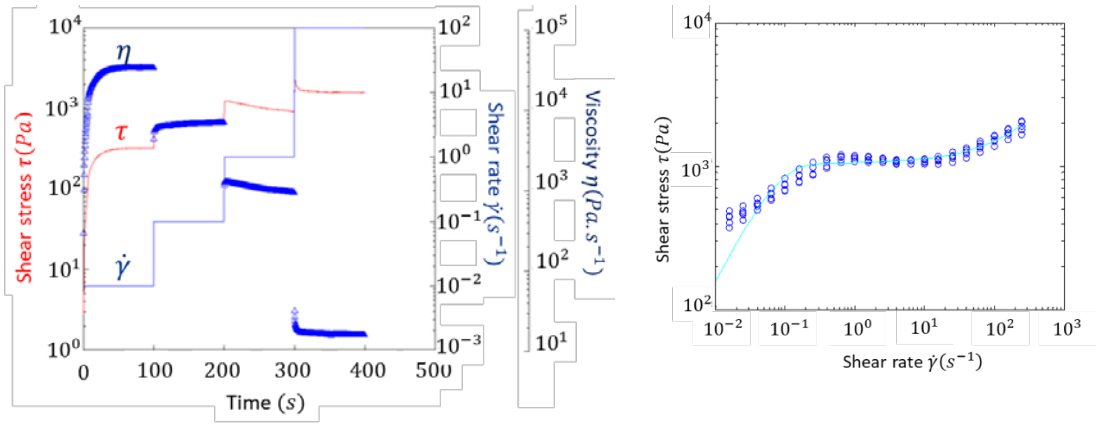
- Rheological measurement on a toothpaste showed yield stress and thixotropy
- Kinetic and a rheological model selected and optimized to fit the experiments
- Rheological models implemented in ANSYS Fluent to simulate the toothpaste flow in an agitated tank.

1. Introduction

Due to their multi-ingredients composition, toothpastes are shear thinning (decreasing viscosity with increasing shear rate), they display a yield stress τ_y (no flow for stresses lower than τ_y) and they are thixotropic (time evolving viscosity under constant solicitation, due to progressive evolution of the material structure) [1]. Toothpaste SIGNAL® Complete 8 was used in the present study.

2. Rheological characterization

A rotative strain-imposed rheometer ARES provided by TA Instrument is used to perform the measurements. The sample is placed between 2 parallel disks of 25 mm or 40 mm diameter, distant of about 1 mm. The operating temperature is set to 20°C.



(a) (b)

Figure 1. (a) Transient tests presented as a function of time. (blue line) imposed shear rate steps ; (red line) measured stress; (blue triangles) measured viscosity. (b) Steady tests: shear stress $\tau\ (Pa)$ as a function of the shear rate $\dot{\gamma}\ (s^{-1})$.

Two types of tests were conducted: transient and steady. During the transient tests, shear rate $\dot{\gamma}$ steps were imposed to the sample and the shear stress τ and viscosity η were recorded in time. As for the steady tests, the τ and η values at long times are measured for each imposed value of $\dot{\gamma}$.

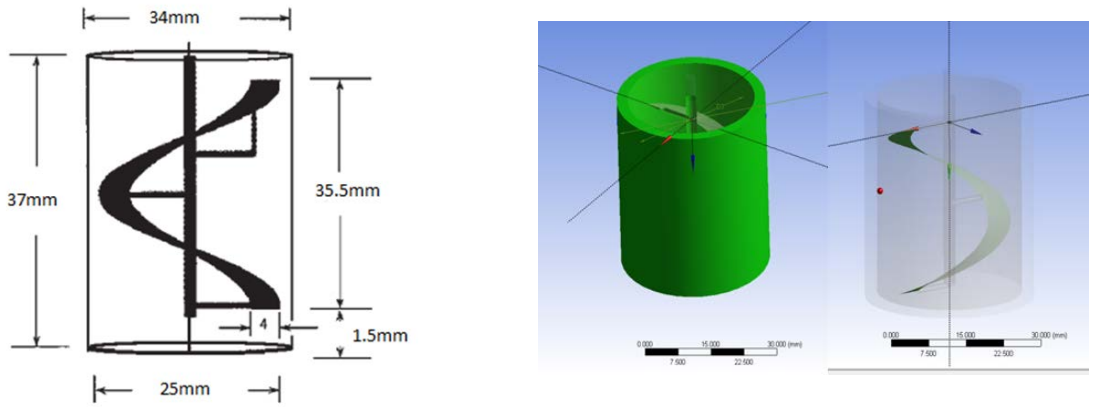
The transient tests, Fig. 1(a), evidenced the thixotropic behavior of the toothpaste. The steady tests, presented in Fig. 1(b), show a shear thinning character, with a yield stress $\tau_y \approx 10^3$.

Following [2], a kinetic and a rheological model were optimized to describe best the structural evolution in time of the toothpaste and the evolution of viscosity as a function of the shear rate.

3. Flow simulation

The purpose of the simulations was to reproduce the flow of a toothpaste sample in a tank equipped with a ribbon agitator, shown in Fig. 2(a), integrated to the ARES rheometer.

The geometry, designed with ANSYS Design Modeler, consists of two volumes: a cylindrical volume V1 containing the ribbon and an annular volume V2, surrounding V1, at the tank walls Fig. 2(b). Two meshes were generated with ANSYS Meshing, of 2,365,013 and 6,060,741 tetrahedral cells, refined near the walls. Both meshes were divided into two sub-meshes, one in V1 and the other in V2.



(a) (b)

Figure 2. -(a) Dimensions of the geometry. (b) Geometry used for the sliding-mesh simulations.

The simulations were conducted with ANSYS Fluent. The rotational velocity of $N = 0.573\ rps$ yielded a Reynolds number $Re = 4.66 \times 10^{-3}$, indicating laminar flow for a Newtonian fluid. The V1 sub-mesh was rotated at N, sliding against the static V2 sub-mesh. No-slip conditions were enforced at the tank and ribbon walls. On the free surface the shear stress was set to zero. The rheological model determined above was parametrized in Fluent. Navier-Stokes equations were solved using QUICK and central-difference schemes.

We will present the velocity vectors and profiles for different times. The calculated torque on the agitator will be compared to the one obtained experimentally.

Parametric study of customizable 3D-printed droplet-microfluidic device

Jan Klusák, Jan Mucha, Marek Večeř*

VSB-Technical University Ostrava, FMT, department chemistry,
Tr. 17. listopadu 15, 70833, Ostrava-Poruba, Czech Republic

**Corresponding author: marek.vecer@vsb.cz*

Highlights

- 3D printed droplet generator is enough accurate to produce droplets with single modal PSD.
- Clear effect of output channel geometry at the same flow conditions.
- Individual and collective behavior of droplets–limiting flow rate ratio of O/W phase.
- Correlation of droplet size on to the volumetric flow rater ratio.

1. Introduction

Droplet-microfluidic devices are becoming more and more powerful platform in chemical, material, biological and pharmaceutical applications where small, highly controllable droplets and particles with uniform size are essential. 3D printing provides effective tool for rapid production of cheap and complex 3-dimensional droplet generators. We apply FDM (fused deposition modeling) 3D printing technology to fabricate customizable microfluidic device [1] with droplet chips which allows production of highly monodisperse droplets, emulsions and double emulsions (droplet-in-droplet) in this work. By varying the channel diameter and droplet chips geometry we are able to generate W-O-W and O-W-O droplets with defined parameters. Several types of material have been tested to find optimal transparency of droplet fluidic chips. Customizable 3D printed microfluidic device with different types of fluidic chips was successfully tested over a range of flow conditions.

2. Methods

Water droplets was prepared in the flow of oil continuous phase. Density, viscosity and interfacial tension was determined for both used liquids. FDM 3D printing technology was used for manufacturing microfluidic chips with various width of output channel. High speed visualization and advanced image analysis [2] was used for droplet primary data treatment.

3. Results and discussion

Four 3D printed microfluidic chips was evaluated under similar flow conditions. CT scan of each channel was performed to obtain actual information about channel profile geometry. Primary geometrical parameters of droplet was detected and statistical evaluation of results was performed. Droplet size normalized by channel width as a function of ratio of volumetric flow rate of dispersed phase to the volumetric flow rate of continuous phase gives single line (1) showed in Figure 1.

$$\frac{d}{h} \approx 1.8\left(\frac{Q_D}{2Q_C}\right)^{0.2} \quad (1)$$

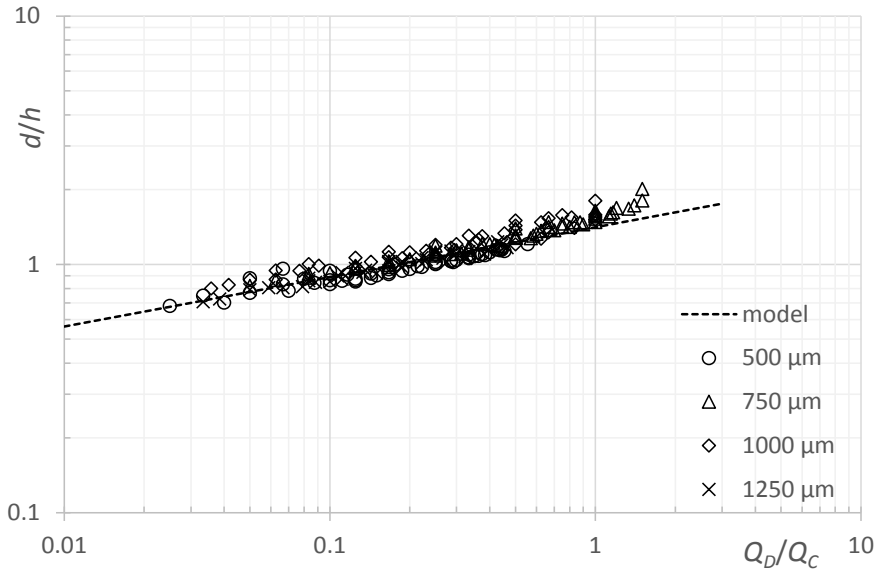

Figure 1. Equivalent droplet size normalized by channel width as a function of volumetric flow rate ration of dispersed to continuous phase.

4. Conclusions

Simple method of 3D printing was used for manufacturing of droplet generator with sufficient accuracy. Image analysis was used to evaluation of experiments. Effect of surface tension, viscosity and effect of different surface active agents was evaluated and satisfactory correlation of droplet size on the volumetric flow rate ratio was obtained.

SIMULATION OF FLUIDIZED BED DRYER FOR COPPER CONCENTRATE THROUGH CFD + DEM.

Sebastian Perez, Javier Norambuena, Yerko Aguilera, Juan Pablo Vargas, Juan Jarufe

Abstract:

The fluidized bed drying equipment has the function of drying the copper concentrate containing 8 to 10% moisture, to leave it with a humidity less than 0.2%. The process consists in the transfer of heat, through the fluidization air, which is a mixture of combustion gases plus fresh air, this is transferred through a bed of gravel. The flow is extracted by a fan by dragging the dry concentrate, which is separated from the stream by a dust collector located outside the equipment. The equipment studied is part of a copper smelter in Chile and has a processing capacity of 123 t / h of dry concentrate, this dry concentrate is able to enter the copper converter to be melted and continue with the process until reaching to be metallic copper.

A computational fluid dynamic simulation (CFD) of the equipment was performed, which allowed us to see the behavior of the fluidization air through the pressure profiles, velocity vectors. Then a coupling of the CFD simulation was carried out with a discrete element modeling program (DEM) to study the behavior of the concentrate particles interacting with the fluid dynamics condition.

The results obtained from the simulations are presented in the form of figures showing the velocity vectors and the orientation of the flows reached both by the fluid and by the particles of the concentrate.

The validation of the results was carried out indirectly comparing the results of the sensors located inside the equipment on an industrial scale with the results observed in the simulation. The variation between the simulated model and the measured operational condition shows differences less than 1.7% for the parameter measured.

Conclusion

The study of a fluidized bed dryer is a highly complex process, however, making simplifications, and applying numerical methods using computational tools such as Ansys Fluent or Rocky DEM, it is possible to know the internal behavior of the flows with acceptable margins of error for engineering equipment design.

Numerical Study of Fluid Mixing at Different Inlet Flow Rate Ratio

Md Readul Mahmud[1], Vladimir Viktorov[2], Carmen Visconte[2]

1 SECS, Independent University, Bangladesh (IUB); 2 DIMEAS, Politecnico di Torino, Turin, Italy

**mahmud.readul@iub.edu.bd*

Highlights

- A new Y-Y passive SAR mixer is designed and analyzed.
- Numerical simulation is done using Fluent for inlet flow rate ratio from 1 to 3.
- Mixing efficiency, flow pattern and pressure drop is calculated.
- Y-Y mixer shows the lowest pressure drop and have 90% mixing efficiency.

1. Introduction

Micromixer is a device which mix fluids regardless of their properties and nature such as density, viscosity, surface tension etc. in micro-scale. Micromixers and micro reactors are used in a wide range of chemical reactions, biochemical reactions, drug development and delivery, medical diagnosis, chemical synthesis and food industries [1] [2]. In micro scale the flow is typically laminar due to low Reynolds number [3]. In this paper, we designed a new SAR Y-Y mixer, and mixing performance and pressure drop is performed numerically by varying the inlet flow-rate ratio (1 to 3). In order to have a point of reference, the Y-Y micromixer was compared to the already established Chain, Tear drop and H-C micromixers.

2. Micromixer Design

The detailed geometrical configuration of Chain, Tear-drop, H-C and Y-Y micromixers is shown in Figure 1. All mixers are made of four identical elements which are connected with each other in various way to maximize mixing performance. The minimum dimension of all mixers is 4 mm.

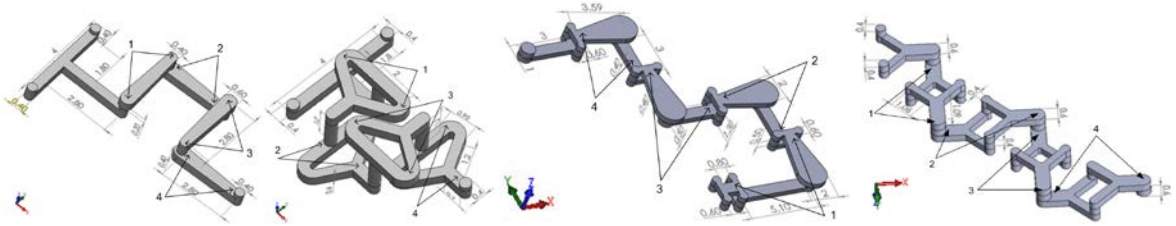

Figure 1. Design of the (a) Chain (b) Tear-drop and (c) H-C (d) Y-Y mixers with important parameters (unit in mm)

3. Numerical Method

ANSYS FLUENT 15, a commercial computational fluid dynamics software was employed to numerically determine mixing efficiency and pressure drop. The value of Reynolds numbers was used as one of the primary parameters for this study and is calculated as $Re = \frac{\rho v d}{\mu}$. Where ρ and μ are the fluid density and dynamic viscosity, respectively, v is the fluid velocity evaluated at the rectangular channel, and d is the characteristic length. A cut-cell Cartesian method was used to generate hexahedral cells suitable for the complex geometry used in computational fluid dynamics

(CFD) simulations. Standard deviation of species concentration was calculated at a cross-section of the mixing channel to evaluate the mixing efficiency using the standard equations [4]. The grid dependency test for all mixers were performed varying numbers of grids.

4. Result and Discussion

Figure 2 revels the efficiency of all four mixers curves for different inlet flow-rate ratios and the curves show the same trend, the efficiency slightly increases for higher inlet flow-rate ratios, especially at $30 \leq Re \leq 100$. The overall mixing efficiency is more than 90% at all Reynolds numbers, regardless of the inlet flow-rate ratios. The numerical data are in line with experimental values.

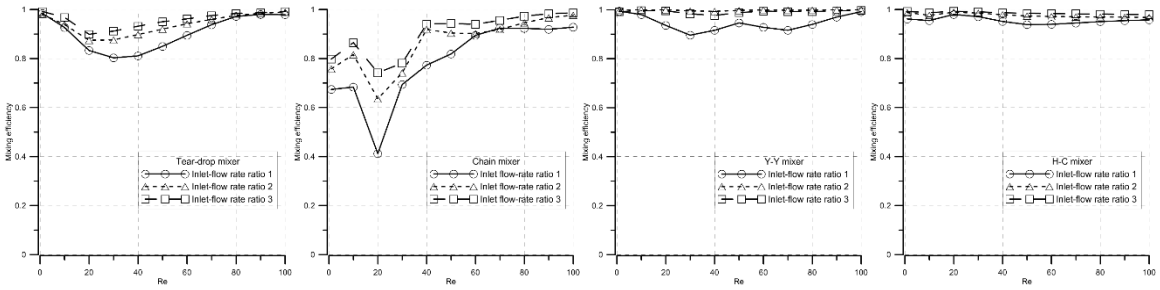

Figure 2. Numerical mixing efficiency of the mixers at the exit of the fourth element (Ratio 1 to 3)

As demonstrates in Figure 3, numerical curves of all mixers have the same trend, i.e. pressure-drop increases with the increase of flow rate. It is also clear that Y-Y has the lowest pressure drop.

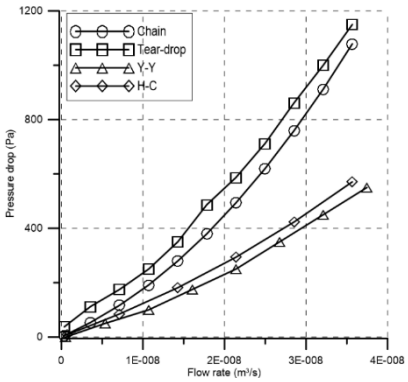

Figure 3. Numerical pressure drop of the four micromixers, varying flow rate

5. Conclusions

Four passive mixers, which uses fluid folding, rotation, expansion and construction along with splitting and recombination to improve mixing, is presented. The numerical model was used to analyze the effect of different inlet flow-rate ratios (1 to 3) at $1 \leq Re \leq 100$. The results showed that mixing efficiency depends on the Reynolds number as well as inlet flow rate ratio. The mixing efficiency of the Y-Y and H-C mixers is very good (greater than 90%) over the entire examined range of Reynolds numbers but Y-Y has the lowest pressure drop among the all presented micromixers.

1. Introduction

The common route of refining the impurities of copper and other non-ferrous metals is pyrometallurgical. The penalties in the price of copper for the level of impurities vary from 0.9 to 4.1 US/lb. The classic equipment of operation is the rotatory furnace of pyrorefining. The operation involves two sequential process steps: (a) oxidation - complexing; according to reaction of Eq(1):$\underline{S}+O_2 = SO_2$, and (b) reduction, according to reaction of Eq(2): $\underline{C} + \underline{O} = CO$. Refining with arc electrolysis is considered an alternative means of removing impurities from the molten copper without introducing deoxidizing agents. The use of this electrochemical method replaces the chemical reactions involved in the oxidation and reduction processes by electrochemical reactions. In this work, we will be studied the dynamic behavior of the anodic oxidation of the oxyanion as the supply of oxidizing agent of impurities in the blister copper through modeling and simulation using program Comsol.

2. Methods

The arc electrolysis furnace consists of a cylindrical crucible (see Figure 1). The crucible is contained in a furnace of silica refractory bricks heated with silicon carbide electrodes. A single graphite electrode enters through the top seal of the crucible. Copper blister and slag are fed from the top prior to heating and sealing the crucible.

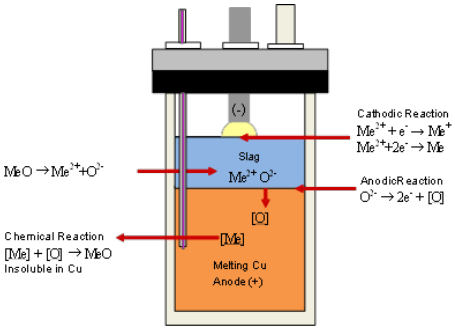

Figure 1. Scheme Arc Electrolysis Furnace

The mesh was refined at the walls and slag – metal and arc -slag interfaces. Complete mesh consists of 6,274 elements, minimum quality of 0.1208 and average quality of 0.8981. The system consists of 5 domains, 19 edges and 15 points. The physical properties of the subdomains of the system are given in the following Table 1. Where k, is the thermal conductivity, h is the heat transfer coefficient by convection. Q, u, and v are values that are obtained by simultaneously solving the equation of the conductive medium DC and Navier-Stokes, respectively. To solve the energy equation the temperature at which the furnace is initially located is 1500 K and to evaluate the heat transfer by radiation $\varepsilon = 0.5$ and $\sigma = 5.67 \times 10^{-8}$ [W/m²K⁴].

Table 1. Physical properties of the subdomains.

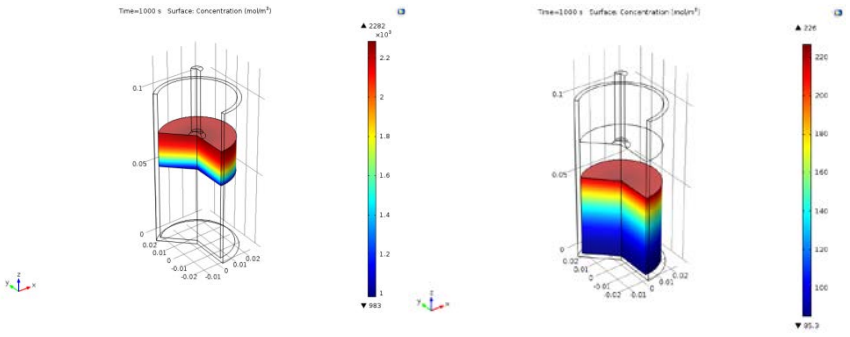
Subdomain	Crucible	Copper	Slag	Arc	Electrode
k, W/mK	3	400	3	50	30
ρ, kg/m³	3000	7800	3500	10	2000
C_p, J/kgK	1900	500	1200	10	2000
h, W/m²K	20	-	20	30	40
Q, W/m³	0	ec.Qh	ec.Qh	ec.Qh	ec.Qh
u	-	u	u	-	-
v	-	v	v	-	-

To solve the mass equation the oxygen concentration at which the slag is initially is 2,446 mol/m³, Value obtained by the stoichiometric oxygen contained in the Cu_2O in the slag and the volume of the slag. In Eq(3):

$$N_O\left[\frac{mol}{m^2 s}\right] = V_{slag}\,[m^3] \times c_O\left[\frac{mol}{m^3}\right] \times \frac{1}{z_O F[C]} \times J_z\left[\frac{A}{m^2}\right]$$

The oxygen diffusivities (Fukunaka et al, 1991) in the slag and oxygen in the blister copper are 10^{-7} m²/s and 10^{-6} m²/s, respectively. The metal-slag interface is modeled as a boundary condition of flow discontinuity where it is entered Faraday's Law, the mass transfer of oxygen to this interface is by natural convection and is modeled by its coupling with momentum transfer and is generated by temperature gradients modeled by its coupling with transfer heat. Where C_0 is the concentration of oxygen in the slag obtained from the mass transport equation and *Jz* is the total current density obtained from the coupling with the conductive medium DC equation for the *z* component of the current density.

3. Conclusions



The simulation results in an arc temperature of 2,067 K that forms a movement created by natural convection generated by temperature gradients that in turn generate concentration gradients.

Figure 2. *Profile Concentration of oxygen in Slag, mol/m³ (left) and in Blister Copper, mol/m³ (right).*

In the slag speed reaches a maximum of 6.79 x 10^{-7} m/s, and in the molten copper 10^{-10} m/s. In Figure 2, the simulation of the oxygen mass transport in the slag shows that the initial oxygen with a concentration of 2,446 mol/m³ develops after 1,000 s of simulation a profile with a maximum of 2,282 mol/m³ in the slag - gas interface that goes down to 983 mol/m³ in the metal slag interface where the electrochemical oxidation reaction occurs. The simulation of mass oxygen transport in copper shows that the oxygen not present initially, as a result of the electrochemical oxidative oxidation reaction, develops a profile with a maximum of 226 mol/m³ in the metal slag interface in that descends to reach 85.3 mol/m³ at the bottom of the crucible.

Acknowledgments. The authors thank to the DICYT 051714MF(2017) and Project 155LD of the USACH.

Highlights

- The vertical distribution of particle concentration was calculated using CFD-DEM.
- A parameter was found to ascertain the dispersion state in the tank.
- An equation was proposed to predict particle concentration at the vertical height.

1. Introduction

Solid–liquid mixing is widely used in crystallizers and chemical reactors with catalysis. In these processes, some difficulties occur by which solid particles aggregate and collide with stirring blades. Particle collision causes particle breakage and abrasion. Furthermore, when scaling up to the scale to industrial equipment, the particle dispersion state usually becomes insufficient. It is important to qualify the solid particle concentration distribution in the tank and to ascertain the dispersion state to solve these problems. However, it is difficult to measure the detailed particle concentration in the tank under many conditions. Therefore, for this study, Euler–Lagrangian simulations were performed with various particle diameters, particle densities, impeller speeds, impeller diameters, and tank diameters to qualify the vertical distribution of solid particle concentrations in the vessel. We also identified the factors affecting the dispersion state.

2. Analytical method

The Euler–Lagrangian approach, which tracks all particle motion, was used. Turbulent flow in the vessel was represented by Large Eddy Simulation. The particle–particle and particle – solid surfaces interactions were modeled using distinct element method. Simulations were conducted using Computational Fluid Dynamics software (FLUENT 18.0; ANSYS Inc.). The simulated system was a flat-bottom cylindrical vessel with four baffles and a six-blade paddle impeller. Tank diameter T was changed from 10 cm to 30 cm with geometrical similarity. The diameter was equal to liquid height H. The impeller diameter D was $T/2$. Blade width b was $T/10$. The impeller bottom clearance was $T/3$. The impeller speed N was 4.0–6.0 s^{-1}. The fluid was presumed to be water. The solid particle density was changed from 1011 to 2500 kg/m^3. The diameter of the 5000 particles varied: 100–400 µm. The tank interior was divided into 50 zones in the vertical direction. The particle concentration in each zone at height C_i and the particle concentration of the entire tank C_{av} were calculated. The standard deviation of particle concentration σ_c was calculated using C_i and C_{av}. The time-averaged values of σ_c, $\sigma_{c,av}$ were used as particle dispersion state evaluation indexes for the vessel.

3. Results and Discussion

Fig. 1 portrays the relation between $\sigma_{c,av}/C_{av}$ and $u_t/(N D^{0.8})$. Here, u_t, N, and D respectively represent the terminal velocity of a single particle, impeller speed, and impeller diameter. Results from Fig. 1 show that $\sigma_{c,av}/C_{av}$ is correlated with the value of $u_t/(N D^{0.8})$, irrespective of the particle properties, impeller speed, and vessel size. Furthermore, results show that the particles are well dispersed in the tank in the range of at $u_t/ND^{0.8} < 0.03$, and that most of the particles are deposited on the bottom in the range of $u_t/ND^{0.8} > 0.06$. These results demonstrate that using the scale-up factor of '$ND^{0.8}$ = constant' enables the change of dispersion state in the small tank to be reproduced when scaling up to the large tank. The vertical component of fluid velocity near the bottom is presented in Fig. 2. The y-axis shows $\overline{v_z}/(ND^{0.8})$, which was of the time-averaged value $\overline{v_z}$ of the vertical velocity near the tank bottom (z/H = 0.1) along the tank centre section divided by $N D^{0.8}$. The figure shows that the distributions of vertical fluid velocities have nearly the same profile, irrespective of the impeller speed or tank diameter. The uniformity of particle concentration in the vertical direction, $\sigma_{c,av}/C_{av}$ can be arranged according to the ratio of u_t to $ND^{0.8}$, probably because the distribution of $\overline{v_z}/(ND^{0.8})$ near the bottom, which is the fluid flow suspending the particles, shows a similar profile.

Fig. 3 portrays the vertical distribution of particle concentration in the range of $0.03 < u_t/(ND^{0.8}) < 0.06$. This figure shows that the dispersion state of the particles varies greatly in this range. Because $\sigma_{c,av}/C_{av}$ depends strongly on $u_t/(ND^{0.8})$, the particle concentration C/C_{av} is normalized by $u_t/(ND^{0.8})$ in that range, as portrayed in Fig. 4. Results show that, by multiplying $u_t/ND^{0.8}$, it is integrated roughly into one line. Fitting was performed using an exponential function for $0.03 < u_t/(ND^{0.8}) < 0.06$. The following equation was found.

$$(C/C_{av})\, u_t/(ND^{0.8}) = 0.0297 + 0.0427 \exp(-7.12\, z/H) \qquad (1)$$

Using equation (1), the particle concentration at the vertical height can be predicted at ±30 % irrespective of the particle property, impeller speed, and vessel size.

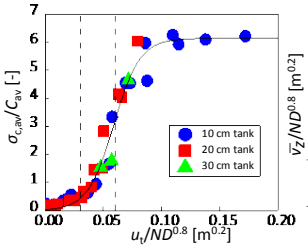

Fig. 1 Relation between $u_t/ND^{0.8}$ and $\sigma_{c,av}/C_{av}$

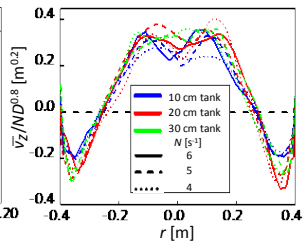

Fig. 2 Distribution of $\overline{v_z}/ND^{0.8}$ at z/H =0.1 in r-z plane

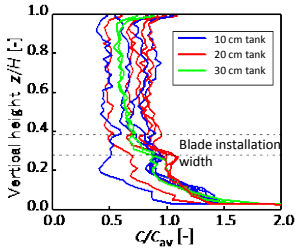

Fig. 3 Particle concentration at $0.03 < u_t/ND^{0.8} < 0.06$

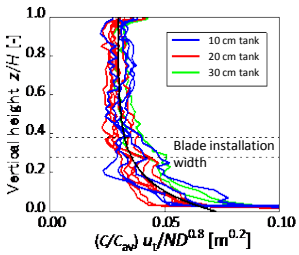

Fig. 4 Particle concentration normalized by $u_t/ND^{0.8}$

4. Conclusions

The vertical distribution of the particle concentration in the stirred vessel was analyzed using Euler–Lagrangian method. Results show that the deviation of particle concentration is correlated with the ratio of terminal velocity of single particle u_t to $ND^{0.8}$. In addition, in the range of $0.03 < u_t/(ND^{0.8}) < 0.06$, an equation (Eq. (1)) was established as capable of predicting the particle concentration distribution in the vertical direction based on $u_t/(ND^{0.8})$.

This study was supported by JSPS KAKENHI (Grant Nos. 19K05118 and 17K06886).

OIL/WATER FLOW IN A HORIZONTAL PIPE EXPERIMENTAL AND SIMULATION - DISPERSEDED FLOW PATTERN

D. S. SANTOS[1], M.G. RASTEIRO[1], P.M. FAIA[2], F.A.P. GARCIA[1]

[1]Chemical Process Engineering and Forest Products Research Centre (CIEPQPF), Department of Chemical Engineering, University of Coimbra, Portugal,

[2]Center of Mechanical Engineering, Materials and Processes (CEMMPRE), Electrical and Computers Engineering Department, University of Coimbra, Portugal.

In multiphase fluids flow, the formation of dispersed patterns, where one of the phases is completely dispersed in the other one (continuous medium) is common, for example, in crude oil extraction and during the transport of water/oil mixtures.

In this work, experimental and numerical studies were carried out for the flow of an oil/water mixture in a horizontal pipe, the dispersed liquid being a paraffin (oil with density 843 kg.m^{-3} and viscosity 0.025 Pa.s) and the continuous medium a water solution doped with NaCl (1000 $\mu S.\,cm^{-1}$). The tests were made for oil concentrations of 0.01, 0.13 and 0.22 v/v and velocities of the mixture between 0.9 and 2.6 m.s^{-1}. Experimental work was performed in a pilot rig equipped with an Electrical Impedance Tomography (EIT) system. Information on pressure drop, EIT maps, volumetric concentrations in the vertical diameter of the pipe and flow images were obtained. Simulations were performed in 2D geometry using the Eulerian-Eulerian approach and the k-ε model for turbulence modelling. The model was implemented in a Computational Fluid Dynamics (CFD) platform with the program COMSOL Multiphysics version 5.3. The simulations were carried out using the Schiller-Neumann correlation for the drag coefficient and two equations for the viscosity calculation: Guth and Simba (1936) and Pal (2000). For the validation of the simulations, the pressure drop was the main control parameter.

The simulations predicted the fully dispersed flow patterns which were confirmed experimentally and the pressure drop calculated when using the Pal (2000) equation for the viscosity calculation showed the best fit. By withdrawing samples of the oil/water mixture for different positions on the vertical diameter, which were later analysed through optical microscopy, it was possible to confirm the dispersion of the oil phase in the water phase, the size of the oil drops being dependent on the oil concentration and flow velocity. The results of the images of the flows obtained by the photographs, EIT and simulations were in good agreement, the same being observed for the 1D concentration profiles referred to the vertical pipe diameter.

Keywords: Oil/water flows, dispersed flow pattern, pressure drop, Euler-Euler model.

Enhancing the Thermal Efficiency of Hydrogen Compressor by the use of LOHC Falling film.

Arian Shoshi[1]*, S. Ehsan Emamjomeh[1], Eberhard Schlücker[1]

1 Institute of Process Machinery and Systems Engineering, Friedrich-Alexander-Universität Erlangen-Nürnberg (FAU)
**Corresponding author: arian.shoshi@fau.de*

Highlights

- Transient CFD Simulations for compressing hydrogen gas.
- LOHC falling film investigation inside compressor chamber.
- Optimizing LOHC layer for the increase of volumetric efficiency.

1. Introduction

Liquid Organic Hydrogen Carriers (LOHCs) are chemical compounds, which they store hydrogen by bonding it chemically during the hydrogenation process in chemical reactors. The hydrogenation process to take place, heat, is required relatively to high temperatures at elevated pressures. The release of hydrogen during the dehydrogenation process requires more energy in terms of heat at even higher temperatures. By compressing hydrogen gas to very high pressures up to 1000 bar in hydrogen compressors, very high discharge temperatures are reached since the compression process undergoes close to the adiabatic process. The generated heat during the compression in the most cases is wasted to the surrounding. The current research represent an approach for using this heat. LOHCs are stable in liquid state up to 300 °C and there is no risk in vapor formation. Therefore, they offers an excellent use as a cooling liquid in hydrogen compressors, in this way improving the thermal efficiency and the volumetric efficiency of the compressor. The new prototype of this compressor designed at Institute of Process Machinery and Systems Engineering is currently carrying out the first tests with very promising results.

2. Methods

The described compressor is a plunger type operating always upward and use a LOHC falling film as coolant liquid formed along at the inner walls of compressor chamber for absorbing the compression heat. The flow of falling film from the top to bottom dead center of the compressor form a LOHC layer above the front end of the plunger. This LOHC layer has a crucial role in preventing hydrogen to leak outside the compressor chamber. Falling film ensures cooling of the walls in order to avoid also the heating of hydrogen gas brought during the suction phase. Beside this, LOHC liquid level above the plunger in a significant way decrease the detrimental space, by filling this clearance between the compressor head and the piston, which is left in order to prevent the mechanical collusion. The detrimental space therefore is nearly “zero”. A thin layer of the hot LOHC together with the compressed hydrogen by the end of the stroke is discharged in the separator, for separating hydrogen form LOHC. Hot LOHC afterwards follows the dehydrogenation process in reactor. The high-pressure hydrogen can be used wherever is required but the best

example of use is in mobility since the LOHCs plays an important role in hydrogen logistic as well. This compressor is an important component of a new hydrogen storage system or hydrogen transport system for making the hydrogen available with high pressures and without wasting energy in terms of heat. For better understating and validating the results, in parallel simulations and experimental tests are investigated. For observing the behavior of LOHC falling film and optimizing the LOHC layer, a Plexiglas cylinder same as the real compressor chamber were used. The figure 1 shows formation of the LOHC layer above the plunger

3. Results and discussion

Ongoing research represent results only for the transient state operation. Due to the safety issues, for the early phase, nitrogen gas and loaded LOHC is used during the all experiments. Until now, pressures up to 630 bar are reached with one stroke starting from 2 bar absolute pressure. The presented compressor is driven with a hydraulic unit at relative low velocities starting from 10-40mm/s. The results depicted in Figure 2 shows a temperature rise of nitrogen gas above 110 °C by 630 bar. Compressing a diatomic gas such as nitrogen, hydrogen, undergoing an adiabatic process from 1 bar (abs) to 1000 bar, results in temperature rise of gas above 2000 K.

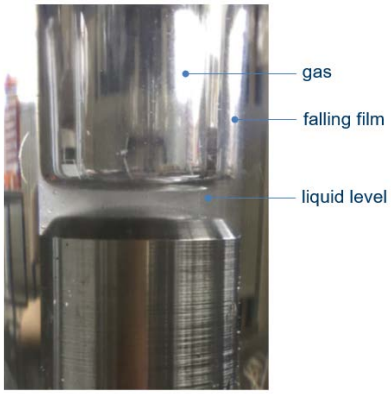

Figure 1. LOHC Falling film.

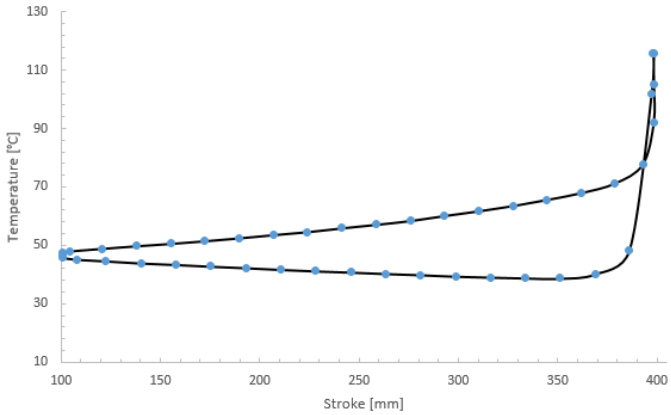

Figure 2. Temperature rise of nitrogen gas during compression up to 630bar.

4. Conclusions

This conceptual research describes a way of internal cooling of a hydrogen compressor for enhancing the thermal efficiency. Currently are running tests still with nitrogen for the higher pressures and as long it is reached a safe and a stable state hydrogen will be used. Thereafter, the validation of the data take place to justify the thermal efficiency.

Highlights

- Filament diameter variations affect the obtained extrudate mass flow
- Feedback control of filament feeding velocity based on filament diameter
- Implemented control strategy results in more uniform extrudate mass flow

1. Introduction

Fused Deposition Modeling (FDM) is a promising manufacturing method for customized pharmaceutical products, such as patient-specific implants [1]. In FDM, thermoplastics in form of a filament are used as a feedstock material. In addition to the imposed mechanical requirements on the filaments, there are also geometrical requirements [2]. The main reason is the utilization of the nominal diameter to determine the required filament feed velocity to achieve the desired extrudate mass flow. Since there is no feedback control in FDM printers, variations of the filament diameter directly translate into inconsistent flowrates [3], as indicated in Figure 1 (left). These inconsistencies can lead to excess material or to voids and cavities that can influence the object porosity, geometry and mechanical strength. The aim of this study was to evaluate if extrudate mass flow variations can be compensated by adjusting the filament feed velocity based on measured filament diameters to obtain consistent extrudate mass flow.

2. Methods

Commercial grade acrylonitrile butadiene styrene (ABS) filament (White ABS 1.75mm 1 KG, RepRap Austria, Neuhofen/Krems, Austria) was used as received. The filament diameter was measured with a laser gauge (Laser 2025T, Sikora GmbH, Bremen, Germany). The filament was discretized into 1 mm compartments and each compartment was assigned with a representative diameter. A custom-built FDM printer [4] was used to extrude the material. The extruded material was analyzed gravimetrically with an analytical scale (Cubis® MCM66, Sartorius, Göttingen, Germany).

3. Results and Discussion

The printing process was conducted with a constant filament feed velocity, assuming a filament diameter of 1.75 mm. The diameter variations were similarly introduced into the extrudate mass flow. Assuming a worst-case scenario of a 0.05 mm systematic error, a mass deviation of 6 % would be introduced into the product, as shown in Figure 1 (right). For most pharmaceutical

products containing at least one drug, this would lead to an intolerable deviation from the nominal drug dosage.

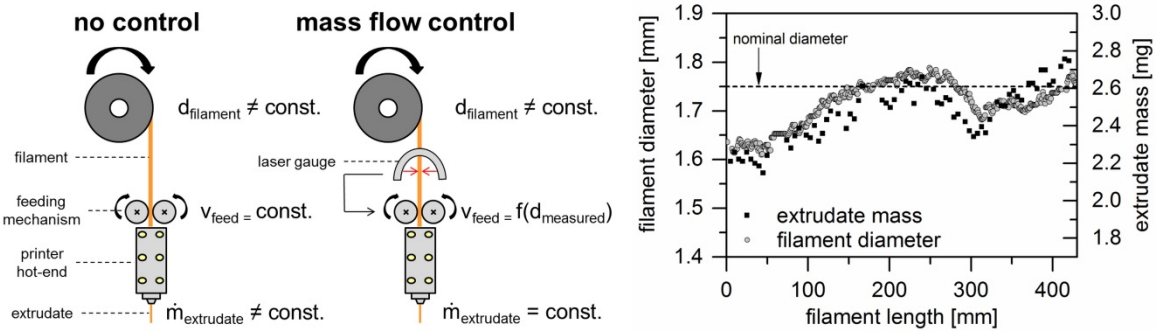

Figure 1. Schematic of the printing process with and without mass flow control (left) and measured filament diameter and corresponding extrudate mass without mass flow control (right).

In a next step, the measured filament diameter was used to adjust the filament feed velocity to obtain the desired extrudate mass flow. A constant diameter of 1.75 mm would have led to sample weights of m_{set} = 48.1 mg, as indicated in Table 1. However, the utilized filament piece for this experiment had a diameter of 1.699 ± 0.021 mm (arithmetic mean ± standard deviation, n = 7). Based on this deviation from the nominal diameter, a theoretical mean sample weight of $m_{no\ control}$ = 45.33 mg was expected for each compartment, which is similar to a mass deviation of approximately -5.8%. The applied control strategy led to an improved mean sample weight of $m_{controlled}$ = 47.31 mg, which is similar to a mass deviation of only -1.6%.

Table 1. Expected extrudate mass and measured extrudate mass with mass flow control.

m_{set} [mg]	$m_{no\ control}$ [mg]	$m_{controlled}$ [mg]
48.1	45.33 ± 1.11 (n = 7)	47.31 ± 0.90 (n = 7)

4. Conclusions

Systematic and random deviations from the nominal filament diameter were successfully compensated by the presented control strategy, which resulted in a more uniform extrudate mass flow. This is particularly important for 3D printing of pharmaceutical products to control the drug dosage. The control strategy can be integrated as a Quality by Design tool into the printing process and allows the application of a wider range of filaments.

Online monitoring of emulsion polymerization by SRS and Raman spectroscopies

Manis Gheghiani[1*], Noémie Caillol[2], Serge Henrot[2], Timothy McKenna[3], Nida Sheibat-Othman[1]

1 University of Lyon, University Claude Bernard Lyon 1, CNRS, LAGEPP UMR 5007, F-69100, Villeurbanne, France ; 2 Axel'One, Solaize, France ; 3 Université Claude Bernard Lyon 1, CPE Lyon, CNRS, UMR 5265, C2P2-LCPP group, Villeurbanne, France

**Corresponding author: manis.gheghiani@univ-lyon1.fr*

Highlights

- Monitoring of emulsion polymerization with NIR and Raman spectroscopies
- Spatially resolved spectroscopy (SRS) for heterogeneous process
- Prediction of the polymer fraction and particle size with PLS

1. Introduction

Online monitoring of polymerization processes is essential to ensure the process security, product quality and process productivity by allowing process control and reconfiguration of the operating conditions when necessary. Monitoring of emulsion polymerization is particularly challenging due to the multiphase nature of the reaction. In this kind of systems, it is important to monitor the different concentrations (monomer, polymer, and surfactant) as well as the key product properties, like the polymer molecular weight or the particle size. Currently, calorimetry constitutes the primarily online technique used for monitoring of polymerization processes. Spectroscopies, like Raman and Near Infrared (NIR), are becoming widely employed online. Based on NIR spectroscopy, the Spatially Resolved Spectroscopy (SRS) has been developed to study heterogeneous media and obtain information related to the light scattering and thus the particle. SRS and Raman spectroscopies are investigated in this study to evaluate the potential of SRS to predict the polymer fraction and the particle size online in emulsion polymerization.

2. Methods

A batch polymerization period was first conducted, during which polymer particles were nucleated, followed by a semi-continuous reaction to allow their growth follows. The reactions were done in a 1 L reactor with mechanical stirring, between 300-400 rpm. First, the surfactant was dissolved in water and degassed using nitrogen and the mixture was heated to 70 °C using a thermostated bath with silicon oil. The co-monomer mixture was then added and the polymerization was initiated by adding the initiator, KPS. During the reaction, the nitrogen gas flow was moved out of the reaction medium to the top of the reactor to maintain an atmosphere saturated with nitrogen. At the end of particle nucleation, the semi-continuous phase was started by adding the monomer mixture under starved conditions. Samples were collected at specific time intervals to measure the solids content (SC, i.e. mass fraction of solid) using a thermobalance and the particle size using dynamic light scattering (DLS, Malvern Nano ZS®).

Throughout the reaction, online analysis was provided with Raman spectroscopy using an OceanOptics QE65000 and an immersion probe with a wavelength laser excitation of 785 nm. SRS spectroscopy, based on NIR spectroscopy, from Indatech-Chauvin Arnoux was used with angles of measurement to the light source at 180° (for transmission), 175°, 170° (for scattering) and 30° (for backscattering).

3. Results and discussion

The results presented in the following figure show the prediction of masse fraction of polymer by both the SRS and Raman spectroscopy. Extensive data analysis combined with multivariate calibration using Partial Least Square (PLS) regression was necessary to exploit the online data. The figure shows that the prediction of the polymer fraction can be established by both spectroscopies and fits well with the reference measurement made offline on the thermobalance.

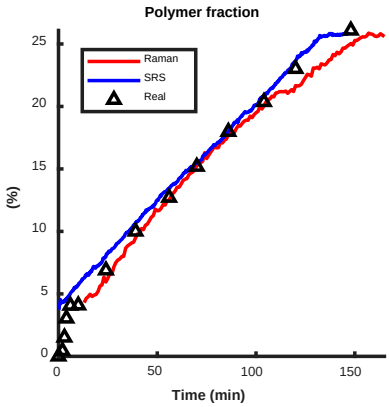

Figure 1. Polymer fraction estimated by gravimetry, Raman and SRS.

The prediction of the diameter of particles was also investigated by both spectroscopies. The SRS was more adapted for this study than Raman spectroscopy mainly due to the specific probe configuration that makes it particularly sensitive to light scattering due to particles and is therefore sensitive to the particle size distribution.

4. Conclusions

Online monitoring of the polymer fraction and the diameter of polymer particles was established by using Raman and SRS spectroscopies. Both methods gave rather good predictions of the chemical information, like the polymer fraction, but the SRS was more suitable for the prediction of physical parameters like the mean diameter of particles.

Effect of flow regimes on reaction yield in a T-shaped micro-reactor.

Matteo Antonelli, Alessandro Mariotti, Chiara Galletti, Maria Vittoria Salvetti, Roberto Mauri, Elisabetta Brunazzi*

Dipartimento di Ingegneria Civile e Industriale, Università di Pisa, Largo L. Lazzarino 2, 56122 Pisa, Italy

Highlights

- Experimental and numerical reaction yields in a T-shaped micro-reactor.
- Reaction yield depends on both Reynolds number, Re, and Damköler number, Da.
- With segregated flow regimes, the reaction yield decreases with increasing Re.
- In the engulfment regime, the reaction yield increases with increasing Re.

1. Introduction

Micro-devices, constituted by channels with typical dimensions < 1 mm, are well suited for many applications ranging from mixing to chemical reaction, dispersion and emulsification. Micro-reactors could allow a large intensification of many pharmaceutical and fine-chemistry processes, due to continuous operation, enhanced heat transfer and well controlled residence time, resulting in an increase of the reaction yield. A key role is played by the mixing that, however, should be promoted with special techniques because the flow in micro-channels is laminar; a simple way to enhance mixing is to design micro-devices where the flow symmetries are broken, and a transverse convection is induced. A large variety of micro-mixer geometries has been proposed. The simplest configuration is the T-shaped micro-rector, whose mixing behavior has been largely characterized in literature both experimentally and numerically by feeding it with water. Although its simplicity, several complex flow regimes, even time periodic ones, have been found, depending on Reynolds number, i.e. Re [1][2]. So far, large attention has been payed to the characterization of the mixing process in these regimes, but there is scarce knowledge about their effect on the yield of a chemical reaction. In particular, the reaction yield is affected not only by the manner the reactants come into contact (i.e. mixing), but also by the reaction kinetics (chemical reaction). Hence, an important role is played by the Damköhler number, i.e. *Da*, representing the flow to chemical time-scale ratio.

The present work is aimed at investigating the effect of *Da* and *Re* on the yield of a chemical reaction in a T-junction, by combining experiments and computational fluid dynamics (CFD).

2. Methods

A T-shaped micro-reactor, shown in Fig. 1a, is used to carry out flow visualization experiments. The reaction that has been chosen is A+B→C+D and a large excess of B was used to have a pseudo-first order kinetic, i.e. $\frac{dC_A}{dt} = -kC_A$, where C_A is the concentration of A. Moreover, the reaction is catalyzed by an acid E, so that the kinetic constant $k = f(C_E)$. The reaction can be

observed experimentally through flow visualization as the reactant A has a color that disappears while converting into products. A syringe pump feeds the mixer inlets with equal flow rates. One inlet stream is an aqueous solution of A and E, while the other stream is an aqueous solution of B. By arranging the concentrations of B and E, the kinetic constant k is varied in the range from 1 to 20 s^{-1} to span a range of Da in addition to Re.

An upright microscope with a magnifying lens of 4x and a halogen lamp are used to observe the mixing of the streams inside the mixer. The images are collected by using a monochromatic high-speed camera having a resolution of 920x2048 pixels and a frame rate up to 387 frames/s. Flow visualization images are processed off line to convert pixel intensities into normalized depth-averaged A concentration images [1] and thus to estimate the reaction yield.

Numerical modeling was carried out by solving continuity, momentum and chemical species transport equations using ANSYS Fluent v19 code [3]. In order to better capture the reaction region, the grid was refined in the region of high reaction rates through the mesh adaption technique.

3. Results and discussion

Both the numerical and the experimental investigations were carried varying the *Re* from 10 to 260 and *k* from1 to 22 s^{-1}. Fig. 2b shows for example the average concentration of A along the mixing channel as estimated from the CFD and from the experimental image analysis for k = 10 s^{-1} and for different *Re*, in the range *Re* = 10-60. A good agreement between experiments and CFD can be observed. Moreover, with increasing *Re*, the concentration of A in the outlet increases indicating lower yield. This is due to the lower residence time in the reactor.

(a) 
(b) 
Figure 1. (a) T-junction. (b) Concentration of A along the mixing channel as a function of Re.

4. Conclusions

The effect of both *Da* and *Re* on the reaction yield in a T-junction is investigated experimentally and numerically. At low *Re*, with segregated flow regimes, the reaction yield decreases with increasing *Re* because of the lower residence time. Instead, increasing *Re* in the engulfment regime, leads to an increase of reaction because the enhanced mixing.

Scale-up strategies for the blending of miscible liquids with large viscosity differences

Nur Azmina Hadirah Binti Hamdan[1], Joelle Aubin[1*], Martine Poux[1], Catherine Xuereb[1]

1 Laboratoire de Génie Chimique, Université de Toulouse, CNRS, Toulouse, France

Highlights

- $N.t_m$ versus Re* allows identification of stirrer or added liquid regimes
- Re* does not allow $N.t_m$ to be replicated across scales
- Impeller tip speed or specific power replicate $N.t_m$ better across scales

1. Introduction

Blending of small quantities of additives that have higher viscosity and/or density than the bulk is a common operation in the process industries (personal care, food, water treatment), it is however a difficult task. A few studies have addressed the subject and it was found that a modified Reynolds number, $Re^* = \rho N D^2/\mu_a$ allows identification of whether the added liquid has an effect on mixing time compared with turbulent blending [1, 2]. [2] also looked the effect of scale on blend time in these systems and found that large viscosity differences may affect small scale more than in large scale vessels and that depending on the scale the operating regimes (stirrer controlled or added liquid controlled) may change. Whilst correlating dimensionless mixing time ($N.t_m$) with Re* may be useful for determining if turbulent blending correlations can be used for these systems, it does not provide guidance for scaling-up or down. The objective of this work is to identify which stirred tank operating parameters should be kept constant to replicate blending miscible liquids with large viscosity ratios across equipment scales.

2. Methods

Experimental set-up. The tanks employed in this work are dish-bottomed cylindrical tanks with dimensions, $T_1 = H_1 = 0.19$ m and $T_2 = H_2 = 0.6$ m, which correspond to volumes of 5 L and 171 L, respectively. The tanks are equipped with four equally spaced Perspex baffles of width $w = T/10$ placed 90º to each other. An axial flow Mixel TT impeller ($D = T/2$) used to blend the liquids with an off-bottom clearance of $C = T/3$, where C is defined as the distance from the vessel bottom to the lowest horizontal plane swept by the impeller.

Fluids and operating conditions. The fluid in the bulk of the tank was tap water at 20°C. The impeller speed was in the range 130-400 rpm for the 5 L tank and 90-185 rpm for the 171 L tank, which correspond to fully developed turbulent flow. The viscous additive was a solution of carboxymethyl cellulose (CMC) at concentrations ranging from 1% w/w to 7% w/w. For CMC solutions with concentrations less than 2% w/w, the rheological behaviour was quasi-Newtonian and the viscosity ranged from 0.1 to 1.3 Pa.s. However, for higher concentrations, the additive had an increasingly shear-thinning behaviour. The apparent viscosity at 10 s^{-1} (approximate shear rate in injection zone)

was taken as a reference, being 11 Pa.s, 35 Pa.s, 580 Pa.s and 820 Pa.s for 4-7% CMC solutions. Nevertheless, the amount of viscous fluid added to the bulk was relatively small, being 1 mL or 10 mL, and this was assumed to have no impact on the turbulent flow regime in the tank.

Mixing time measurements. Macro mixing time was determined using a coloration-decolouration method based on an oxido-reduction between sodium thiosulfate and iodine. The water in the tank is initially coloured brown with an iodine solution. CMC is dissolved in sodium thiosulfate and this solution is then injected into the bulk at the liquid surface using a large syringe, midway between the shaft and the tank wall and midway between two baffles. The sodium thiosulfate solution decolours the brown iodine solution. The macro mixing time is evaluated visually and is determined as the time taken for all of the iodine to have disappeared. For each operating condition, the experiment was repeated four times and an average value was used for analysis.

3. Results and discussion

Figure 1 (left) shows a constant dimensionless mixing time in the 5L tank for Re* ≥ 10 corresponding to the stirrer controlled regime, whilst for decreasing values of Re* lower than this limit, $N.t_m$ increases, which corresponds to the added liquid controlled regime. Indeed, for viscosity ratios $\mu_a/\mu_b < 10^3$–10^4, mixing time may be predicted by conventional correlations for turbulent blending. It is noted however that this does not hold when working in the 171L tank, suggesting that Re* may not be the appropriate scale-up invariant. On the other hand, for a given viscosity ratio, $N.t_m$ is better replicated at both scales when impeller tip speed (Figure 1, right) or power per unit volume are kept constant, at lease for lower viscosity ratios.

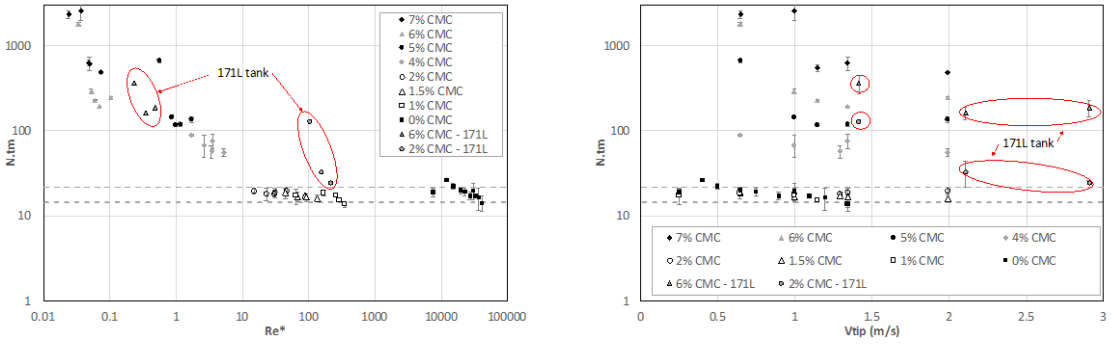

Figure 1. Dimensionless mixing time in the 5L and 171L tanks as a function of Re* (left) and impeller tip speed (right).

4. Conclusions

Mixing time is unaffected by additive viscosity for $\mu_a/\mu_b < 10^3$–10^4, however it increases significantly for higher ratios. Also, $N.t_m$ is not constant over the entire turbulent flow regime as the viscosity ratio increases. $N.t_m$ correlates better with the modified Re* based on the viscosity of the added liquid although Re* does not seem to correctly replicate $N.t_m$ across scales when at large viscosity ratios. $N.t_m$ appears to better replicated at both scales at constant impeller tip speed or power per unit volume.

Characterization of gas-liquid flow photoreactors at the micro- and milli-scale

Anca Roibu, Tom Van Gerven, Simon Kuhn*

Department of Chemical Engineering, KU Leuven, Celestijnenlaan 200F, 3001 Leuven, Belgium

**Corresponding author: simon.kuhn@kuleuven.be*

Highlights

- Photon flux per liquid volume increases with gas transport fraction.
- Optical pathlength is smaller in gas-liquid phase in comparison to single phase.
- Actinometry has potential for quantification of scattering and liquid residence time.

1. Introduction

Flow photo microreactors are a promising tool for gas-liquid photoreactions such as photooxidations and fluorinations due to their small penetration depth and the promotion of segmented flow which leads to good mass transfer of the gas in the liquid [1,2]. However, reaction condition optimization in microreactors and scale-up to milli-reactors requires an extensive parameter study [4,5]. Nevertheless, the optimal light source intensity, reagent concentration and total flow rate are determined by photon transport and hydrodynamics in the employed gas-liquid photoreactors. When these phenomena are understood at a fundamental level, the optimization and the scale-up procedure become faster and cost efficient. Chemical actinometry is an important tool to characterize photoreactors and was previously used to determine the optical pathlength and photon flux in single liquid phase in a microstructured reactor [6]. However, the observations found in single-phase may not apply to two-phase flow due to the light scattering at the gas-liquid interface and hydrodynamics determined by the presence of the gas bubbles. The aim of this study is to experimentally determine the optical pathlength and photon flux in gas-liquid micro- and milli-scale photoreactors and compare it with the case of single liquid phase.

2. Methods

The microreactor used in this work consists of a glass plate with a serpentine channel characterized by a volume of 0.6 mL and a diameter of 1 mm. The milli-scale reactor is a Corning Advanced-Flow G1 Photo Reactor which is composed of heart-shaped elements and is characterized by a volume of 8 mL and a channel height of 1.1 mm. Both reactors are irradiated by green Light-Emitting Diodes (LEDs). The photon flux and the optical pathlength are experimentally determined by visible-light actinometry following a methodology previously reported [6]. The actinometric measurements are performed in single liquid phase and in gas-liquid two-phase flows. The total flow rate is 1.3 $mLmin^{-1}$ in the microreactor and between 35 and 42 $mLmin^{-1}$ in the milli-scale reactor. Nitrogen is used as inert gas with volumetric gas transport fractions (β_G) comprised between 0.2 and 0.9 in the microreactor and between 0.2 and 0.5 in the milli-scale reactor.

3. Results and discussion

To ease the comparison, the values of the photon flux per liquid volume obtained in two-phase flow are normalized by the values found in single phase. As shown in Figure 1, the photon flux in two-phase flow experiences an exponential increase with the gas transport fraction reaching 240% at β_G=0.9 in the microreactor and 54% at β_G=0.5 in the milli-scale reactor. This increase can be caused by light scattering. Another possibility is that the liquid residence time is higher than considered in calculations due to the slip and occurrence of local back flow through the liquid films [7]. Currently, a residence time distribution investigation is carried out in order to experimentally determine the mean liquid residence time. Moreover, it was found that the optical pathlength in two-phase flow is 31% smaller at β_G=0.9 compared to the single phase microreactor and 17% smaller in the milli-scale reactor irrespective of the gas fraction.

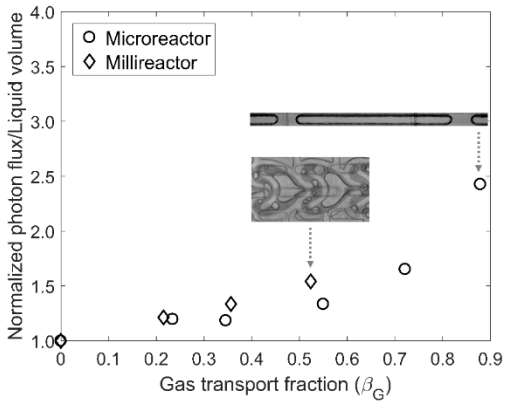

Figure 1. The variation of normalized photon flux per liquid volume with the gas transport fraction (β_G) in the microreactor and the milli-scale reactor. The insets illustrate the flow pattern at β_G = 0.88 in the microreactor and at β_G = 0.52 in the milli-scale reactor.

4. Conclusions

Our study shows that the presence of gas bubbles has a significant impact on the amount of photons received by the liquid phase and on the distance travelled by photons within the reactor at both micro- and milli-scale. The correlation of the actinometric measurements with the photon transport and hydrodynamics could extend the application of actinometry to the quantification of light scattering and liquid residence time in two-phase photoreactors.

Non-linear rheology of granular matter under large amplitude oscillatory shear

Rishab Handa[1], Christian Wagner[1] and Jorge Fiscina[1]

1 Experimental Physics, University of Saarland, 66123 Saarbrücken, Germany

rishabhanda93@gmail.com

Keywords: Chebyshev polynomial, Lissajous-Bowditch curve, nonlinear rheology

The structure and dynamics of granular materials is a problem of fundamental and industrial interest. Investigating the granular flow near jamming transition can yield insight into the energy landscape of granular media. Large amplitude oscillation shear rheometry is a well-defined technique that offers to shear material at rates similar to huge deformation that occurs in industrial processing operations. In this study, we show that the viscosity of granular materials can be significantly tuned by orders of magnitude by applying normal force of an order of few Newton. Also our comparative study of dry and wet granular systems confirms that dry granular media flow considerably slower than wet granular systems, contradicting to the common assumption of wet granular material being more viscous than dry granular material. We have utilized a new framework to characterize the non-linear stress-strain response and seemingly have identified different dynamical regimes of granular materials in the context of LAOS rheometry.

Highlights

- Liver microtissue spheroids were cultured in a HF membrane bioreactor
- Membrane bioreactor enabled the maintenance of cell functions up to 25 days
- O_2 concentration profiles into the spheroids and bioreactor were evaluated
- A proper oxygenation was proven by oxygen uptake and mass transfer

1. Introduction

The development of bioartificial devices that are able to favour the liver reconstruction is still challenging[1]. Our strategy was to create human liver microtissue spheroids metabolically active by using an optimized crossed HF membrane bioreactor whose design and structural features ensure a uniform microenvironment and adequate oxygenation[2]. When culturing large spheroids, the lack of a perfusing vascular network, as occurs in vivo, could imply a reduced supply of oxygen and nutrients leading to impairment of cell viability and functions. The bioreactor consists of two bundles of hollow fiber (HF) polyethersulfone (PES) membranes cross-assembled in alternating manner. One bundle of HF membranes provides cells nutrients and metabolites whereas the other HF bundle removes catabolites from cell compartment mimicking in this way the in vivo arterious and venous blood vessels. The combination of these two fiber set creates three compartments: two intraluminal compartments of PES HF in which the medium flows and one extraluminal compartment represented by extracapillary network formed by the fibers in which spheroids are cultured.

2. Methods

The bioreactor consists of two bundles of PES HF membranes cross-assembled in alternating manner and potted with polyurethane adhesive within glass housing. The membranes were characterised in order to establish the physico-chemical, structural and transport properties. The bioreactor fluid dynamics were characterized in terms of cumulative residence time distribution (RTD). Spheroids of primary human hepatocytes were realized in agarose mold and then cultured in the extralumen compartment of the bioreactor. The oxygen uptake, urea synthesis and albumin production rates as well as biotransformation functions were evaluated with time. The oxygen concentration profile inside the spheroids and in the extra-capillary space was determined through mathematical modelling of the mass and momentum transfer under steady-state conditions. A periodic unit element (750×750×500 μm) representative of the perfusion system in

the bioreactor was chosen to decrease the computational complexity of the model. The equations were numerically solved using COMSOL Multiphysics®.

3. Results and discussion

Human hepatocyte spheroids with uniform size and shape were formed through self-assembling and cultured into the bioreactor (Fig.1). Adjacent spheroids fused, giving rise to larger microstructures around the fibers forming liver-like tissue, which retained functional features in terms of urea synthesis, albumin production, and diazepam biotransformation up to 25 days. The metabolic function data strongly corroborates that within the bioreactor a proper oxygenation and supply of nutrients were provided to the cells ensuring a physiological amount even in the spheroids core. The oxygen uptake rate and the mathematical modelling of the mass transfer directly elucidated that liver microtissue spheroids are not exposed to any oxygen mass transfer limitation. The minimum oxygen concentration reached at the center of multiple spheroids with diameter of 200 μm is significantly higher than the one of the perivenous zone in vivo (42-49 μmol/L), while for larger microtissues (400 μm diameter) the oxygen concentration drops to values that are equal to the maximum concentration found in the liver periportal zone (Fig. 1). Both experimental and modelling investigations led to the achievement of significant results in terms of liver cell performance. Indeed, the creation of a permissive microenvironment inside the bioreactor supported the formation and long-term maintenance of functional human liver microtissues.

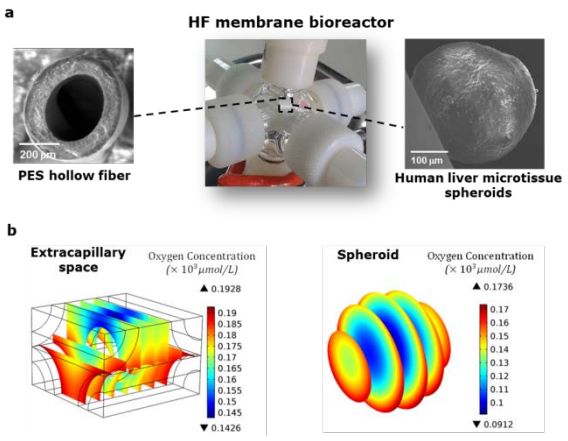

Figure 1. a) Hollow fiber membrane bioreactor used for culture of liver microtissue spheroids; b) oxygen concentration profiles in a large spheroid within a unit element of the bioreactor and in the extra-capillary space in the element.

4. Conclusions

The bioreactor provided a well-controlled microenvironment at molecular level thanks to the selective permeable properties of the membranes and fluid dynamics conditions. The oxygen concentration profiles into the spheroids and in the extracapillary space giving a microscopic view over the cellular microenvironment confirmed the capability of the bioreactor to provide adequate oxygenation to the microtissues.

Highlights

- Polycaprolactone (PCL)/Graphene-based nanomaterial (GbN) membranes favor cell response
- Differentiation of C6 cells to astrocytes on PCL/GbN membranes was better than on PCL
- Different oxygen content on the GbNs affects the cellular response
- Chemical defects in GbNs could be involved in the mechanism of neural activation

1. Introduction

Recent studies in tissue engineering and regenerative medicine have demonstrated that graphene-based nanomaterials used as scaffolds for in vitro stem cells cultures, induce cell differentiation toward specific tissues [1]. Furthermore, in our previous work we observed that graphene oxide (GO), and particularly reduced graphene oxide (rGO) doped in the matrix of polymer membranes of polycaprolactone (PCL), induced a significant improvement on neural differentiation of human Neural Progenitor Cells (hNPC) towards neurons, as well as a higher neural functional activity after maturation [2]. However, there is a lack of data in the literature covering the comparison of the effect of incorporating graphene-based nanomaterials with different chemical and physical characteristics on polymer scaffolds for the modulation of neural differentiation. The aim of this work is to broaden the comparison of different type of GbNs immersed on PCL/GbN composite membranes to be able to find out more information about the potential properties of GbNs that might trigger the differentiation of stem cells to neural cells.

2. Methods

In this study flat composite membranes with PCL and GO, with different oxygen content and produced using different exfoliation procedures, were used. The nanomaterials produced by anodic exfoliation contained either 2% (GO2%Ox) or 20% (GO20%Ox) of oxygen groups respectively (supplied by the Carbon Institute, INCAR-CSIC, Oviedo) [3]. Furthermore, GO was also produced using a modified Hummer's method, followed by a reduction of oxygen groups by a hydrothermal process, forming rGO. Then flat PCL/Graphene-based Nanomaterials (GbN) composite membranes (PCL/GO2%Ox, PCL/20%Ox, PCL/rGO) were fabricated using phase inversion following the procedure described elsewhere [4]. Plain PCL membranes were also produced for comparison.

Membranes were characterized by SEM, Raman and cyclic voltammetry. Furthermore, C6 cell cultures were carried out on every type of membrane and the differentiation degree was quantified by assessing the nuclear size, length and number of cellular processes and percentage of cells that could express GFAP protein (an astrocyte's specific protein marker).

3. Results and discussion

Figure 1 shows confocal microscopy images showing the proliferation (Figures 1a-e) and differentiation (Figures 1f-j) stages of C6 seeded on the different membranes and in tissue control plate (TCP) as control. At day 1, TCP showed better cell proliferation (Figure 1a), though interestingly at day 3 (Figure 1f), C6 cells on TCP differentiated towards fibroblast instead of astrocytes. The differentiation to astrocytes was particularly better for PCL/rGO membranes (Figure 1j) and, at a lower extent, in PCL/GO20%Ox membranes (Figure 1i). Contrary to expectations, despite GO2%Ox nanomaterials have the closest Raman spectrum to CVD-quality graphene [3], PCL/GO2%Ox membranes presented the worst cell differentiation among the PCL/GbN membranes (Figure 1h).

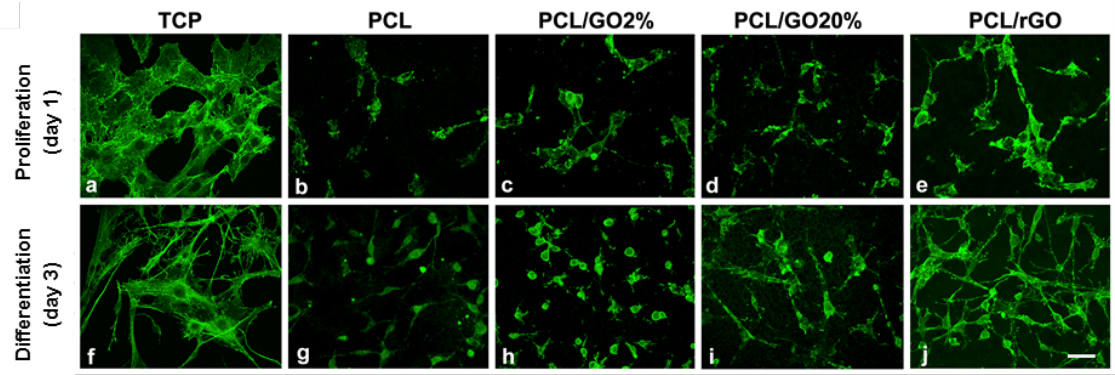

Figure 1. Confocal images showing the length of emitted projections of non-differentiated (day 1) and differentiated (day 3) C6 cells (F-Actin staining in green). Cell morphology at day 3 on TCP corresponded to fibroblasts. The emitted projections (astrocyte-like) on PCL/rGO and PCL/GO20%Ox were significantly longer than in the rest of membranes. (Scale bar 30 μm)

4. Conclusions

The evidences shown in this work highlight that graphene based nanomaterials with chemical defects on PCL/GbN composite membranes might be more favorable than pristine graphene to modulate the differentiation towards neural cells for neural in vitro models. However, the actual mechanisms behind the effect of GbNs on neural stimulation need to be explained, and therefore, further studies have to be performed.

Financial support through project InnVal17/20 (IDIVAL, Spain) and nanomaterials supply by Carbon Institute, INCAR-CSIC, are gratefully acknowledged.

Adsorption of uremic toxins onto Mixed Matrix Membranes Adsorbers (MMMAs)

Matilde De Pascale[1*], Maria Grazia De Angelis[1], Monica Faria[2], Maria Norberta de Pinho[2], Cristiana Boi[1]

1 Department of Civil, Chemical, Environmental and Materials Engineering (DICAM), University of Bologna, via Terracini 28, Bologna, Italy; 2 Instituto Superior Técnico, Chemical Engineering Department, Lisbon, Portugal

Highlights

- Preparation of Cellulose Acetate-zeolite (HEU) Mixed Matrix Membranes Adsorbers (MMMAs).
- MMMAs removal efficiency is enhanced compared to the one of the pristine adsorbent.
- MMMAs permeability increases with respect to the one of pure polymeric membrane.

1. Introduction

Renal failure is a debilitating and chronical condition in which kidneys are no longer able to remove toxins and excess fluid from the body. For patients with terminal kidney disease, that were approximately 3.2 million at the end of 2017 [1], haemodialysis is the primary support treatment. Two of the main drawbacks of the therapy are the massive use of water, about 120 L per patient per treatment, and the uncomplete removal of uremic toxins from blood. Our work is focused on the preparation and characterization of novel porous Mixed Matrix Membranes Adsorbers (MMMAs) to remove the toxic compounds present in the spent dialysate. The purified water might be reused, to produce new dialysis fluid for the same patient, in order to reduce substantially the amount of pure water required for a single dialysis treatment.

2. Methods

Porous MMMAs based on Cellulose Acetate (Sigma Aldrich®) and ZUF (HEU) zeolite (Zeolith-Bentonit-Versand.de®) were prepared through the phase inversion casting technique [2], [3]. MMMAs with different amounts of ZUF were fabricated and characterized to investigate the removal of uremic toxins (urea, creatinine and uric acid) from aqueous solutions. Adsorption tests were performed in batch and in continuous mode (Fast Protein Liquid Chromatography). MMMAs removal capacity from aqueous solution was evaluated for the single uremic toxin and for a mixture of them.

3. Results and discussion

Results of the permeation tests showed the increase of the hydraulic permeability with the filler (ZUF) loading: the water permeability coefficient B_0 (m^2) is enhanced from 6.6E-16 m^2 to 1.2E-15

m^2 going from the pure cellulose acetate membrane to the MMMAs (30% ZUF). In Figure 1 is reported the urea and uric acid percentage removed from aqueous solution as a function of the ZUF wt%. The results are obtained in batch adsorption mode.

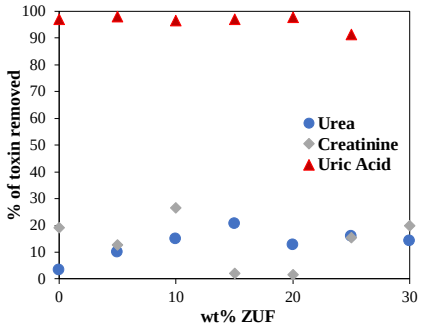

Figure 1. Percentage of uremic toxin removed as a function of ZUF wt%.

The removal of uric acid is easy, and it is almost independent on the loading of zeolite present in the membrane while for urea the percentage of ZUF plays and important role in the adsorption process. From the results shown in Figure 1, is also understandable that the membrane itself is actively involved in the adsorption mechanism.

4. Conclusions

MMMAs with ZUF were successfully prepared and tested to evaluate their removal capacity and their hydraulic permeability. The preliminary results indicate the potentiality of porous materials and MMMAs in toxin removal for the hemodialysis process and justify the future investigation of other combinations of polymers and fillers.

Use of salinity gradients for the recovery of valuable components from wastewater

Marie-Charlotte Sparenberg, Israel Ruiz Salmón, Patricia Luis[1]

1 UCLouvain, Materials & Process Engineering (iMMC-IMAP), Place Sainte Barbe 2, 1348 Louvain-la-Neuve, Belgium

Highlights

- Osmotic membrane distillation-crystallization allowed the recovery of target salts from synthetic wastewater.
- The economic evaluation showed the potential benefit of recovery.
- Optimal operation conditions are essential to achieve economic viability.

1. Introduction

Osmotic membrane distillation-crystallization is a novel technology that makes use of salinity gradients as the driving force to concentrate solutions until reaching the saturation concentration and thus, allowing the crystallization of target components. In this study, osmotic membrane distillation-crystallization is applied to recover sodium carbonate, potassium nitrate and sodium sulphate from synthetic industrial wastewater solutions. The technical viability of the process [1], discussed in terms of transmembrane fluxes, mass transfer coefficients and crystals purity, is completed with an economic study. The key operation conditions that determine the economic viability of the crystallization process are evaluated for each recovered salt [2].

2. Methods

The osmotic membrane distillation–crystallization contactor used in this study was the hollow fiber membrane contactor 2.5 × 8 Extra-Flow Module from LiquiCel (Membrana GmbH, Germany). The feed solution (*i.e.,* aqueous solution of pure Na_2CO_3, Na_2SO_4, KNO_3, or mixtures) was pumped to the membrane through the lumen side (inside of the hollow fibers) of the membrane. The osmotic stream (NaCl) circulated in counter-current mode through the shell side (outside of the hollow fibers). The influence of concentrations of the feed and osmotic solutions as well as the flow rates on the process performance was studied. In order to assess the economic viability of the process, the annual costs and salt sale profits were evaluated and the final benefit of salt recovery was determined as a function of the operation conditions.

3. Results and discussion

The experimental results showed that varying the concentration of the osmotic solution was the main parameter affecting the transmembrane flux. The concentration of the three salts in the feed had slight influence while no significant effect was observed when flow rates in both the feed and

the osmotic side were varied. High purity crystals of $Na_2CO_3.10H_2O$, $Na_2SO_4.10H_2O$ and KNO_3 was obtained (Figure 1).

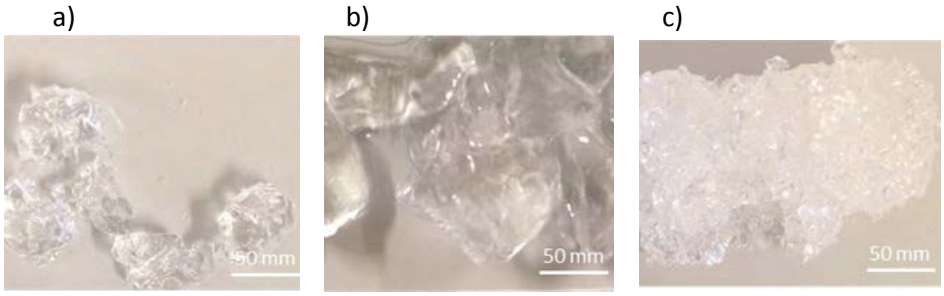

Figure 1. Crystals of a) $Na_2CO_3.10H_2O$; b) $Na_2SO_4.10H_2O$; and c) KNO_3

Figure 2 illustrates the influence of the initial osmotic concentration (ranging from 100 to 300 g L^{-1}) on the economics of the process for the three salts, with initial feed concentration and flow rate of 100 g L^{-1} and 500 L h^{-1} respectively and initial osmotic flow rate of 27 L h^{-1}. It can be clearly seen that the osmotic concentration has a major impact on the economic viability of the process. Increasing this concentration leads to a higher driving force hence a higher flux, less membrane area and lower costs.

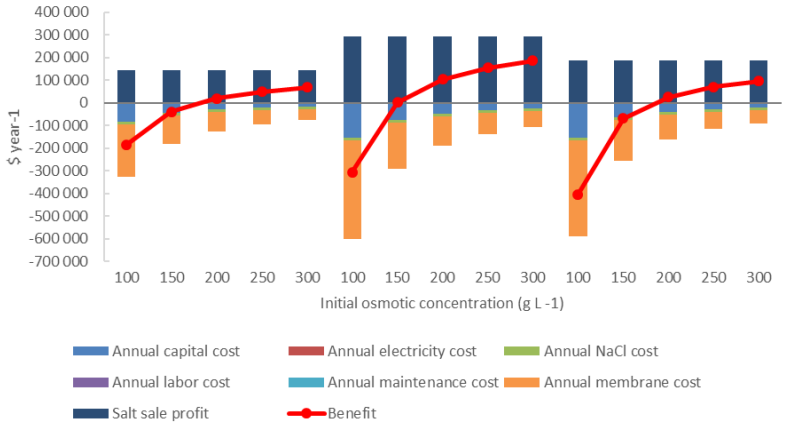

Figure 2. Costs, salt sale profit and benefit for the crystallization of the three salts. Initial feed concentration and flow rate are 100 gL^{-1} and 500 Lh^{-1} respectively and osmotic flow rate is 27 Lh^{-1}.

4. Conclusions

High purity crystals of $Na_2CO_3.10H_2O$, $Na_2SO_4.10H_2O$ and KNO_3 were obtained using osmotic membrane distillation-crystallization in synthetic wastewater. Using the highest possible concentration of osmotic solution (limited by the solubility of the salt i.e. 358 g L^{-1} at room temperature for NaCl) is desired because of its marginal costs and high impact on the economics.

Highlights

- A 4-scale model ranging from the channel scale to the plant scale was developed.
- Pressure drops and polarization have minor effects on the process performance.
- Ionic short-circuit currents *via* manifolds may halve the Round Trip Efficiency.

1. Introduction

The renewable energy market is rapidly increasing. Most of renewable energy sources are intermittent, e.g. wind and solar among them. This has led to the need for new large scale energy storage systems. In this regard, the Acid/Base Flow Battery (AB-FB) represents an innovative, safe and sustainable way to store energy with high performances [1]. The energy density accumulated in an AB-FB, in the form of pH and salinity gradients, can theoretically reach 7 kWh/m^3 which is higher than the values relevant to the most used technologies (e.g. pumped hydropower and compressed air). The core of the battery is the stack where two membrane separation processes are carried out: bipolar membrane electrodialysis during charge phase and its opposite bipolar reverse-electrodialysis during discharge. A stack consists of repetitive units called cells or “triplets”, composed by a cation exchange membrane, a salt solution, an anion exchange membrane, an acidic solution, a bipolar membrane and a basic solution. The aim of this work is to develop a simulation tool able to predict the operation and performances of the battery.

2. Methods

The modelling tool was developed using a multi-scale approach. The lowest scale is the single channel. At this level, all variables are discretized along the main flow direction and correlations coming from Computational Fluid Dynamics [2] are implemented in the model in order to evaluate the concentration polarization effects and the channel pressure loss. The medium-low scale simulates the triplet, computing its electrical behavior and all fluxes through the membranes (ohmic, diffusive, osmotic and electro-osmotic). The medium-high scale simulates the stack and predicts its pressure losses and ionic short circuit currents *via* manifolds [3]. The highest scale simulates the external hydraulic circuit, the electrolyte solutions storage tanks and the transient behavior of the battery. All the levels of the multi-scale model are fully integrated and predict the distribution of the process variables as well as meaningful performance parameters, such as the Round Trip Efficiency (RTE).

3. Results and discussion

Preliminary experiments show a good agreement with the model predictions. Thus, a sensitivity analysis was performed in order to assess the effect of stack features and operating conditions. Under most conditions simulated, pumping power and voltage drop due to concentration polarization have only minor effects on the process efficiency. Conversely, ionic short circuit currents *via* manifolds affects significantly the system performance. Just as an example, Figure 1 reports simulation results concerning the impact of the parasitic currents on the cell currents, triplet by triplet: the lower the ratio reported in the y-axis of the figure the higher the parasitic currents impact. Each line refers to a different electric current supplied to an external circuit (discharge, Fig.1a) or coming from it (charge, Fig.1b). As the external current decreases, the impact of parasitic current losses becomes more important (see distance from the horizontal line at $I_{cell}/I_{cell,max}$ =1). RTE reduction due to ionic short circuit currents ranges from 13 to 46 % (RTE range 21–31 %).

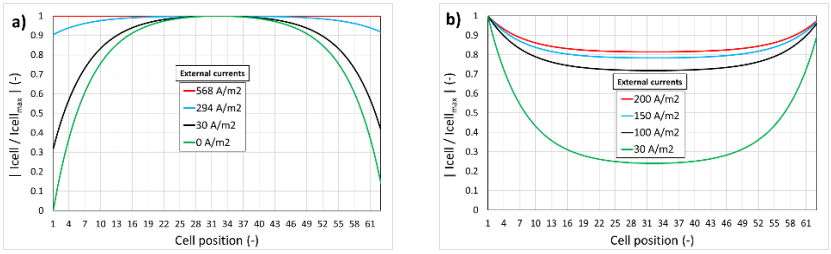

Figure 1. Ratio between cell current and maximum cell current along the stack for discharge (a) and charge (b). Stack of 63 triplets, membrane area 0.19x0.21 m^2, spacer thickness 500 µm, manifolds diameter 8 mm, mean flow velocity 0.4 cm s^{-1}, starting composition: acid 1M HCl-0.25M NaCl, base 1M NaOH-0.25M NaCl, salt 0.02M HCl, 0.25M NaCl.

4. Conclusions

A mathematical multi-scale tool was developed in order to simulate AB-FB units. From a sensitivity analysis, pumping power and polarization were found to slightly affect the battery performance. On the other hand, ionic short-circuit currents represent the major issue, leading up to almost halved values of RTE (~30 %). These preliminary results provide important insights for improved designs, and further studies are ongoing to achieve competitive RTE values, e.g. larger than 70%.

How the fouling can affect the transport and energy generation in PRO process

Endre Nagy[1*], Imre Hegedüs[1]

Highlights

- Developing new expressions involving the fouling layer.
- This layer forms quickly and lowers essentially the performance..
- Seawater/river water pair provide not enough energy.
- An alternate solute might be the switchable polarity ionic liquid.

1. Introduction

Accumulation of a foulants on the membrane layer (or inside it) during energy generation by pressure retarded osmosis process, applying e.g. seawater/river water pair affects strongly the transport process and the power generation. Several paper studied the efficiency of the energy generation by seawater/river water pair [1,2]. The conclusion was, that the commercially available membrane does not provide nowadays enough selectivity and water transport to make this process economic. On the other hand, the mass transport through the transport layers, including the fouling layer, should accurately be described to be able to predict reasonably the process efficiency. In a study we have shown how the literature models have been extended for the fouling layer, as well [3]. Accordingly, this new transport model describes the real effect of the fouling layer on the mass transport process, namely on the solute and the water transport. Equations developed involve also the separate expression of the internal interface concentrations, thus they make possible to predict the osmotic pressure difference, and thus the power density more accurately than the literature expressions.
On the other hand if one wants to use draw solution with much higher solute concentrations than the seawater than the solution used should be regenerated for its repeated usage. It seems that a switchable polarity solvent might be suitable to it. For its investigation, high molecular weight dibutyl-(2-(2-metoxyethoxy)-ethyl)-amine was prepared, which forms water soluble ionic liquid in water+CO_2 system. This ionic liquid can then switch back to the molecular (non-water soluble) form by expelling CO_2 at 90 ^oC.

2. Methods

Organic fouling experiments using alginate are used to validate the model and observe the effects of feed salinity, cross-flow velocity, membrane orientation, feed spacers on foulant accumulation rates. Increasing feed salinity and cross flow velocity both lead to a decrease in foulant accumulation in PRO orientation. It will also be shown deviances in the osmotic pressure

difference, using the individual interface concentrations of the active layer, and the literature approach. On the other hand, we have measured the energy generation with the ionic liquid prepared. Its regeneration have also been investigated.

3. Results and discussion

During the building the fouling layer, the water flux was significantly decreased, depending on the thickness of the fouling layer. Figure 1 illustrates the power density as a function of the draw side osmotic pressure, at three different thickness of the fouling layer, S_c. Its decrease is essential.

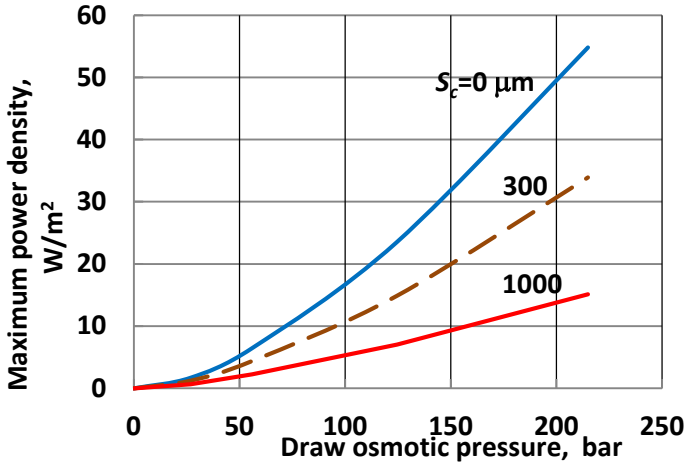

Figure 1. Maximum power density as a function of draw solution osmotic pressure and cake structural parameters in PRO system for a river water feed Parameters used were: C_f =0.862 g/L (0.015 mol/L; river water); k_d = 8.43 × 10^{-5} m/s; k_f = 2.07 × 10^{-5} m/s; A = 1.8 × 10^{-7} m/s-bar; B = 5 × 10^{-7} m/s (A, B are water and solute (NaCl) permeabilities)

It will also be shown the effect of the ionic concentration on the energy generation and results will be compared with those obtained with NaCl solution. On the other hand, the regenerability of the ionic liquid will be discussed as alternative solution to the seawater/river water pair. Namely, the easy regeneration of the solutes would enable to use high concentration draw solution, which can produce much higher energy density than the seawater/river water pair.

4. Conclusions

The production of the “blue” energy needs still essential improvement to become more economic. This presentation try to answer some questions to be solved for it.

Highlights

- The conformational change of DNA-aptamers can be used as nanovalves in membrane pores.
- DNA-aptamer gating membranes respond to a molecular rather than a bulk stimulus.
- DNA-aptamers are versatile building blocks for bioinspired nanostructured hybrid membranes.

1. Introduction

Aptamers are oligonucleic acids that can be selected to specifically interact with in principle any kind of target molecule. An important asset of aptamer conjugates is the fact that upon specific binding, their spatial conformation may change drastically, depending on a fine equilibrium between mainly electrostatic and hydrophobic interactions. Recently, if has been shown that this specific conformational change can be exploited for controlled release applications in particles and membranes, where aptamers serve as a "nanovalve" which selectively triggers the opening or closing of a nanopore depending on the presence of a target molecule [1]. Such systems add an important degree of freedom in the design of stimuli-responsive systems which conventionally respond to bulk stimuli such as pH, temperature, light or electrical and magnetic fields. Figure 1 schematically shows as an example the conformational which an AMP-aptamer undergoes upon target binding.

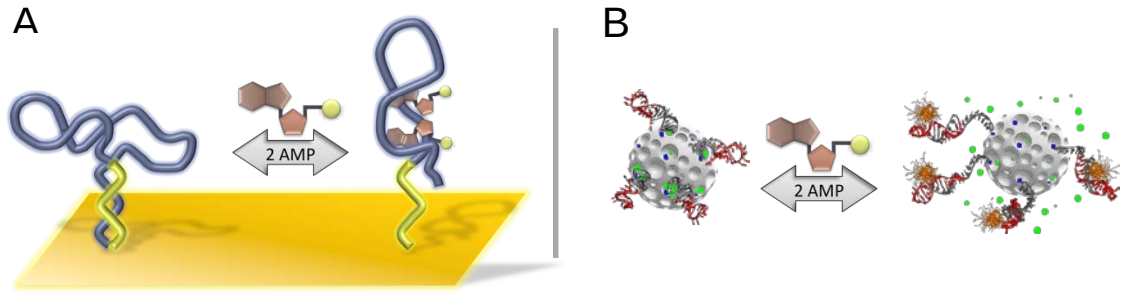

Figure 1. Conformational change of a DNA-Aptamer upon molecular target recognition (A, here: AMP) and use for gating the solute permeation in nanoporous matrices (B).

2. Methods

The build-up of the DNA-aptamer gating membrane was monitored in real-time by quartz crystal microbalance with dissipation monitoring (QCM-D) and multi-parameter surface plasmon

resonance (MP-SPR). The DNA-aptamer used was specifically recognizing adenosine monophosphate (ATP) but not guanine monophosphate (GTP, negative control). DNA/AAO membranes were manufactured by surface modification of the AAO membrane that allow subsequent self-assembly of the DNA. The permeability of the DNA-aptamer gated AAO membranes was measured spectrofluorometrically using a single-photon counting spectrofluorimeter and fluorescein as a tracer dye. Successful and selective gating was proven by (1) using GTP as negative control and (2) using a scrambled sequence of the DNA-aptamer which has no specificity for the molecular target ATP.

3. Results and discussion

The AAO membranes were modified with a DNA-aptamer that specifically recognizes ATP as a small molecular target. Upon target recognition as a molecular stimulus, the DNA-aptamer gated membranes responded with a nanopore opening whose degree depended on the target (ATP) concentration (Figure 2, left) and was according to the K_D of the DNA-aptamer (Figure 2, right).

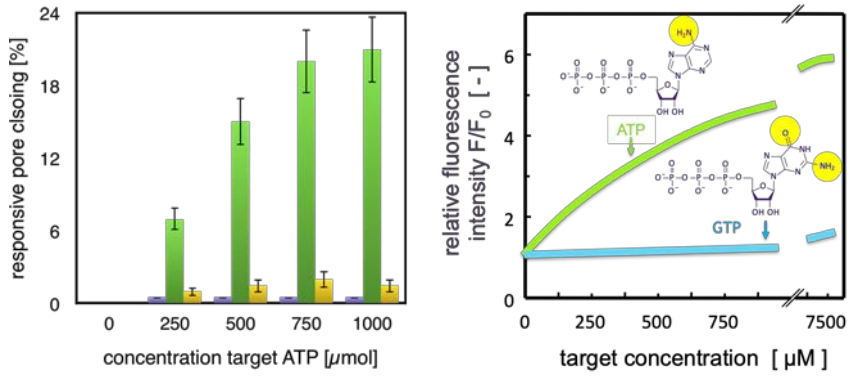

Figure 2. Left: Permeation of fluorescein across a DNA-aptamer gated AAO membrane as a function of the concentration of the DNA-aptamer molecular target ATP; Right: Dissociation constant K_D of the DNA-aptamer for ATP and GTP, respectively.

The scrambled sequence of the DNA-aptamer and the molecular target GTP did not result in any response of the membrane, i.e., the membrane pores remained closed (Figure 2, left), corroborating that the conformational change of the DNA-aptamer upon specific target recognition was the sole trigger for modulating permeation of fluorescein across the membrane.

Owing to the reversibility of the conformational change of the DNA-aptamer, permeate flow of fluorescein could be repeatedly switched on and off depending on the concentration of ATP, simulating in this way to a certain extent the function of transporter proteins in biological membranes.

4. Conclusions

DNA-aptamers are highly versatile building blocks for creating bioinspired stimuli-responsive membranes. The conformational change of the DNA-aptamer is highly specific and reversible, allowing to modulate permeation of solutes across the membrane based on a molecular stimulus.

Highlights

- A high-silica CHA-type zeolite membrane was prepared by using TEAOH.
- The CO_2 permeance of the membrane showed 3.5×10^{-6} mol m^{-2} s^{-1} Pa^{-1}.
- The CO_2 permeance was 2-fold value of that of TMAdaOH.

1. Introduction

At the present time, carbon dioxide is generally separated by chemical absorption. As an alternative to the chemical absorption, membrane separation technologies have attracted much attention due to their low energy consumption and compact device designs. Among the large number of membrane materials, zeolite have been extensively studied owing to their high chemical and mechanical stabilities. Particularly, CHA-type zeolite membranes show the excellent CO_2 permeability and high selectivity because the CHA-type zeolite has a suitable pore size (0.38×0.38 nm) for CO_2/CH_4 owing to the effects of molecular sieving.

In our previous study, it was found that the CHA membrane with a high Si/Al ratio showed of a high water flux for water/ethanol pervaporation and high CO_2 permeance for CO_2/CH_4 gas separation [1]. On the other hand, there were few reports about the preparation of CHA zeolite with a high Si/Al ratio using organic structure directing agents (OSDAs) except for N,N,N-trimethyl-1-adamantammonium hydroxide(TMAdaOH). In this study, we prepared a high silica CHA membrane using tetraethyl ammonium hydroxide (TEAOH) as OSDA. The gas permeances and separation properties for this membrane were determined by gas permeation test.

2. Methods

The high-silica CHA-type zeolite seed crystals were prepared by the following literature [2]. High-silica CHA-type zeolite seed crystals were applied to the outer surface of a porous α-alumina support tube (pore size: 0.5–1.0 μm; Hitachizosen Corp.) by rubbing. The membrane synthetic gel was prepared with TEAOH, ion exchanged water, sodium hydroxide, and FAU-type zeolite. The α-alumina support tube with the high-silica CHA type zeolite seed crystals was placed in a Teflon container, and immersed in the synthesis gel. After installing the Teflon container in an autoclave, the hydrothermal treatment was performed at 160 ℃ for 3 days. The membranes were characterized by XRD and FE-SEM. The single gas permeance of N_2, CO_2, and CH_4 for the CHA membranes were measured at 40 ℃. Gas separation properties for the membranes were confirmed

by the gas permeance (mol m^{-2} s^{-1} Pa^{-1}) which was calculated as the permeate flow rate of each gas divided by the partial pressure difference and membrane area.

3. Results and discussion

Fig. 1 shows XRD patterns of the CHA membranes prepared by TEAOH. The peaks at 2θ=9.4°, 20.5°, and 30.4° correspond to (1 0 0), (2 0−1), and (3−1−1) planes of the CHA-type zeolite and large peaks appearing at 2θ=35.2°, 37.9°, and 43.2° are related to the α-alumina support. Typical peaks positions of the FAU-type zeolite (2θ=6.8°, 11.9°, and 15.6°) were not observed. This result indicates that a CHA type zeolite layer was successfully formed on the surface of the α-alumina support by using TEAOH. Fig. 2 shows cross-sectional FE-SEM images of the CHA membrane. The thickness of the polycrystalline zeolite layer was ca. 10 µm.

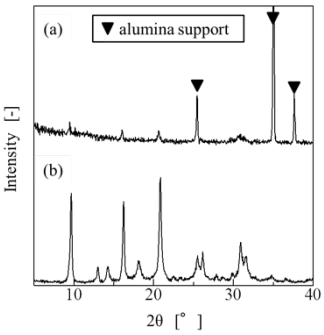

Fig.1 XRD patterns of (a) CHA membrane and (b) CHA seed crystal

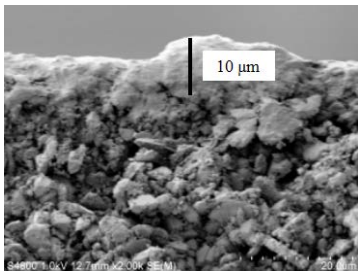

Fig.2 FE-SEM image of CHA membrane

Table 1 shows the comparison of gas permeation properties for CHA membranes prepared using TEAOH and TMAdaOH [1]. The CHA membrane of TEAOH showed the two-fold CO_2 permeance than that of TMAdaOH with the similar CO_2/CH_4 selectivity. Generally, the permeance is proportional to the reciprocal of the membrane thickness. The thickness of the CHA membrane of TMAdaOH reported to be about 3.0 mm. Therefore, the increase of CO_2 permeance by using TEAOH is not due to the membrane thickness. This reason might be the differences of pore structure caused by OSDAs.

Table1 Gas permeances and selectivity of CHA membranes prepared using TEAOH and TMAdaOH

Membrane		TEAOH	TMAdaOH [1]
Permeance [mol m^{-2} s^{-1} Pa^{-1}]	CO_2	3.5×10^{-6}	1.7×10^{-6}
	N_2	3.4×10^{-7}	1.2×10^{-7}
	CH_4	3.6×10^{-8}	1.8×10^{-8}
Selectivity [-]	CO_2/CH_4	97	98

4. Conclusions

In this study, the high-silica CHA-type zeolite membrane was synthesized on the α-alumina support tube by TEAOH as OSDA. The membrane showed the excellent separation performance for CO_2/CH_4 gas.

Highlights

- Micro-CT for structural analysis of ion-exchange membranes in their swollen state.
- Membrane swelling caused by the resin, shrinkage with increasing concentration.
- Method allows determination of ion-exchange area of heterogenous membranes.
- Sand equation shown not to hold for small pieces of the membranes.

1. Introduction

Electromembrane separation processes based on the use of ion-exchange membranes (IEM) play a very important role in production of potable water and increasingly in areas of waste water treatments. It is known that the performance of the whole process largely depends on the quality of the IEMs. These membranes can be classified into two major groups: (i) homogeneous, and (ii) heterogeneous. While homogenous generally posses better electrochemical properties they suffer from low mechanical and chemical stability. In these two aspects, they are outperformed by heterogenous ones which is however, at the expense of electrochemical performance. One of the ways how to improve the properties of heterogenous IEMs is too understand the relation between their structure and the exhibited behavior and later design membranes with optimal properties for a given application. This puts a requirement on having available analytical techniques that would allow to reconstruct 3D structure of these membranes and describe its composition quantitatively and qualitatively. At the same time these analyzed membranes should be practically tested regarding their performance.

To address the aforementioned problem we developed a technique which reconstructs 3D structure of membranes by micro-computed tomography and quantifies the composition not only in terms of volumetric composition but also in terms of surface composition which in turn provides very important data on the available ion-exchange area. Our method can work with both dry and wet (fully swollen) membranes which also allows one to study structural changes of membranes associated with swelling. We test our approach on testing the suitability of the Sand equation for determination of the fraction of conductive (ion-exchange) domains by combining our analytical technique with electrochemical measurement performed in a specific fluidic cell.

2. Methods

We developed a specific cell which allows microCT scanning of the samples in both dry and wet state. The details of this technique along with description of the evaluating methods can be found in [1]. Later the same piece of analyzed membrane can be integrated within a fluidic chip that allows electrochemical characterization. In this work, we measured so called transition times which are later used in the Sand equation to evaluate fraction of conductive domains. The details can be found in [2].

3. Results and discussion

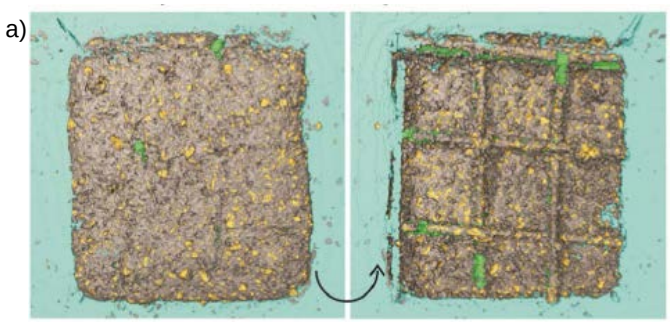

Figure 1. MicroCT surface analysis of a heterogeneous cation-exchange membrane.

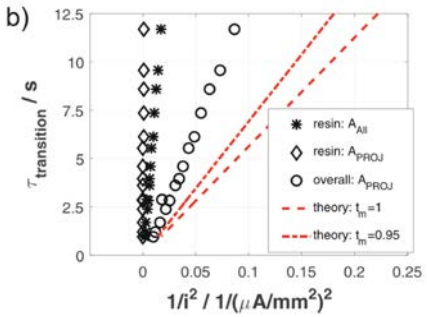

Figure 2. Measurement of the transition times in the dependence of the applied electric current.

Figure 1 and 2 show respective results of our studies focused on estimation of the ion-exchange area with two methods. The first one is based on the analytical reconstruction of the surface area by micro-CT and the other one on electrochemical measurement of transition times and substitution into the Sand equation. While microCT analysis is a direct technique that can locate the ion exchange-resin particles responsible for the actual ion-exchange (yellow color in Figure 1), the measurement of transition times is indirect technique that relies on several simplifications. Our results show that the electrochemical technique, although it might provide reasonable numbers, does not agree with results from microCT (compare red lines with black ones in Figure 2). Unlike that the Sand equation works very well for ion-exchange resin particles which can be considered as homogeneous and satisfies conditions under which Sand equation works.

4. Conclusions

Our technique based on micro-computed tomography allows to analyze the volumetric and surface structure of the heterogenous ion-exchange membrane, which are essential in electromembrane separation processes. By using this technique, we are able to characterize studied membranes in terms of composition and geometry. When combined with electrochemical measurements, we can relate the behavior of the membranes to the exhibited behavior.

Highlights

- Combination of QCM-D/MP-SPR enables fast screening of membrane antifouling properties.
- Fouling observed on QCM-D/MP-SPR sensors concurs with that in ultrafiltration tests.
- QCM-D and MP-SPR are powerful methods for predicting fouling in membrane separations.

1. Introduction

Water membrane filtration processes are commonly affected by membrane fouling which until today is accepted to be to a certain degree inevitable. Therefore, attempts are being made to at least minimize the impact of fouling by either modifying the membrane surface chemically, or by adopting adequate operation strategies. Finding the right strategy, however, is often based on a time-consuming trial-and-error approach. Hence, on one hand, accurate, fast, and non-invasive techniques would be desirable in order to verify the efficiency of the membrane surface modification. On the other hand, real-time monitoring of the early-stage development of membrane fouling would enable adapting the optimal process operating conditions.

Unfortunately, current monitoring techniques neither reach such efficiency nor sensitivity. For example, it has so far been impossible to reliably detect the very first adsorbed layers of foulants, which occur at the nanoscale but play a crucial role on the subsequent development of the fouling phenomenon. Furthermore, conventional characterization techniques, such as contact angle measurements, are indirect and prone to lead to false conclusions about the anti-fouling strategy adopted.

This work presents an approach of overcoming the limitations of conventional methods by combining two advanced surface-sensitive techniques for monitoring membrane fouling, namely quartz crystal microbalance with dissipation monitoring (QCM-D) and multi-parameter surface plasmon resonance (MP-SPR). It will be shown that these non-invasive techniques are both highly feasible for characterizing the build-up of the very first fouling layers at the nanoscale, and that they possess a high potential of significantly accelerating the screening of the efficiency of membrane modifications.

2. Methods

As a model membrane polymer, polyamides (PA) modified with polyethylene glycol (PEG, n=12) at different degrees (0, 25, 50, and 75%, respectively) were tested as these had been employed

previously as the membrane material in an ultrafiltration (UF) process [1]. Ultra-thin films of these polymers were cast onto QCM-D and MP-SPR sensors by spin-coating. QCM-D and MP-SPR sensors had an area of less than 1 cm^2. Bovine serum albumin (BSA) was used as a model foulant in the UF process, as well as for the combined QCM-D/MP-SPR monitoring system.

3. Results and discussion

Non-invasive and real-time monitoring of adsorption of BSA on the PA films revealed that QCM-D and MP-SPR enable a very fast detection with high temporal resolution. As an example, Figure 1 (left) illustrates how almost 90% of the steady-state signal was reached in an interval of only 40 seconds.

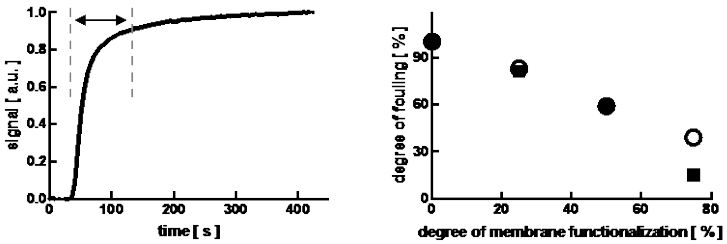

Figure 1. Left: Response of an ultra-thin PA film to the exposure to 100 $mg \cdot l^{-1}$ of BSA in water as measured by QCM-D. The arrow indicates the time interval needed to reach 90% of the signal. Right: Degree of fouling measured on polyamides with different degrees of functionalization by PEG and deposited as ultra-thin films on QCM-D (open circles) and MP-SPR (filled squares) sensors.

Both QCM-D and MP-SPR detected in very good agreement how the fouling tendency was reduced significantly with increasing content of PEG in the polyamides (Figure 2, right). This corroborates that QCM-D/MP-SPR are excellent and fast screening tools for studying membrane antifouling properties.

Although the working principle of both techniques is entirely different, QCM-D and MP-SPR proved to be highly complementary: protein fouling layers were tendentially detected to be of higher mass by QCM-D than by MP-SPR. The underlying reason for this phenomenon is the amount of associated water which is detected by QCM-D, but not so by MP-SPR. Nevertheless, and most importantly, it was observed that the degree of fouling measured for different PA-PEG films in QCM-D and MP-SPR was in very good agreement with fouling data obtained during independent UF experiments using the very same membrane materials [2].

4. Conclusions

QCM-D and MP-SPR are powerful techniques to reliably monitor the build-up of the very first membrane fouling layers even at the nanoscale. A further advantage of this sensorial screening system is that it not only saves time, but also resources: the deposition of ultra-thin PA films on the sensors requires only a few microliters of polymer solution and the microfluidic set-up saves sample volume, which in principle allows a high-throughput screening.

A strategy for implementing QCM-D/MP-SPR as a water membrane filtration monitoring tool will be presented, and the operating window of this approach will be critically discussed.

Development of a new process for preparing polymeric membranes without the use of organic solvent

K-W. Li[1], J-P.Mericq[1], C. Faur[1], D. Quemener[1], A. Deratani[1], D. Bouyer*[1]

Highlights

- Green membranes (without organic solvent)
- New process for preparing polymeric membranes
- Coupling thermally induced phase separation and cross-linking

1. Introduction

Phase separation using non-solvent coagulation bath of a polymer solution is the most widespread industrial process to manufacture membranes. During the industrial process, large quantities of organic solvent are used that may lead to crucial environmental and health problems. Our objective in this work was to develop a novel process for membrane mass production in agreement with the principles of green chemistry. HydroxyPropyl Cellulose (HPC), a biosourced and water-soluble polymer was therefore used in this work, thus preventing the use of classical organic solvent, such a NMP, DMAc, DMF etc. Mastering this phase separation process was very appealing, but needed the following requirements:

- Fully understand how phase separation proceeds in water as temperature is above LCST
- Establish the relationship between PS, evaporation and crosslinking mechanism
- Determine the permeation performances of the obtained membranes

2. Methods

Starting from a polymer solution composed pf HPC and water (weight ratio 20%/80%) a phase separation was induced by increasing the temperature above the lower critical solution temperature (LCST) (Fig. 1). Then, a chemical crosslinking using Glutaraldehyde (GA) was performed to prevent the re-solubilization of the membrane during further use for water filtration. A porous morphology was finally obtained and observed by SEM. The membranes were fully characterized (stability, porosity, mechanical properties…) and the filtration properties were tested using a dead-end filtration system.

3. Results and discussion

The flat membrane obtained using the original phase separation process used in this work (LCST-TIPS process) showed porous morphologies, showing a phase separation by spinodal decomposition (Fig. 1). After several weeks in water, the membrane exhibited a perfect stability, i.e. no re-solubilization was observed.

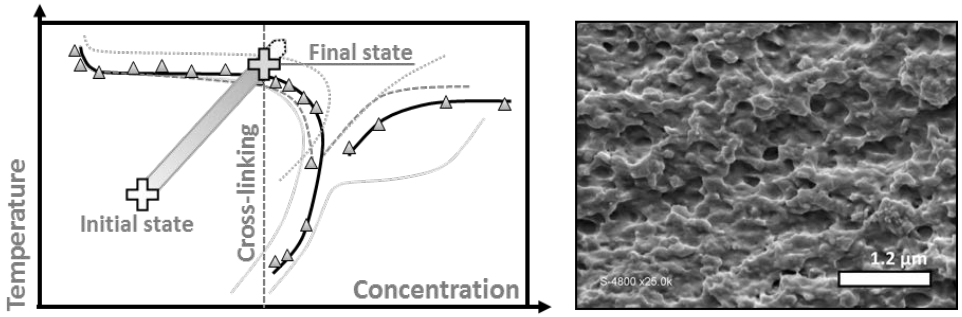

Figure 1. Phase diagram of HPC and behavior during membrane elaboration process; SEM of HPC membrane section.

A first filtration stage exhibited a flux was between 0 and 40 $L.h^{-1}.m^{-2}$ at 3.5 bar. After a thermal treatment, a flux up to 160 $L.h^{-1}.m^{-2}$ was obtained (Figure 2a). Hysteresis filtration experiment was then performed: the transmembrane pressure was raised slowly until it reaches the maximum value of 3 bars, then it was decreased to its initial value. Figure 2b represents normalize flux versus pressure, showing that the transmembrane flux was unchanged after the conditioning step.

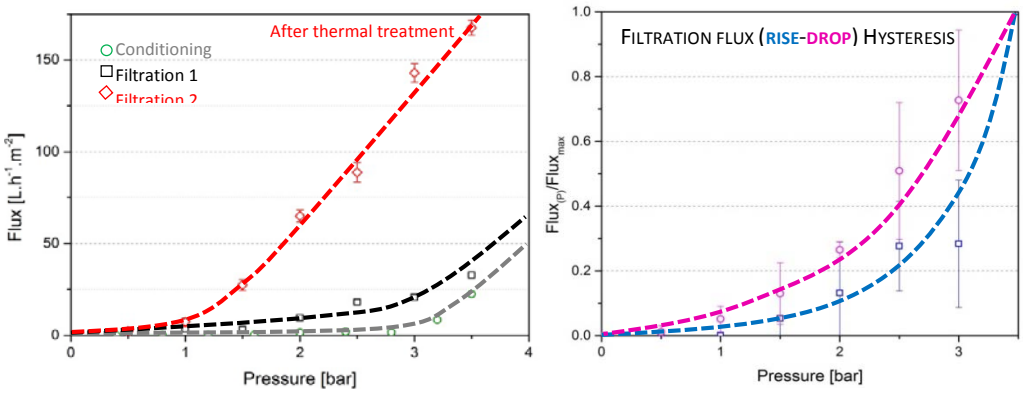

Figure 2. Flux measurement for HPC membrane, conditioning, filtration at room temperature and second filtration after a thermal treatment.

4. Conclusions

This work demonstrated that a porous and stable membrane can be obtained from water-soluble and biosourced polymer, i.e. without organic solvent in the formulation. An original phase inversion process was developed, based on a LCST-TIPS process coupled to chemical cross-linking.

Engineering of biohybrid systems by membrane emulsification

Emma Piacentini*, Lidietta Giorno

Institute on Membrane Technology, National Research Council, ITM-CNR, via P. Bucci, 17/C, I-87030 Rende (Cosenza), Italy

Highlights

- Membrane emulsification is a suitable technology to design biohybrid-engineered systems
- Enzyme-loaded PVA microspheres were produced by membrane emulsification
- Improved operational stability and optimal enzyme-substrate interaction was accessed
- Droplets with controlled structure and glucose-sensitive release properties were developed

1. Introduction

Membrane emulsification is a micro-manufacturing process that allow designing micro-nanostructured multi-material components with target particle size and sizing distribution and complex 3D structures []. The method offers many advantages in the micro-manufacturing of particles able to meet modern demand for a new generation of dispersed materials able to assist or replace important physiological functions by cell encapsulation and/or biomolecules delivery. In particular, membrane emulsification is emerging as a more promising formulation method to produce monodispersed particles with target size in mild operative conditions and with low energy consumption.

The present work will demonstrate the suitability of membrane emulsification process for the development of micro-nanostractured biohybrid systems for biomedical applications. The introduction of new strategies in membrane emulsification method to decrease the shear stress conditions maintaining high productivity will be illustrated to promote the use of membrane emulsification when biological systems, living organisms or derivatives thereof are used. Enzyme-loaded particles and glucose-responsive delivery systems will be described as cases study. The general idea is to functionalize droplet interface by using a biomolecule with a specific biological activity to design advanced biohybrid devices.

2. Methods

Microporous membranes have been used for liquid droplets production (emulsion). One phase (referred as dispersed phase), containing target biomolecules, is dispersed into the other (referred as continuous phase) by forming droplets at the membrane pore opening, where the two phases meet, as a result of the pressure gradient driving force and the interfacial tension existing between the dispersed phase and the membrane wetted by the continuous phase. The integration of membrane emulsification technology with appropriate secondary reactions (cross-linking) allowed

extending to the production of micro-/nano-carriers with different architecture and physical structure. Lipase has been used as a model enzyme to demonstrate the potential of the use of membrane emulsification process in the production of enzyme-loaded PVA particles. A multiple emulsion, containing a bio-receptor (Con A) that specifically recognizes and interacts with an artificial ligand (Glucose), was manufactured by the membrane process and used as a model system. Structural properties of the produced particles (i.e. size, size distribution, surface properties) as well as the functional activity (i.e. catalytic activity for the enzyme loaded particles and glucose-sensitive release for the drug delivery systems) have been evaluated

3. Results and discussion

Uniform droplets (span = 0.4) with a size equal of three times the pore size of the membrane has been produced at the optimized fluid-dynamic conditions by membrane emulsification.

The method allow to obtain a specific activity comparable with the one of the free enzyme when has been used for enzyme-loaded particles production. This can be explained considering the structural properties of the enzyme. Lipase is an interfacial enzyme and exhibit the active form in the presence of a water/oil interface. When enzyme immobilization was carried out by entrapment, the carrier is formed in the presence of the enzyme. The lipase is oriented at the interface in the open form that is also the active form.). On the other end, Con A is able to promote marker substance release as a function of glucose stimulus when membrane emulsification has been employed for biomolecule-responsive particles fabrication. The high affinity between Con A and glucose determined a preferential preferential interaction between them, causing the protein displacement from emulsion interface with phase separation and marker substance release.

4. Conclusions

An effective approach for cell and/or biomolecules encapsulatuion and delivery as well as the construction of carriers with tailored properties are crucial for biohybrid sistems engineering. Results demonstrated that the mild operative conditions applied extend the application of membrane emulsification toward the encapsulation of shear-sensitive compounds such as proteins (antibody or enzyme) and cells. It is expected that membrane emulsification can improve the use of particulate materials for many applications in bioscience and bioengineering by tuning the structural and functional properties of micro/nanostructured biohybrid particles.

Highlights

- A novel flow battery, based on pH and salinity gradients, is presented.
- Ion exchange membrane parameters are estimated by electrochemical measurements.
- The performances of the device are promising for an efficient electrical energy storage.

1. Introduction

Electrodialysis (ED) and Reverse Electrodialysis (RED) are processes based on the selective transport of ions through ion exchange membranes (IEMs). The former, in which electrical energy is used to desalinate brackish water to produce fresh water, is one of the most valuable alternative to the common membrane desalination processes. The latter is used to produce electrical energy by directly converting salinity gradient energy. The combination of RED and ED processes leads to an electrical energy storage system [1], i.e. a concentration gradient flow battery that converts electrical energy into salinity gradients (charge phase) and recovers the energy exploiting the salinity gradient (discharge phase).

A higher energy density can be obtained using both salinity and pH gradients. This new technology is called Acid/Base Flow Battery (AB-FB) where bipolar membranes (BPMs) and typical IEMs are used to obtain acid and base streams during the charge phase and to produce electrical energy from electrolytes with different pH and salinity during the discharge phase. The use of hydrochloric acid and sodium hydroxide solutions (1 M) leads to an electromotive force (EMF) over the BPM of 0.83 V, one order of magnitude larger than the EMF that can be extracted from salinity gradients [2].

In the present work the performances of this new AB-FB were studied by changing operating conditions such as feed solutions composition and number of repeating units. Electrochemical measurements have been also carried out to study monopolar membranes properties.

2. Methods

A lab-scale setup (provided by Fumatech, Germany) equipped with a variable number of triplets (Acid/Base battery repeating unit) with a membrane active area of 10 x 10 cm^2 was used for the experimental campaign. The triplet was composed by a cation exchange membrane (CEM), an anion exchange membrane (AEM) and a BPM, each one separated from the adjacent by a spacer

500 μm thick. Two DSA electrodes were used in the end-compartments to convert ionic fluxes into electric fluxes. A cross-flow arrangement was adopted for feeding solutions that were prepared by using demineralized water and NaCl, HCl and NaOH. The aqueous electrode rinse solution was 0.25 M in Na_2SO_4. The performances of the AB-FB have been experimentally studied under different charge and discharge conditions with different acid and base concentrations.

Electrochemical measurements (among these, Electrochemical Impedance Spectroscopy, EIS, was used) have been carried out in order to investigate the effect of electrolytes composition on membranes permselectivity, membrane and interface resistances of the monopolar membranes.

3. Results and discussion

Open Circuit Voltage (OCV) values of the device were recorded by changing the concentration of acid and base aqueous solutions (reaching 1 M). These solutions were mixed with NaCl in order to reduce the concentration gradient of NaCl over the monopolar membranes. During the discharge phase, too high current density values can lead to delamination of bipolar membranes with consequent device failure. At high number of triplets, part of the electrical energy generated can be dissipated due to the onset of parasitic currents inside the stack. Charge-discharge flow battery cycles have been also studied starting from “pure” NaCl solutions (beginning of charge phase), then estimating round-trip efficiency of the system as function of operating conditions.

Membranes resistance were estimated by data fitting (with an appropriate electric equivalent circuit) of the electrochemical impedance spectra recorded by changing solution compositions and flow velocity. Membrane resistance was not so influenced from flow velocity whilst values of boundary layer resistance changes by changing the hydrodynamic conditions.

4. Conclusions

A novel flow battery based on pH and salinity gradients is presented. Feeding more concentrated acid and base solutions leads to an increase of the obtainable energy from the device, although at high number of triplets part of the generated energy is dissipated in parasitic currents. During discharge phase, too high current density values cannot be reached due to possible delamination phenomena of bipolar membranes. Membranes characteristics were estimated by electrochemical measurements and they could be used as input in system modelling activity. Further experimental studies are necessary to improve the efficiency of the system.

Highlights

- Innovative membrane synthesis coupling phase inversion and sol-gel techniques
- Asymmetric monophasic hybrid (CA/SiO_2) membranes with enhanced hemocompatibility
- High water fluxes with total urea removal and total albumin rejection

1. Introduction

Artificial organs associated to clinically well-established membrane-based treatments assure in extracorporeal blood circulation devices the metabolic functions of a failing organ like the hemodialyzer for the kidney. The hemodialysis (HD) membrane is the key component of the artificial kidney as it is responsible for removing accumulated uremic toxins, excess ions and water while simultaneously retaining vital components from the blood of End Stage Renal Disease (ESRD) patients [1,2]. The technical and medical progress of the artificial kidney depends on two major factors: 1) hemocompatibility of the membrane/blood interfaces, and 2) enhancement of the flow management/mass transfer associated to the metabolic functions of the artificial kidney.

The present study reports the synthesis and characterization of hybrid CA/SiO_2 membranes containing 5 wt.% silica via the coupling of the phase inversion and the sol-gel techniques taking into account a two-fold goal: 1) development of integrally skinned asymmetric CA/SiO_2 ultrafiltration (UF) membranes with high water permeability, preferential permeation of uremic toxins and total retention of vital blood components; 2) tailoring of membranes with hemocompatible surface morphologies.

2. Methods

The surface morphology of the membranes was characterized by Scanning Electron Microscopy (SEM). Mass transfer studies associated to the metabolic functions of the kidney are conducted in a custom-made benchmark device with a membrane surface area of 60 cm^2 as a surrogate system of the artificial kidney. Permeation experiments are carried out to yield hydraulic permeability (Lp), Molecular Weight Cut Off (MWCO) and rejection coefficients (*f*) to a set of reference solutes including urea, creatinine, uric acid and Bovine Serum Albumin (BSA).

3. Results and discussion

Monophasic hybrid integrally skinned asymmetric membranes containing 5 wt.% of silica, CA/SiO_2-5, were synthesized by a novel method that combines phase inversion with acid-catalyzed sol-gel process [3]. Fig. 1 displays the SEM image of a monophasic asymmetric cross section of the CA/SiO_2-5 membrane characterized by a very thin dense layer and a much thicker porous substructure. Permeation studies reveal that the hydraulic permeability of the hybrid CA/SiO_2-5 membrane is 82 kg/h/m2/bar, which is approximately 2.5 times higher than the value of the pure CA membrane (32 kg/h/m^2/bar), total permeation of urea and complete retention of bovine serum albumin (BSA).

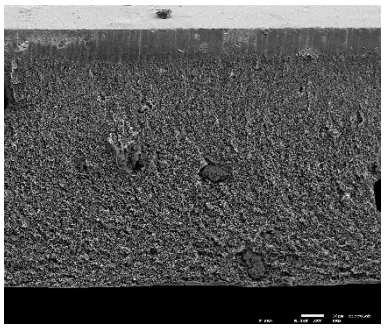

Figure 1. SEM image of the cross section (500x) of the hybrid integral asymmetric CA/SiO_2-5 [3].

4. Conclusions

In this work hybrid CA/SiO_2 membranes containing 5 wt.% silica were synthesized via the coupling of the phase inversion and the sol-gel techniques. Permeation studies show that the integration of silica into CA membranes by the innovative phase inversion/sol-gel method results in high flux ultrafiltration membranes with enhanced mass transfer properties pertaining to the metabolic functions of the kidney. In particular, the study shows that the CA/SiO_2-5 membrane is capable of complete removal of urea, the surrogate marker for small molecular weight uremic toxins while simultaneously retaining the vital protein found in blood, albumin. The versatility of the novel synthesis method allows further tailoring of structures and permeation properties of CASiO_2 membranes for the Artificial Kidney with high efficiency for specific removal of other critical uremic toxins.

Nanofiltration removal of perfluorohexanoic acid: the role of salts concentration and pH

Álvaro Soriano, Daniel Gorri, Ane Urtiaga

Department of Chemical and Biomolecular Engineering, University of Cantabria. Av. Los Castros 46, Santander 39005, Spain

Highlights

- The removal of PFHxA from industrial process waters by two NF membranes was studied.
- Excellent PFHxA rejection and intermediate fluxes when treating model PFHxA solutions were observed.
- Presence of salts in the water matrix severely decreased PFHxA rejection.

1. Introduction

Perfluoroalkyl substances (PFASs) are a family of man-made organic compounds classified as persistent organic pollutants due to their recalcitrance in the environment and their high bioaccumulation potential [1]. For these reasons, chemical manufacturers are progressively replacing regulated long-chain PFASs by 6:2 fluorotelomers and shorter-chain perfluoroalkyl homologues such as perfluorohexanoic acid (PFHxA) [2]. On the other hand, PFHxA can also be a 6:2 fluorotelomer alcohol biodegradation product [3]. Thus, increasing production of substitutive compounds is leading to rising concentrations of persistent PFHxA in the environment. Since conventional wastewater treatments are ineffective in PFASs treatment, current research efforts are focused on separation (nanofiltration (NF), reverse osmosis and adsorption) and advanced oxidation technologies. However, most of the studies focus on already phased-out long-chain PFASs at very low concentrations. Treatment of industrial process streams, that constitute the major source of PFASs emissions to the environment, is rarely studied. Hence, this work studies the separation of PFHxA by nanofiltration at industrial emission levels

2. Methods

PFHxA ($C_5F_{11}COOH$) molecular weight is 314.05 g mol^{-1}. Accordingly, two NF commercial membranes, ESNA1-LF and ESNA1-LF2 (Hydranautics), recommended for water softening and pesticides removal were selected. The NF membranes were evaluated in terms of PFHxA rejection and permeate flux, in the pressure range 2.5-20 bar. The flat-sheet membrane coupons were housed in a cross-flow filtration test cell (SEPA-CF, GE Osmonics). The feed solution was maintained at constant temperature (20°C) in a jacketed tank connected to a refrigeration system and the cross-flow velocity was kept at 24.7 cm s^{-1} using a variable-speed diaphragm pump. Two types of feed samples were prepared: (i) 100 mg L^{-1} PFHxA aqueous solutions at neutral pH, and (ii) model solutions to emulate the salts content of real process waters with 100 mg L^{-1} of PFHxA, 36 mg L^{-1} of NaCl, 575 mg L^{-1} of $CaSO_4$, and 98 mg L^{-1} of $NaHCO_3$, at pH = 7.84 ± 0.1. PFHxA was quantified using UPLC-MS/MS.

3. Results and discussion

Figure 1 shows the influence of the water matrix on the PFHxA observed rejection (R_{obs}) and the volumetric flux (J). For both membranes, PFHxA rejection was severely affected by the chemistry of the solution while the permeability remained reasonably constant. Whilst very high PFHxA rejection values were obtained when treating pure PFHxA aqueous solutions (ESNA1-LF: 96.1 – 99%; ESNA1-LF2: 95.4 – 97.9%), the presence of salts considerably reduced the rejection performance (ESNA1-LF: 67.2 – 70.4%; ESNA1- LF2: 70.2 – 76.5%). This could be attributed to the high counter-ion concentration in the feed side of the membranes that could induce a shielding effect on the negatively-charged surface of the two NF membranes. Thus, the diminished electrostatic repulsion between the charged NF membranes surface and the perfluorohexanoate anion form of PFHxA in solution at neutral pH, would leave the steric-exclusion role as the dominant separation mechanism.

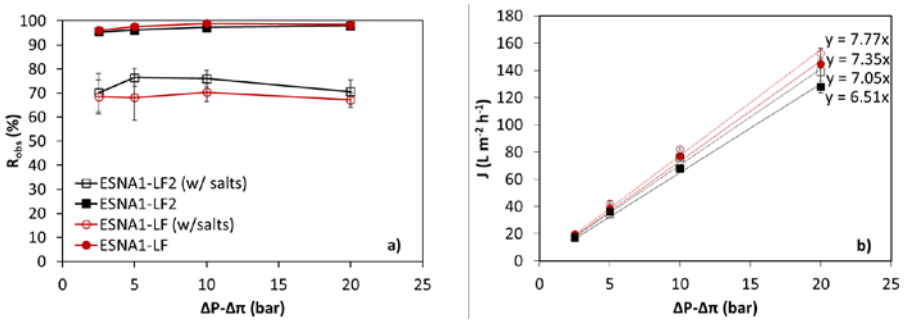

Figure 1. (a): PFHxA observed rejection (R_{obs}) and (b): water flux (J_v) versus the effective pressure gradient. 100 mg L^{-1} of pure PFHxA aqueous solutions and PFHxA synthetic process water feed with salts.

4. Conclusions

Two nanofiltration membranes (ESNA1-LF and ESNA1-LF2, Hydranautics) were tested in the separation of persistent perfluorohexanoic acid (PFHxA) at concentration levels typically found in industrial process waters. Both membranes showed excellent PFHxA rejection performance and intermediate water productivity when treating pure aqueous PFHxA solutions at neutral pH. However, the presence of salts in the water matrix severely decreased PFHXA rejection. These findings point to a drastic change in the electrostatic repulsion mechanism between the dissociated PFHxA and the charged membranes surfaces, negatively influenced by the presence of positive divalent counter-ions. Decontamination of complex water matrixes impacted with PFHxA that are generated in the chemical process industry could need tighter and more selective nanofiltration or reverse osmosis membranes.

Acknowledgments. Funding of project CTM2016-75509-R (MINECO Spain/FEDER) is gratefully acknowledged

Highlights

- Manufacturing new mixed matrix membranes (PPSU/SiO_2).
- Preparation of silica nanoparticles incorporated with PEI.
- The antifouling performance of PPSU membranes greatly improved.
- The nanocomposite membrane presented excellent removal efficiency of copper ions.

1. Introduction

Polyphenylsulfone membranes (PPSU) are a promising option for separation applications due to their high versatility to control pore size distribution and their chemical and thermal stability. However, the applications of PPSU membrane are limited due to their hydrophobicity which decreases water permeability and increases membrane fouling in an aqueous environment [1].
During the past decade, blending of the membranes with organic/inorganic modifiers such as nano-particles and copolymers has become the most common approach to improve membrane performance. Specially nanocomposite membranes which are composed of polymers and nanoparticles have received special attention [2]. Silica nanoparticles (SNPs), due to their low cost and surface OH moieties, may be selected as a promising filler for membrane modification as they improve the hydrophilicity [3] and water flux capacity of the membranes [4, 5].
In the present work, PPSU membrane will be fabricated by addition of modified silica nanoparticles. The performance of the prepared membrane will be analysed. Then the results will be used to enhance the membrane rate of water transport, hydrophilicity and copper rejection. Finally, the comparison of the performance of synthesised membranes will be presented.

2. Methods

All PPSU blended membranes were prepared using the non-solvent induced phase inversion method [6]. In the preparation of the blend membranes, PPSU with different concentration of SiO_2 nanoparticles was employed as the membrane bulk material. The morphology, the distribution of the silica nanoparticles and the presence of chemical functional groups in the prepared membranes have been investigated via field emission-scanning electron microscopy (FE-SEM) and attenuated total reflectance Fourier-transform infrared spectroscopy (ATR-FTIR). Finally, the performance of the prepared membranes were characterised and compared in terms of hydrophilicity, water flux, fouling resistance and copper rejection.

3. Results and discussion

Water flux over time of the prepared membranes was investigated at 500 kPa constant pressure (Fig. 1). As shown in the figure, water flux of PPSU/SiO_2 membrane is remarkably higher than that of the neat PPSU membrane due to its higher hydrophilicity and higher pore size as these characteristics were enhanced with the addition of silica nanoparticles. In addition, it is quite clear that the water flux declined which may be due to clogging of the membrane pores by the presence of copper ions. Also, the result of copper rejection is shown in Figure 2. As can be seen in the figure, the copper rejection of the neat PPSU membrane was reported 43%. However, the results were altered to about 57% and 79% for 0.2 wt% and 0.4 wt% of PPSU/SiO_2 membranes, respectively. These changes indicated that silica nanoparticles played a significant role in enhancing the copper rejection ratio of the blended membranes.

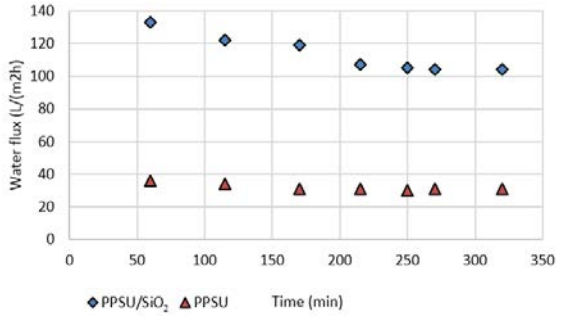

Figure 1. Water flux of PPSU membranes

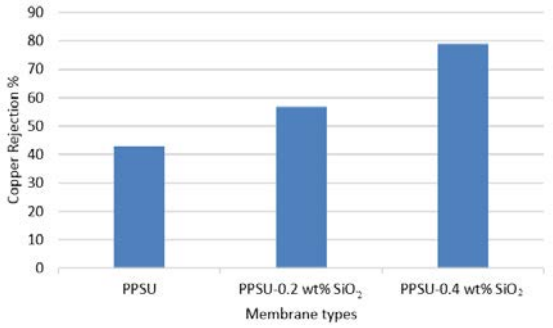

Figure 2. Copper rejection of PPSU membranes

4. Conclusions

A new approach was used to modify PPSU membrane using a phase inversion method in order to improve the membrane properties such as hydrophilicity and anti-fouling. The addition of modified silica nanoparticles to the polymer casting solution resulted in a considerable improvement in the fabricated membrane hydrophilicity and water flux.

Environmental benefits of SGE-RED energy recovery using LCA

Carolina Tristán, Marta Rumayor, Marcos Fallanza, Antonio Dominguez, Raquel Ibañez, Inmaculada Ortiz

Chemical and Biomolecular Engineering Department, Universidad de Cantabria, Av. Los Castros s/n 39005 Santander, Spain

**Corresponding author: inmaculada.ortiz@unican.es*

Highlights

- The SGE-RED process environmental benefits are proved by a cradle-to-gate LCA method.
- The best RO desalination plant-RED scenario, regarding environmental issues, is found.
- LCA results will enable to identify the SGE-RED process bottlenecks and challenges.

1. Introduction

Salinity gradient energy (SGE) is a promising alternative source of energy, currently attaining growing attention among the scientific community. Reverse Electrodialysis (RED) is arising as one of the most advantageous membrane-based technologies for recovering energy from the controlled mixing of two solutions of different salinities. At present, research efforts are mainly focused on RED technical development as well as modelling and optimisation [1, 2]. Nonetheless, the environmental sustainability of an SGE-RED system must be compared against other energy renewable sources to verify the potential environmental benefits.

In this regard, the Life Cycle Assessment (LCA) is an effective tool used to evaluate the environmental sustainability of products, processes or services against a well-known benchmark [3]. Our research group is currently addressing the evaluation of the potential environmental benefits of SGE-RED units for the recovery of energy from desalination discharge effluents. The study comprises the evaluation of the use of natural resources and the carbon footprint associated with an SGE-RED energy recovery process to partially substitute fossil-fuelled based supply to a reverse osmosis (RO) desalination plant, which features an intensive energy use

2. Methods

A “cradle-to-gate” LCA methodology has been applied in this study. First, a simple system (System-1) comprised by an SGE-RED is analysed (Figure 1(a)). The impacts related to the generation of a 1 kWh from the SGE-RED unit —defined as the functional unit in the LCA methodology— have been assessed and compared with other renewable power resources. The second system (System-2) integrates the SGE-RED unit in a RO desalination plant (Figure 1(b)). The energy supply required to treat 1 m^3 of seawater (SW) or brine water (BW) in the RO plant is partially delivered by the SGE-RED unit and the RO untreated brine by RED is directly released to the marine environment.

A mathematical model has been built for each system. The EGS-RED model consists of a set of mass and energy balances and experimental parameters obtained in previous activities [2]. The inputs and outputs obtained from the model are collected in the LCI. The infrastructure influence is evaluated by modelling the construction of an SGE-RED unit considering the lifetime of the membrane as the main variable.. A sensitivity analysis is performed including the following variables: flow water streams; streams concentrations; temperature; and membrane lifetime to evaluate different operation scenarios.

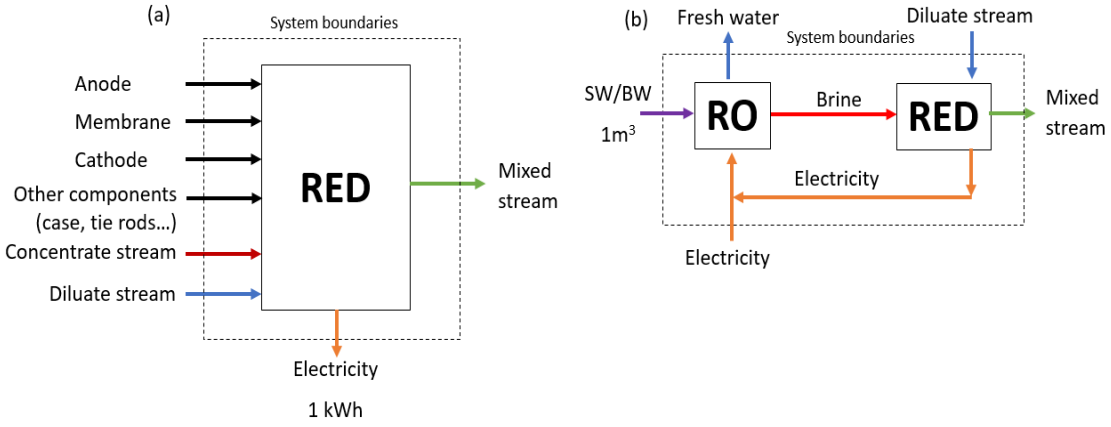

Figure 1. Boundaries of (a) System-1 (RED design) and (b) System-2 (RED integrated in a reverse osmosis (RO) plant)

LCA is completed using the GaBi Professional software applying the mid-point method CML 2001. In this project, global warming and brine discharge impacts are considered. Global warming potential (GWP) is assigned as the main impact indicator to assess the carbon footprint of the analysed alternatives. The potential damage caused by concentrated brine effluents is evaluated by a new impact category developed within the study.

3. Results and discussion

LCA results enable to identify the bottlenecks and challenges of SGE-RED process and its implementation in a RO desalination plant. The System-1 results shows the environmental effects of a 1,0 kWh SGE-RED system and allow their comparison with other renewable power sources. The System-2 results demonstrate the potential environmental benefits of the RO-RED hybrid system in the different proposed scenarios. The sensitivity analysis indicates the combination of the tested variables that ensures that the process is beneficial from an environmental perspective when compared with similar process options.

4. Conclusions

The LCA tool enables the quantitative assessment of the environmental benefits of the SGE-RED technology in a systematic way, and helps in finding the optimum environmental related RO-RED scenario.

Long-term assessment of Energy Recovery from Salinity Gradients

Lucia Gómez-Coma, Victor Ortiz-Martínez, Carolina Tristán, Marcos Fallanza, Alfredo Ortiz, Raquel Ibañez, Inmaculada Ortiz*

Chemical and Biomolecular Engineering Department, University of Cantabria, Avda de los Castros s/n 39005, Santander, Spain

Highlights

- Salinity Gradient Energy from desalination and wastewater treatment plant streams
- Mathematical modelling tool for evaluation of different scenarios.
- RED Technology for energy recovery and biomedical applications.

1. Introduction

Salinity Gradient Energy (SGE) is considered one of the most attractive renewable energy sources since it is completely clean and sustainable with no toxic gas emissions [1]. The main technology to harvest the SG energy is Reverse Electrodialysis (RED), which has emerged as a promising membrane-based technology for renewable energy generation by mixing two solutions of different salinity. The state of the art and technical challenges for a wider implementation of the technology have been excellently reviewed in a recent work [1]. Besides, the proximity of two streams with different salinity is important for its final implementation; apart from the well-known mixing between sea and river waters different scenarios have been analyzed such as, the mixing of desalination streams, brine with brackish water, seawater and WWTP streams, respectively. More recently the downscaling of the RED technology has addressed the development of new lab-on-a-chip (LOC) biomedical devices, e.g. medical implants powered by RED technology [2] concluding that RED technology offers great opportunities for new, long-lasting and safer biomedical devices.

In this sense, the development of robust model tools for the study of SG power generation and RED performance under diverse scenarios and different operational and system conditions is still essential for the optimization of this technology. Thus, we aim to contribute to the wider implementation of the SGP-RED technology by advancing comprehensive models supported by the experimental evidence. For this purpose, in this work we have evaluated, theoretical and experimentally, the performance of a SGP-RED laboratory plant for the long-run applied to the energy recovery from desalination wastes and we have defined the maintenance protocol.

2. Methods

The experiments were performed using a RED stack composed of 20 cation and anion exchange membrane pairs with membrane areas per cell of 200 cm^2 and polyethersulfone spacers, both supplied by Fumatech®. The electrode rinse solution (ERS) was constantly flowed in a closed loop. The schematic setup is shown in Figure 1. Experiments were performed by using an electronic load device (Chroma Systems Solutions 63103A, USA) [3]. The stack was continuously fed with stream solutions coming from desalination plants. To perform the modelling of the process, the software Aspen Custom Model V9 (AspenTech) was used based on the equations that describe the phenomena occurring inside the cell, establishing the following assumptions: (i) co-current flow

distribution, (ii) purely sodium chloride aqueous solutions and (iii) evaluation of the parameters at the average conditions between inlet and outlet [3].

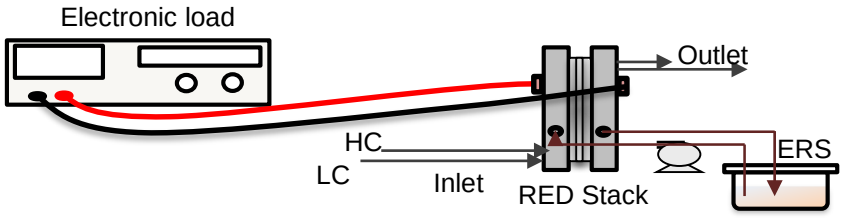

Figure 1. Experimental setup. HC: high concentration solution; LC: low concentration solution.

3. Results and discussion

First, we performed the analysis of the energy recovery by mixing two solutions of different characteristics. Figure 2.a displays the gross power (W/m^2) achieved under different scenarios and the experimental results against current (A), showing that predicted curves are in concordance with lab scale results. The deviation between simulated and experimental results over time was lower than 10%. In view of the simulated data for the experimental assessment we worked with 2 industrial streams, S1 and S2, with a concentration of NaCl of 0.94 M and 0.04 M respectively, together with other ions and we tested the stability of the plant with time. Figure 2.b) depicts the results obtained over one month of continuous operation. Gross Power remained constant for this period when a simple maintenance protocol was applied.

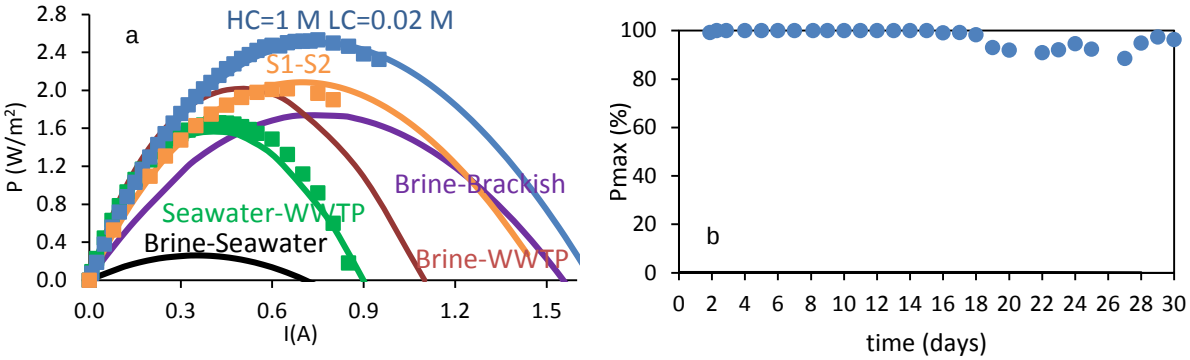

Figure 2. a) Power performance resulting from the combination of different scenarios; b) Long-run testing of RED stack fed with water streams from desalination plants.

4. Conclusions

A stable performance of the SGP-RED technology working with rejections of desalination plants has been proved in continuous operation with a simple maintenance protocol. The good agreement between the experimental results and simulated data with the mathematical model validated the design tool that can be expanded to down-scale operations using miniaturized devices.

Highlights

- The water permeation rate through the polymer layered membrane was linearly proportional to the pressure indicating the permeation mechanism was Hagen-Poiseuille flow.
- The water permeation rate steeply increased at around 30 °C.
- The effective diffusion coefficient of model components in the membrane increased with temperature.

1. Introduction

Membrane separation is separation technology that selectivity separates materials via pores and/or tiny gaps in the membrane structure. And membrane technology plays an important role in conserving energy during purification process. Especially, separation of saccharides is an important issue in the production process of food industry. On the other hands, smart responsive polymer has various types such as thermoresponsive, photo-responsive, pH-responsive and etc. Especially thermoresponsive polymers are easy to control[1]. In this study, thermaoresponsive polymer layered membrane is prepared and its permeation behaviors of solvent and model saccharides through the membrane are investigated.

2. Methods

The polymer system composed of polyacrylamide and poly (acrylic acid) was used as a positive thermoresponsive polymer exhibiting an upper critical solution temperature (UCST). Acrylic acid/acrylamide monomer solution was deposited onto a support membrane and thermally polymerized. This operation was repeated to prepare the thermoresponsive polymer layered membrane. The water permeation rate of the prepared membrane was determined from the water mass flux with N_2 gas pressure. The overall mass transfer coefficient (K_{OL}) was determined from a measurement of mass transfer flux of methyl orange or saccharides in the glass cells sandwiching the membrane. The effective diffusion coefficient (D_{eff}) in the membrane was evaluated from the membrane mass-transfer coefficient (k_m) obtained under fully turbulent conditions. The mass transfer experiment of the model components was investigated at different temperature conditions (25 °C and 60 °C)

3. Results and discussion

The water permeation rate through the polymer layered membrane was linearly proportional to the pressure indicating the permeation mechanism was Hagen-Poiseuille flow. The effect of temperature on the water permeation through the membrane was examined. The water permeation rate steeply increased at around 30 °C (Fig. 1), indicating that the membrane showed UCST behavior. The D_{eff} of model components in the membrane increased with temperature. The increase in the D_{eff} was larger than the contributions of temperature and viscosity to the bulk diffusion coefficient. This supposed that the polymer framework of the membrane swelled with increasing temperature, which led to the reduction of mass transfer resistance. These findings indicated that positive thermosensitive control of mass transfer was successfully achieved using the polymer layered membrane.

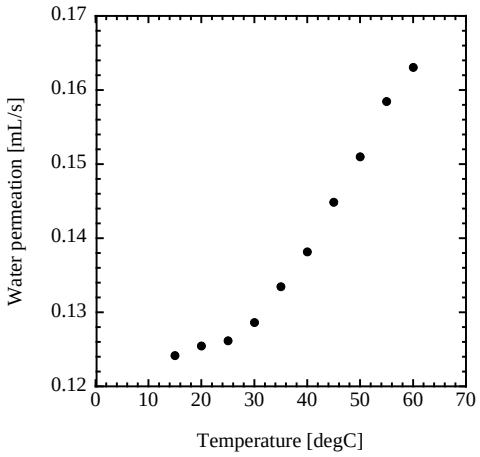

Figure 1. Water permeation through the polymer layered membrane at various temperatures (pressure: 0.1 MPa).

4. Conclusions

Thermaoresponsive polymer layered membrane were prepared, and its permeation behaviors of solvent and model components through the membrane were investigated. In water permeation through the membrane, UCST thermoresponsive behavior was successfully shown. In mass transfer behavior of model components through the membrane, it is possible to control K_{OL} and D_{eff} by temperature and suggesting of possibility of separation.

MEMBRANE (MF and UF) APPLIED IN THE 2,3-BUTANEDIOL PURIFICATION PROCESS

Beal, Lademir Luiz[1]; Beux, Assis Reinaldo Dariva[2]

1 and 2 University of Caxias do Sul; Address: Francisco Getúlio Vargas 1130, Caxias do Sul, Brazil

**Corresponding author: llbeal@ucs.br*

Highlights

- The pressure is strongly correlated with the resistance
- The pressure was not a determinant effect to increase the permeate flux.
- There were no significant differences between the flux of permeate in MF and UF.

1. Introduction

In an effort to reduce global dependence on fossil fuels, biofuels have been gaining more space. Biodiesel can partially or completely replace diesel. A byproduct of biodiesel is glycerol, a substrate that can be exploited in the chemical industry and produce other biofuels such as biohydrogen and biomethane. Among its uses is the production of 2,3-butanediol, which can be obtained by fermentative processes, especially using Klebsiela pneumoniae. The production of 2,3-butanediol is well established for batch processes. Some difficulties inherent to fermentative processes with pure cultures, such as contamination, prevent the effective use of obtaining this compound in CSTR. The use of membranes can be interesting as a step of the purification process or used in continuous processes (MBR), reducing the risks of contamination, and providing a greater reduction. Gupta et al. (2005) using flat sheet cellulose acetate MF membrane obtained results where the increase of permeate flux were from 54% to 146% for different gas flow rate. The main goal of this paper is to discuss the different hydraulic behavior using MF and UF membrane, both with hollow fiber configuration, to separate Klebsiella pneumoniae cells and macromolecules compounds.

2. Methods

Two modules of PVDF membranes (UF and MF), in hollow fiber configuration, of asymmetric morphology, contact angle with water of 66º, moderate hydrophobicity and filter area of 0.047 m² were used. The membranes of UF were made in porous support medium, since MF membranes are extruded integrals. Before each cycle of tests, the membranes were subjected to compaction and hydraulic characterization. Total resistance during the fermented assay was assayed at pressures of -400, -250, -150 and 60 mbar for MF and -400, -250, -150 mbar for UF. The test pilot was set at 30 ° C with air injection at the base of the module for cleaning. The flow was measured for 3 hours. The total resistance to filtration was obtained through Equation $J = \Delta P / (\mu \times R_{tot})$, where J is the flow, μ is the absolute viscosity of the permeate and R_{tot} is the total resistance to filtration.

3. Results and discussion

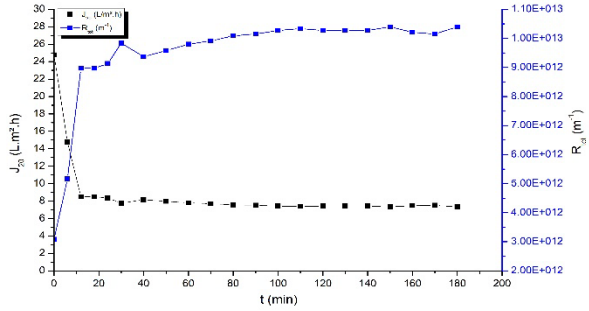

Figure 1 – Flux in MF250.

The partial result obtained had showed that both membrane, MF and UF, have a good and similar behavior when is compared the permeate flux. The permeate flux in 20 minutes decrease almost 60 % and after this moment is practically stable as shown in the Figure 1 (an example of the graphic obtained).

Analyzing the results presented in Table 1 to MF tests it is possible to conclude that the pressure was not a determinant effect to increase the permeate flux, since from 60 to 250 mbar the values were very similar, but when is analyzed the results to 400 mbar the percentage of the permeate flux reduction was higher than the others and the resistance increase percentage was higher than other as well.

Table 1: Behavior of MF and UF modules.

	P (mbar)	Jo ($L.h^{-1}.m^{-2}$)	Ju ($L.h^{-1}.m^{-2}$)	% decrease	Ro (m^{-1})	Ru (m^{-1})	% increase
MF	60	21.6	7.10	67	8.3E+11	2.6E+12	216
	150	30.8	8.20	73	1.5E+12	5.6E+12	277
	250	24.8	7.30	71	3.1E+12	1.0E+13	238
	400	73.9	6.70	91	1.6E+12	1.8E+13	997
UF	50	10.9	6.80	22	1.5E+12	2.2E+12	68
	150	25.3	5.60	78	1.8E+12	8.2E+12	353
	250	36.5	5.40	85	2.1E+12	1.4E+13	579
	400	59.9	6.40	89	2.0E+12	1.9E+13	841

The reduction of the permeate flux in the UF tests were higher than the MF tests and the increase of the resistance was higher than MF as well. The permeate flux (Ju) values were very similar but the pressure effect was more significant for the increasing of resistance than the flux.

4. Conclusions

It is possible conclude that the pressure is strongly correlated with the resistance (r=0.992 to MF and r=0.980 to UF). It is not interesting to use high pressure in this process since there is not positive effect on the permeate flux. The permeate flux is higher in the MF membrane than the UF membrane but without significant differences.

Pervaporation characteristics of PVA-alumina hollow fiber composite membrane for the recovery of by-product in the epoxy resin manufacturing process

Seung-Eun Nam*, Yong Sung Kwon, Ahrumi Park, Young Mi Kim
HoSik Park, You-In Park,

Membrane Research Center, Korea Research Institute of Chemical Technology,

1. Introduction

Pervaporation is a membrane separation technology with high efficiency and energy saving benefits for liquid mixture separation, in particular, for the separation of close boiling or azeotropic mixtures [1]. One of the most frequent industrial application areas of pervaporation is dehydration of solvents that form an azeotrope with water e.g. ethanol, isopropanol, tetrahydrofurane. The membrane contacts with the liquid mixture on the feed side, while permeate is removed as a vapor. The mass transport is driven by the vapor pressure difference between the feed solution and the permeate vapor. The chemical potential gradient across the membrane is the driving force for the mass transport. The driving force and be created by applying either a vacuum or an inert sweep gas on the permeate side to maintain the permeate vapor pressure lower than the partial pressure of the feed liquid. Mass transport in the pervaporation membrane can be explained by the solution-diffusion model [2]. Pervaporation is a well-known alternative method to classical distillation due to its high selectivity and low operational cost. Since the pervaporation is normally applied to remove a minor component of a liquid mixture, high permselectivity is essential for competing with convential means such as distillation and extraction.

Epichlorohydrin (ECH) containing epoxide and organochlorine moieties is a highly reactive electrophilic compound used in the production of glycerol, plastics, and epoxy resins [3]. Epoxy resin is prepared by polymerization of ECH with phenol, Bisphenol-A (BPA) is used as a phenol resin and isopropanol (IPA) is used as solvent. Excess ECH is included in the raw material to control the molecular weight of the produced epoxy resin. After reaction, ECH, IPA, a series of chlorine impurities, and water is remained and distillation process has been widely applied for the recovery of these by-products. However, the impurity content gradually increases after repeated reuse. During the recovery of ECH and IPA by distillation, ECH and IPA form a ternary azeotropic mixture with water impurities, and the recovery of high purity ECH and IPA is difficult only by distillation process. Therefore, in terms of energy efficiency and reuse of unreacted materials, improvements to this process are required. Furthermore, ECH can cause environmental hazards because it is carcinogenic in nature and can have serve adverse effects on ecological systems if its effluent comes into contact with the environment. A hybrid process involving moisture removal by pervaporation and recovery and purification of ECH and IPA *via* distillation can improve the ecofriendly energy efficiency and the product competitiveness by reducing the cost associated with the epoxy resin manufacturing process.

In this study, pervaporation performance and stability of the prepared PVA-alumina hollow fiber composite membrane was evaluated at various operational condition in a highly reactive ECH-containing ternary mixture feed system of ECH/IPA/Water(50/30/20 wt%).

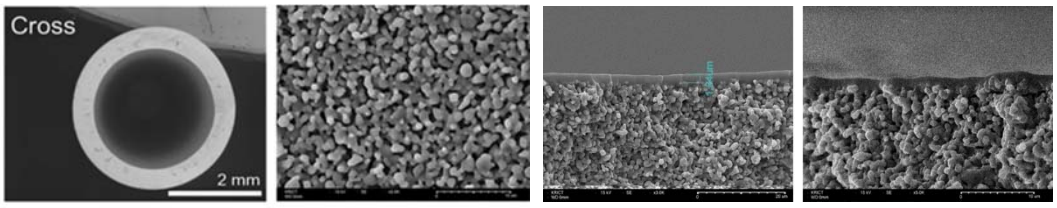
2. Methods

Selection of stable polymeric membrane material for pervaporation in the ECH/IPA/water feed system is a challenging task because ECH is a highly reactive chemical. Poly(vinylalcohol) (PVA, M.W. 85000-124000 g/mol) as active layer material for dehydration aqueous organic solution has excellent membrane forming properties, a high tensile strength, and stability in organic solvents. The crosslinking reaction of PVA was carried out at 50^{o}C for 2hr and the composition of the crosslinking agent was GA/IPA/Water/HCl = 5/89.5/5/0.5 vol%. Pervaporation performance and chemical stability of the prepared composite membrane was evaluated at various operational condition in a highly reactive ECH-containing ternary mixture feed system of ECH/IPA/Water (50/30/20 wt%).

3. Results and Discussion

Figure 1 shows the SEM pictures of (a) the surface and fractured cross-section of the alumina hollow fiber support and (b) the fractured cross-section of PVA-alumina hollow fiber composite membranes. PVA active layer was observed to be a have uniform thickness of less than 2 μm.

The prepared PVA-alumina hollow fiber composite membranes, in this study, showed excellent pervaporation dehydration performance with the feed comprising an ECH/IPA/Water (50/30/20 wt%) azeotropic mixture in long-term stability test: the permeate flux of above 0.135 kg/m^2 hr and separation factor was above 3500 at 30 ^{o}C. As shown in Figure 2, the composite membrane was operated for 500 hours with no observed decrease in performance.



(a) (b)

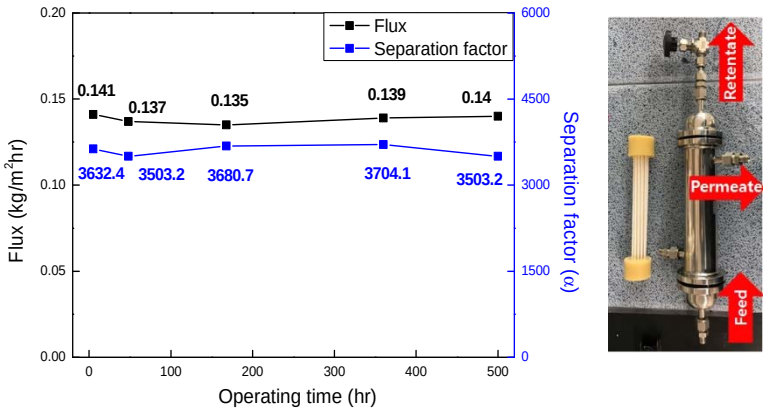

Figure 2. Pervaporation performance of the PVA/alumina composite membrane.

4. Conclusions

The stability and pervaporation performance of PVA-based composite membranes in a highly reactive ECH-containing ternary mixture feed system showed remarkable pervaporation dehydration efficiency. To reduce energy cost, make possible a difficult separation, and improve the degree of separation, pervaporation-based hybrid process are very promising especially in cases where high product purities are required.

Highlights

- Assessment of morphology membrane prediction based on Flory-Huggins model.
- Thermodynamic evaluation of the ternary system PVDF/solvent/water.
- Addressing the systematic determination of solvent-non-solvent interaction parameters.

1. Introduction

Phase inversion by Non-solvent Induced Phase Separation (NIPS) is a widely implemented technique for the synthesis of polymeric membranes [1]. This mechanism is thermodynamically explained through the Flory-Huggins theory based on the Gibbs free energy and interaction parameters of the components: polymer, solvent and non-solvent. Moreover, solvent/non-solvent miscibility importantly affects the rate of their exchange that will ultimately define the membrane morphology. Overall, the membranes morphology prepared by NIPS strongly depends on both thermodynamics and kinetics of the ternary system.

Traditionally, membranes by NIPS have been prepared by arbitrarily selecting the set of components polymer/solvent/non-solvent, which implies an experimental trial-and-error procedure. Currently, several works have attempted to find ways to systematize the selection of the components based on thermodynamic and/or kinetic interactions and tried to correlate these data with morphological parameters of different NIPS-prepared membranes [2-4]

Binodal curves of ternary systems, which represent the polymer/solvent/non-solvent composition ratios, where a polymeric solution precipitates, are usually obtained experimentally and fitted to Flory-Huggins model. However, interaction parameters are usually estimated through different empirical equations or by estimation procedures which depend importantly on the experimental points of the binodal curves. In order to systematize this as a design tool for the synthesis of membranes by NIPS techniques, broadly valid empirical equations for the estimation of interaction parameters should be defined. Moreover, the revision of the best methodology for the experimental determination of the binodal cloud points should be done.

2. Methods

In the present work, the production of PVDF membranes by NIPS is selected as a case study to explore the potential of the ternary phase diagrams in the prediction of certain membrane morphology.

The Flory- Huggins model for a ternary mixing is already developed in the literature [2,3]. The Flory-Huggins interaction parameters for the studied system were obtained before a comprehensive review of the literature. Different strategies were developed to determine the interaction parameters among polymer/solvent/non-solvent simultaneously [3]. However, it was founded a huge amount of different empirical equations that describes solvent/non-solvent interaction parameter. The search of the empirical equation that could be valid over a broad range of systems and conditions was done from the comparison of different equations proposed in the literature using Aspen Custom Modeler as solving software.

3. Results and discussion

The comparison of the experimental binodal curves reported in the literature for different systems PVDF/solvent/water, where the solvent could be dimethyleacetamide (DMAc), N-methylpirrolidone (NMP) and dimethylformamide (DMF), has been done. Broad differences could be found among different authors for the same ternary system. Thus, see for instance in Figure 1 the experimental points of the binodal curves for the system PVDF/NMP/water, reported by different authors. This experimental uncertainty hampered model fitting. Therefore, a detailed study of the experimental methodologies of the literature has been done in order to propose a reliable procedure to implement in following works.

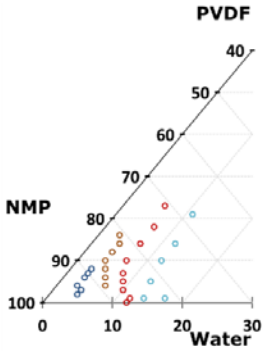

Figure 1. Comparison of experimental points of the binodal curves for the ternary system PVDF/NMP/Water attained from the literature [4-7]

4. Conclusions

The uncertainty in the experimental data of binodal curves due to the experimental difficulty limits the ability to determine broadly valid empirical equations for interaction parameters. Therefore, an experimental protocol to determine the binodal curves has to be proposed out of a thorough literature revision.

Highlights

- Two fluorinated gases have been considered for this study (R-32 and R-134a).
- Gas permeability and gas pair selectivity were compared for material discrimination.
- Rubbery polymers have shown promising properties for the recovery of fluorinated gases.
- Fluorine in the hydrocarbon chains has a remarkable effect on membrane performance.
