Hydrofluorocarbon gases (HFCs) are the third generation of fluorine-based refrigerants. The absence of chlorine atoms in their molecular structures makes HFCs to be considered as ozone-friendly gases. Despite this fact, HFCs are powerful greenhouse gases and the new regulations (EU No 517/2014 and Kigali Amendment to the Montreal Protocol in 2016) are looking for an 85% reduction in their production and consumption by 2047. In this context, research efforts should be dedicated to the development of new separation technologies to facilitate the reuse and recycling of these compounds. Therefore, the application of membrane technology, a cost-effective alternative to cryogenic distillation and pressure swing adsorption, is envisaged to play an important role in the reduction of HFCs emissions.

Membrane technology has reached a state of maturity in the recovery of several gases, such as H_2 from ammonia purge gas or from refinery flue gases, or the recovery of CO_2 from natural gas mixtures, etc [2]. Nevertheless, there is a lack of research data in the separation of fluorinated-based refrigerant gases. In this sense, this work aims at providing novel information about the permeation properties of some of the most used refrigerant gases, R32 and R134a.

Therefore, this work shows the permeation properties of the aforementioned fluorinated-based gases in different membranes (glassy and rubbery polymers) for the first time.

2. Methods

The polymeric films were synthetized by the solvent casting method. The resulting films had an average thickness below 100 µm. Single and mixed gas permeation tests were performed with H_2,

N_2, R32 and R134a at several temperatures (303 - 353 K) and feed pressures (1 - 5 bar). The experimental setup, based on continuous permeation of gases, is described in previous works [3].

3. Results and discussion

This work reports on the effect of pressure and temperature on the refrigerant permeation properties through rubbery polymeric membranes (different PEBAX grades and PVDF-HFP). The experimental results show a linear increase of the permeability of all gases with pressure, a common effect of organic vapors and condensable gases. The activation energy of permeation of the different gases on the polymers which offered the best separation performances was also calculated. This work also presents the study of the effect of the fluorine substitution in the molecular structure by comparing the permeability of the fluorinated gases with their respective hydrocarbon analogues (CH_4, C_2H_6 and C_3H_6).

4. Conclusions

In light of these results, polymer membranes are presented as potential candidates with exceptional properties for the recovery of fluorinated gases.

Hydrophilic and hollow nanocubes functionalized thin film nanocomposite membrane with enhanced nanofiltration performance

Zhipeng Liao, Jiansheng Li

Affiliation and address: Nanjing University of Science and Technology, Nanjing 210094, P.R .China

**Corresponding author: lijsh@njust.edu.cn*

Highlights

- Hydrophilic hollow nanocubes (HHNs) nanofillers were obtained by etching ZIF-8 with tannic acid.
- HHNs were incorporated into the polyamide layer to form thin film nanocomposite (TFN) membranes.
- The prepared TFN membranes exhibit improved permeability and antifouling performance.
- The enhanced performance stems from the structural and compositional characteristics of the incorporated nanofillers

1. Introduction

Nanofiltration has prevailed in water desalination, and is mainly applied to the removal of divalent salts. However, the application of nanofiltration membrane is limited by the intrinsic defects, such as low permeability and poor antifouling property. Incorporation of nanoparticles into the selective layer of composite membrane is an ideal strategy to resolve the dilemma. The structure and composition of nanoparticles are detrimental to the performance of the fabricated composite membrane. Herein, hydrophilic and hollow nanocubes (HHNs) were prepared and incorporated into the selective layer of the composite membrane. The fabricated composite membrane presents excellent permeability, selectivity as well as antifouling property.

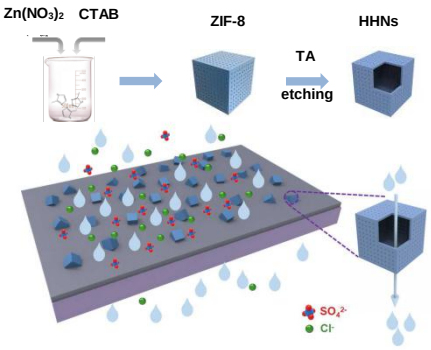

Figure. 1 Schematic diagram of the TFN-4H membrane.

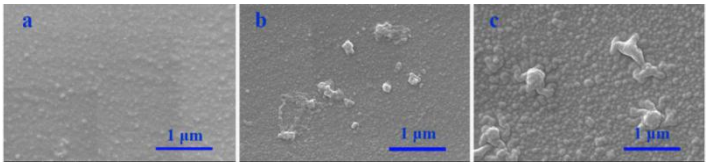

Figure. 2 SEM images of various membranes: TFC (a), TFN-4H (b) and TFN-4S (c) .

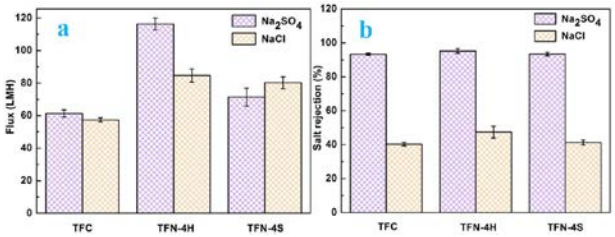

Figure. 3 Performances of various membranes: water flux (a) and salt rejection (b) tested with 1 g/L Na_2SO_4 and NaCl solution at ambient temperature and 6 bar.

2. Methods

Hydrophilic and hollow nanocubes were prepared by etching hydrophobic zeolitic-imidazolate-framework-8 (ZIF-8) using tannic acid. 0.04 wt% HHNs was added to the organic phase and introduced into the selective layer of the nanofitration membrane via interfacial polymerization, the prepared nanocomposite membrane was denoted as TFN-4H (Figure. 1). To highlight the influence of the structure and composition of nanofillers to the performance of composite membrane, equal dose of solid and hydrophobic ZIF-8 was incorporated into the selective layer, the final membrane was denoted as TFN-4S. The filtration performances of the fabricated composite membranes were investigated by Na_2SO_4 and NaCl solution. Meanwhile, the antifouling properties of the composite membranes were studied using humic acid and bovine albumin as the simulated pollutants.

3. Results and discussion

As shown in Figure 2, more and larger nodular structures present on the surface of the composite membranes after the introduction of nanofillers into the selective layer. Besides, there are some incorporate nanofillers exist on the membrane surface. The observed nanofillers are embedded in the selective layer of the composite membranes. It can be concluded from Figure 3, the permeabilities and selectivities of composite membranes modified by nanofillers are better than that of the control membrane. Moreover, the performance of the TFN-4H membrane is much better than that of the TFN-4S membrane. With the introduction of HHNs, the flux and Na_2SO_4 rejection of the TFN-4H membrane increased up to 116.4 L/(m^2·h) (LMH) and 95.24 %, respectively. However, the flux and Na_2SO_4 rejection of the TFN-4S membrane only increased to 71.6 LMH and 93.4 %, respectively. In addition, the TFN-4H membrane presents excellent antifouling property. Oppositely, the antifouling property of TFN-4S membrane is undesirable and even poorer than the control membrane.

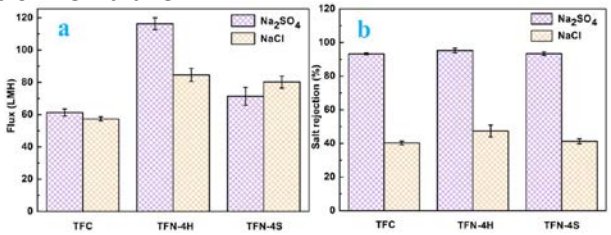

Figure. 4 Time-dependent relative water flux of various membranes tested with 1 g/L Na2SO4 and 1 g/L Na2SO4 + 1 g/L HA solution (a) and 1 g/L Na2SO4 and 1 g/L BSA solution (b) at ambient temperature and 6 bar.

4. Conclusions

The incorporation of HHNs significantly enhanced the permeability and selectivity of the nanocomposite membrane. Compared with the solid and hydrophobic ZIF-8, the prepared hollow and hydrophilic HHNs are more favorable for the improvement of the membrane performance. More importantly, the introduction of HHNs elevated the antifouling property of the composite membrane.

Fabrication and Characteristics of PSS / G-Ch Hybrid Membrane for DMFC

Tomoki Takahashi[1]*, Naotake Horimatsu[2], Katsuto Otake[2]

1 College of Industrial Technology, Nihon University, 1-2-1 Izumicho, Narashino, Chiba 275-8575 Japan;

2 Faculty of Engineering, Tokyo University of Science, 1-3 Kagurazaka, Shinjyuku, Tokyo 162-8601, Japan

**Corresponding author: takahashi.tomoki@nihon-u.ac.jp*

Highlights

- PSS / G-Ch hybrid membranes were prepared.
- The methanol permeability of membranes suppressed by GA cross-linked.
- Fabricated membrane have about equal methanol permeability with Nafion 117.

1. Introduction

The direct methanol fuel cell (DMFC) have attracted considerable attention in fuel cell technology owing to their stable operation, high energy efficiency, portable power source and low environmental burden for mobile electronic devices [1-3]. Protons transfers from anode to cathode are important components in a polyelectrolyte membrane (PEM) with a DMFC system. In addition, methanol crossover (MCO) is another important component. MCO is phenomenon that methanol is transported to the cathode, which decreases the fuel cell efficiency [4, 5]. Thus, both high proton conductivity and low methanol permeability are required for PEM of DMFC. However, these two factors are trade-off relationship. Because, though existence of water is indispensable for protons transfers so that water has methanol and high affinity. In our study, a glycol chitosan (G-Ch) and a sodium salt of polystyrene sulfonate (PSS) were selected as materials of membrane [6]. G-Ch, which is water-soluble derivative of chitosan, can prepare uniform aqueous solution without an acetic acid. This characteristic is used in a protonation of amino groups after mixture of anionic polymer. In addition, we expected to PSS having many sulfonate groups gives PEM the high proton conductivity. We investigated about preparation methods and characteristics in PSS/G-Ch hybrid membrane cross-linked with glutaraldehyde (GA). In addition, we estimated superiority of the hybrid membrane by comparison with Nafion 117.

2. Methods

The PSS powder and G-Ch powder of predetermined quantity were added to ion exchanged water, and it was stirred and was dissolved at 298 K for 24 hours. This PSS and G-Ch mixture solution was cast on the glass petri dish and placed at 298 K for three days. Subsequently, dry membrane was immersed by acetic acid/methanol aqueous solution (volumetric ratio, 5:80:15) for 24 hours to form polyionic complexes between the sulfonate group of PSS and the amino group of G-Ch , as shown in Scheme 1 (a). Furthermore, it was immersed by GA/methanol solution of predetermined concentrations for 24 hours to cross-linked between amino groups of G-Ch, as shown in Scheme 1 (b). Finally, the free-standing membrane was obtained by desorption from glass petri dish with immersing in ion-exchanged water for 24 hours. The obtained membrane was saved in ion-exchanged water. In this work, notation of a membrane sample is described as follows; PSS/G-Ch/GA. The number of notation stands for the gravimetric concentration of PSS in cast solution, the

gravimetric concentration of G-Ch in cast solution, and the volumetric concentration of GA in methanol solution, respectively.

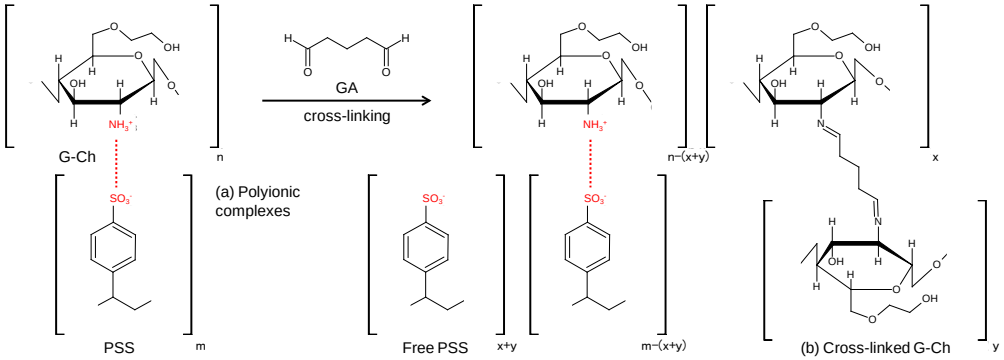

Figure 1. The scheme of the formation of polyionic complexes between PSS and G-Ch and the cross-linked G-Ch.

3. Results and discussion

In this study, we prepared PSS/G-Ch cross-linked by GA hybrid membrane for DMFC, and measured structure of hybrid membrane, water content, methanol permeability, and proton conductivity. From the values of proton conductivity and methanol permeability, we calculated the selectivity parameter. Higher selectivity parameter means that a performance of a hybrid membrane is superior. Table 1 shows the properties of PSS/G-Ch hybrid membranes and Nafion 117 membrane [7]. For the membrane cross-linked by GA, the swelling of PSS/G-Ch hybrid membrane controlled, the methanol permeability reduced, and the proton conductivity increased. The experimental results revealed that the 4/2/2 hybrid membrane exhibited high performance compared to the other composition membranes.

Table 1. The properties of PSS/G-Ch hybrid membranes and Nafion 117 membrane.

membrane (PSS/G-Ch/GA)	thickness [μm]	water content [%]	methanol permeability [$cm^2\ s^{-1}$]	proton conductivity [$S\ cm^{-1}$]	selectivity [$S{\cdot}s{\cdot}cm^{-3}$]
4/2/1	165	89.3	5.4×10^{-6}	0.0061	1136
4/2/1.5	102	71.8	2.4×10^{-6}	0.0120	5003
4/2/2	97	67.3	2.1×10^{-6}	0.0130	6003
Nafion 117	183	23	2.0×10^{-6}	0.1000	-

4. Conclusions

It reveals that the chitosan based hybrid membrane of polyionic complexes have higher proton conductivity value than that of the other polyionic complexes membranes, but lower than that of Nafion membrane, and have just about equal methanol permeability as compared with Nafion. From now on, we think of using the other cross-linking agent to decrease the water content and methanol permeability, more and more PSS to increase the proton conductivity.

Investigating the effect of TiO_2 nanoparticles on the performance of Nanocomposite Membranes from PAN for Produced Water Treatment

Hamid Reza Shahriari[1], Seyed Saeid Hosseini *[1,2]

1 Membrane Science and Technology Research Group, Department of Chemical Engineering, Tarbiat Modares University, Tehran, Iran; 2 Nanotechnology and Water Sustainability Research Unit, College of Science, Engineering and Technology, University of South Africa, Johannesburg, South Africa

**Corresponding author: Saeid.Hosseini@modares.ac.ir*

Highlights

- PAN nanofiltration membranes developed for effective produced water treatment.
- The effect of inclusion of TiO_2 nanoparticles was examined by RSM.
- Membranes with improved separation efficiency were obtained for treating oily wastewater.

1. Introduction

Many governments have regulated discharge limit concentrations in order to at least alleviate the destructive impacts of contaminants on the environment. Several stand-alone or integrated systems are currently in operation for produced water treatment. Among these common systems, membrane filtration offers indisputable advantages while maintaining the high process efficiency. These have attracted researchers to utilize different kinds of membranes for the produced water treatment.

2. Methods

Dope solutions containing prescribed amounts of polymer (22 wt.%), organic and inorganic additives were prepared by moderately dissolving PAN, TiO2 and citric acid in DMF. Dope solutions were cast onto the nonwoven polyester substrates using a knife casting at 70˚C. After a distinct time spans of solvent evaporation, nascent films were submerged in coagulation bath containing pure water with different temperatures. Membranes were characterized by various methods.

3. Results and discussion

Figure 1 shows the cross-section morphology of NF membranes with TiO2 variation. All membranes were asymmetric having both macrovoid and sponge-like structures. It was found that increasing the TiO2 concentration in the dope solution, the porosity of NF membranes was increased from 45.74% to 63.28%. Moreover, both mean macrovoid size and area fraction of macrovoids increased from 29.06 to 51.60 µm and from 0.28 to 0.34 respectively. Also, an increment in TiO2 concentration led to a decrease in contact angle of NF membranes. It is worth mentioning that the reduction of membrane contact angles is not only attributed to the presence of TiO2, but also the surface roughness of the membrane plays an important role in determining the terminal contact angle values. It was also clear that owning to the agglomeration of nanoparticles on the surface of

membrane, number and height of the surface curvatures was increased as the TiO2 content of the dope solution was increased. As stated by Cassie-Baxter theory, the surface hydrophilicity of a pristine hydrophilic surface intensifies when it gets rougher. Therefore, the final contact angle values of NF membranes are determined by the superimposition of surface roughness and modification effects. The emerged changes in the membrane structure might be related to the hydrophilicity enhancement of membrane surface due to the presence of TiO2 nanoparticles which led to the instantaneous demixing process.

Based on the results, the PWF was enhanced from 108.8 to 131.5 (lit.m-2.h-1) through TiO2 addition to dope solution up to 1wt.%. This might be demonstrated by the reduction in the surface contact angles of NF membranes. Despite the positive effect of TiO2 addition on membrane flux, the intensity of PWF variations diminishes at high TiO2 concentrations. The observation could be explained due to the fact that nanoparticles tend to agglomerate on the surface of the membrane, considering their hydrophilic nature. High concentrations of TiO2 in the dope solution, reduces the distance between nanoparticles due to the presence of different forces (i.e.: hydration, bridge, Van der Waals) which provides the chance for them to agglomerate and reduce their surface energy. Also, increasing the TiO2 concentration resulted in an increment in CaSO4 rejection and elevated the rejection from 73.5% to 83%. Considerable changes in the membrane salt rejection could be conceived by the aggregation of nanoparticles on the surface of the membrane. Higher contents of TiO2, increase the viscosity of the polymeric film which delays the demixing process and provides the opportunity for the nanoparticles to form aggregates on the membrane surface to plug the surface pores and reduce the effective membrane mean pore size.

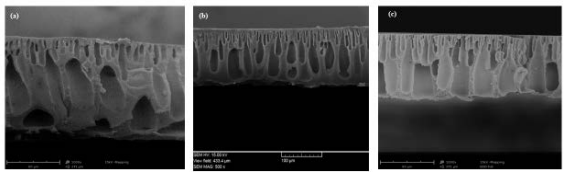

Figure 1. Cross-Sectional images of PAN NF membranes containing (a) (TiO2: 0 wt.%) (b) (TiO2: 0.5 wt.%) (c) (TiO2: 1 wt.%) (Conditions: PAN: 22 wt.%, citric acid: 0.75 wt.%, solvent evaporation time: 2 min)

4. Conclusions

The effect of several fabrication and design parameters including the concentration of TiO2, on the PWF of PAN NF membranes was assessed. RSM technique was employed to explore the effect of the selected variables on the performance and characteristics of PAN NF membranes. Zeta potential and surface hydrophilicity of NF membrane were also intensified. As the TiO2 nanoparticles were added to the dope solution, the area fraction and the membrane porosity were increased. Considering the effect of TiO2 on the membrane performance, both the PWF and the salt rejection of membranes were promoted via the enhancement of membranes hydrophilicity and nanoparticles agglomeration on the surface of membranes.

Effect of the diamine monomer on the structural and desalination properties of thin film composite membranes.

Isam Aljundi[1]

1 Chemical Engineering Department, King Fahd University of Petroleum and Minerals, Dhahran, Saudi Arabia.

*Corresponding author: aljundi@kfupm.edu.sa

Highlights

- Thin Film Composite membranes were prepared from different diamine monomers.
- Polypiperazine membrane showed the highest salt rejection.
- Strong correlation was found between the operating temperature and the salt rejection.
- Increasing the operating pressure or the feed velocity have positive impact on the permeate flux.

1. Introduction

Interfacial polymerization (IP) is the most important method for commercial fabrication of thin-film composite (TFC) RO and NF membranes. The first interfacially polymerized TFC membranes were developed by Cadotte et al. [1] and represented a breakthrough in membrane performance for RO applications. Since then, several methods have been adopted to improve the performance of the polyamide selective layer in terms of enhancement of permeate flux, salt rejection, fouling and chlorine resistance. Among those methods is to change the diamine monomer used in the IP aqueous phase. However, a systematic study on the effect of the side chain of on the aromatic or cycloaliphatic diamine monomers is lacking in the literature. In this project, the effect of the diamine side-chain was investigated in terms of the structure and desalination properties (salt rejection and permeate flux) of the membrane.

2. Methods

The selective polyamide layer of the membrane was prepared by reacting the diamine (2 wt% in distilled water) with TMC in hexane (0.2 g TMC in 100 mL hexane) on top of a previously prepared polysulfone layer. The membranes were dried in a muffle furnace at 75 °C for 5 min for further crosslinking.

The permeate flux and rejection were measured using a cross-flow setup with an effective membrane area of 14 cm2 at different operating conditions of temperatures and pressures. Four diamine were used: Piperazine (PIP), m-xylenediamine (XLN), 1,4-Bis(3-aminoprpyl)piperazine (DAPP), 1-(2-Aminoethyl)piperazine (EAP).

In addition, the effect of operating conditions (T, P, feed velocity, and salt concentration) on the performance of the membranes were also investigated.

3. Results and discussion

The surface morphology of the prepared membranes is shown in Figure 1. It reveals rough surfaces with typical ridge and valley structures of polyamide membranes.

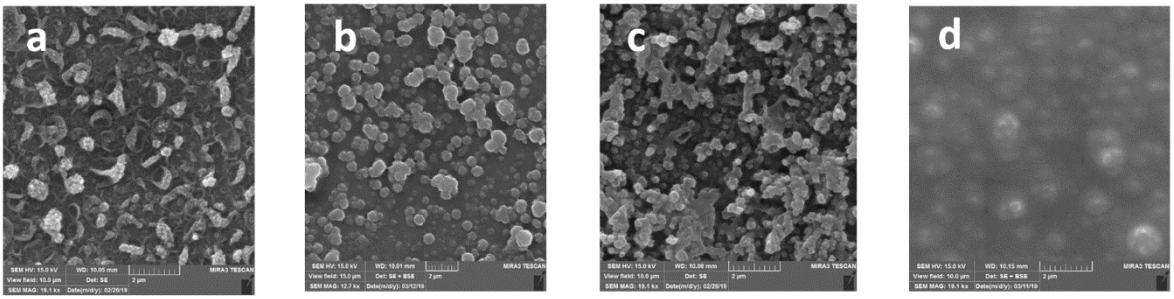

Figure 1. SEM images of the (a) PIP, (b) EAP, (c) XLN, (d) DAPP membranes.

The performance of each membrane was evaluated using different salts. PIP membrane showed the best performance among all membranes where the sulfate rejection was higher than 97%. However, the rejection of sodium chloride was about 73% which is considered high for a nano-filtration membrane. The overall performance was poor for the XLN membrane, however it showed the lowest rejection of NaCl which is advantageous in some applications such as the treatment of fracturing fluids.

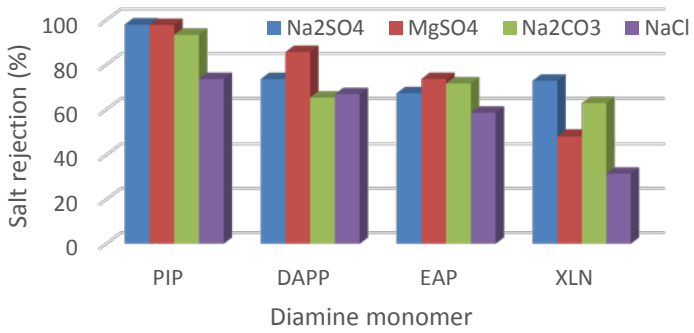

Figure 2. Salt rejection of membranes prepared from different diamine monomers.

4. Conclusions

Four different diamines were used to prepare nanofiltration membranes. The best performing membrane was the one with PIP monomer which showed high rejection along with excellent permeate flux. The hydrodynamics study of the desalination process showed a strong correlation with Reynold's number. In addition, results showed that increasing the operating pressure and Temperatures has positive impact on the permeate flux. However, the salt rejection deteriorated as the temperature increased. Changing the salt concentration in the feed water did not show significant effect on the membrane performance.

Highlights

- Zeta potential measurements reveal important information on electrostatic rejection.
- Increase the cation valence shows an inverse charge of the membrane.
- The co-ion showed an important change in the membrane IEP.

The presence of heavy metal ions in the environment has received important attention due to increased discharge, toxicity in the environment, and other adverse effects which heavy metal ions have on receiving waters [1]. In Chile, copper mining is one of the main industrial activities and has become one of the major discharging heavy metal wastewater. One of this kind of wastewater is associated with the generation of acid mine drainage (AMD). AMD is formed by oxidation of sulfide minerals such as pyrite when it is placed in direct and simultaneous contact with water and oxygen [2]. The main characteristics of this dangerous pollutant are the high degree of acidity (pH of 2-4), the elevated concentrations of sulfate (1-20 g/L), and the presence of metals such as iron, copper, calcium and aluminium, among others [3].

In the literature are reported many methods for the treatment of acid mine drainages such as neutralisation, ion exchange, bioadsorption, biological treatments and solvent extraction [2, 4, 5]. However, all these technologies have disadvantages in their application; most of them have many serious economic, technical, environmental, and efficient limitations. An alternative such as membrane-based technologies such as pressure-driven processes has high performances in the removal of ions and contaminants. Nanofiltration (NF) is an attractive membrane separation technology more used to wastewater treatment and industrial applications. NF offers the advantage of operating at lower pressure and obtaining high permeate flux, leading to lower capital investment and decreasing the cost of operation and maintenance.

The application of NF membranes to treat AMD has been previously studied [3, 6-10]. The performance depends on the constituent membrane characteristics. Typically, NF are thin-film composites (TFC) made from various polymers such as polyamides, polysulfone, sulfonated polysulfone, polyamide and poly(piperazine amide) [11]. The separation mechanism of NF membranes includes the diffusion and convection transport in addition to electromigration related to the charge of the functional groups of the surface of the membrane. The charge acquired on the

surface membrane can be by mechanisms as adsorption of ions, adsorption of polyelectrolytes, ionic surfactants and charged macromolecules [Artug]. Interfacial attraction and adhesion forces are expressed as the electrostatic, acid-base, van der Waals, and hydrophobic forces between the surface of the membrane and feed stream ionic contaminants. Therefore, electrokinetic surface properties are of vital importance to understand the phenomena of electrostatic rejection of NF membranes.

At present, zeta potential can be measured by electrophoresis or measuring streaming potential methods. Electrophoresis method can be used to describe the migration and separation of charged particles (ions) under the influence of the electric field. In contrast, the streaming potential is the potential difference at zero current produced by the convective flow of an electrolyte solution through a stationary capillary or porous plug. Streaming potential measurements have been widely used to characterise charged materials such as membranes [12-17], root surface [18], textile [19], fibres [20] and polymers [21]. Several studies were dedicated to evaluating the performance of a commercial NF with electrolyte solutions containing divalent ($MgSO_4$, $CaSO_4$, $MgCl_2$, and $CaCl_2$) and monovalent (NaCl, KCl, LiCl, and K_2SO_4) ions relating to their behaviour to the surface charge by zeta potential measurement. However, the behaviour of electrolytic solutions of metals such as copper, calcium and aluminium has not been fully studied.

In the present work, the retention properties of a negatively charged commercial NF membrane are investigated with three electrolytes (calcium, copper and aluminium) having co-ion of sulphate and chloride at acid and normal pH condition. The concentration or ionic strength of sulphate electrolyte solution on membrane zeta potential and the effect of co-ion (chloride) were investigated using a combination of streaming potential measurements and theoretical modelling.

Modelling and optimization of a reactive distillation column to obtain high pure cyclohexanone in caprolactam production process.

David Lorenzo[1*], Aurora Santos[1], Carlos Pérez-Galván[2], Cristian Triana[2], Arturo Romero[1], I. David L. Bogle[2]

1. Dpto. Ing. Química y de Materiales, Universidad Complutense de Madrid, Avda. Complutense S/N, 28040 Madrid, Spain; 2. Dpt. Chemical Engineering. University College London, Torrington Place. London WC1E 7JE

**Corresponding author: dlorenzo@ucm.es*

Highlights

- 2-ciclohexen-1-one is easily removed using a reactive distillation.
- NaOH is used as catalyst in a reactive distillation to produce high pure cyclohexanone.
- The reactive distillation model is experimentally validated.
- A reactive distillation model is used to optimize the production of cyclohexanone.

1. Introduction

Cyclohexanone (CX-ONE) is the main compound used in the caprolactam production which is the monomer of nylon 6. The most common cyclohexanone production process starts oxidizing cyclohexane to produce a mixture of cyclohexanol, cyclohexanone and other organic impurities [1-3]. Cyclohexanone purification process involves three distillation columns and a reactor where the cyclohexanol is dehydrogenated to cyclohexanone. However, some of the organic impurities (formed either during cyclohexane oxidation or cyclohexanol dehydrogenation) cannot be removed by a standard distillation because their boiling point are close to cyclohexanone. One of those is 2-cyclohexen-1-one (CX-ENONE), it has drastic effects in the nylon fiber because it can produce a rubber during the polymerization. To reduce the amount of this impurity in the pure cyclohexanone a reactive distillation (RD) step has been proposed using NaOH. Sodium hydroxide promotes the condensation of the impurity and cyclohexanone yielding a dione compound [4]. Dione boiling point is higher than cyclohexanone and can be easily removed within the purification process. Nevertheless, the presence of alkali in the reaction medium also promotes the self-condensation of cyclohexanone, which is a non-desirable loss of cyclohexanone. In this work the RD process is modelled and optimised in order to select the operating conditions that guarantee the removal CX-ENONE with minimum losses of CX-ONE.

2. Methods

The RD column is modelled considering both the physical and chemical processes taking place in the column trays, condenser and reboiler. The RD model developed was validated using experimental data obtained at the laboratory-scale distillation packed column. The selfconstructed model was used to simulate and optimized the RD column operating at industrial-scale which

ensure the minimal unit total cost (UTC), defined as the production cost of a unit of mass of pure cyclohexanone. A mixed non-linear programming problem (MINLP) was formulated and solved using the optimization algorithm which is available in gPROMS[5].

3. Results and discussion

To study the operating condition range and the UTC, different case studies were carried out. Those cases depend on the CX-ENONE amount which is presented in the pure CX-ONE stream within the range 5-15 mg/kg of impurity. The results are summarized in Table 1. They show the optimal operation conditions to obtain a high purity cyclohexanone product with the minimum unitary total cost.

Table 1.

Parameter	Value

Ntrays	41	40	44
Number of reaction trays	37	37	38
d_{col}, m	2.31	2.41	2.36

4. Conclusions

Following validation, the reactive distillation model was used to optimize conditions of operation. The objective function used was the minimization of the unitary total cost to produce a kg of pure cyclohexanone. The model was implemented as a MINLP problem which was solved using the optimiser within gPROMS. The optimal values of NaOH concentration, number of reaction stages, number of trays, pressure, and reflux rate were obtained. Using this information, other design and operation variables were obtained. The model is a powerful tool to study the design of the purification unit to produce high pure cyclohexanone in the caprolactam production process.

Highlights

- A solvent selection tool developed at Syngenta is described through examples.
- Its guiding principles are ease of use, flexibility, and empowerment of chemists.
- Its interactive visualizations help exploring the solvent parameter space efficiently.

1. Introduction

Chemical manufacturing processes, especially for fine chemicals, often take place in the liquid phase. Solvents facilitate reactions, enable separations, and lower viscosity for convenient transport. Where possible, water is typically used, but many phenomena require different properties, better provided by organic solvents. The multitude of possible functional groups leads to even more numerous property combinations. Solvent selection is thus an important decision in chemical process development. Many methods have been put forward to optimize this selection, from high throughput screening to predictive models. The latter typically rely on physicochemical descriptors and can be made more accessible by embodiment in software tools [1, 2]. To get the most value from such tools, the corresponding theories and assumptions must be understood. To achieve both prediction and insight, an in-house tool was built at Syngenta and is described here.

2. Methods

Solvent selection methods have been researched by chemists as well as process systems engineers [3, 4]. Information technology skills are required to produce robust, attractive, and sustainable tools. A multi-functional project team was thus assembled (see Table 1). The basic philosophy was to build a tool empowering trained chemists to explore the process space – not a prescriptive tool with definite decisions, but a *suggestive* one. A main use thereof is defining the next iteration of solvents to try in the laboratory.

Chemists: Main user community	**Process engineers**	**Statisticians**	**Data scientists**
Definition of usage criteria Data for repository	Theories for property/phenomena correlations Functionalities and workflows	Fitting techniques	IT implementation

Table 1. Experts' roles on the project team

Physical and other properties were compiled for approximately 130 solvents in a spreadsheet ("the database"), from the following broad categories: identifiers; measured properties; physicochemical derived descriptors; HSE scores. The following calculations were then automated in the software R-Shiny: 1) similarity and difference searching using hierarchical cluster analysis; 2) multi-criteria

searching in property value space; 3) principal component analysis (PCA) for visualization as maps. All these functions allow dynamic, real time selection of the properties of interest by the user.

To underpin the *use* of the tool, several theories were used; in particular, solvatochromic / Abraham [5] and Kamlet-Taft [6] descriptions. The corresponding sets of properties were selectable together for convenient access to the occasional user.

3. Results and discussion

The R-Shiny tool appears as a typical browser interface. Parameter and visualization choices are set in a "start" tab, leading to real-time calculations in various results tabs. The tool is designed to be usable in many different ways. Cluster analyses yield solvents similar, to, or different from, a specific one. Multidimensional filtering allows several property ranges (e.g., solubility parameters and boiling point) to be matched simultaneously (Fig. 1a). PCA maps based on parameters known to matter for a process (e.g., Kamlet-Taft α, β, π* + boiling point, Fig. 1b) also provide alternatives.

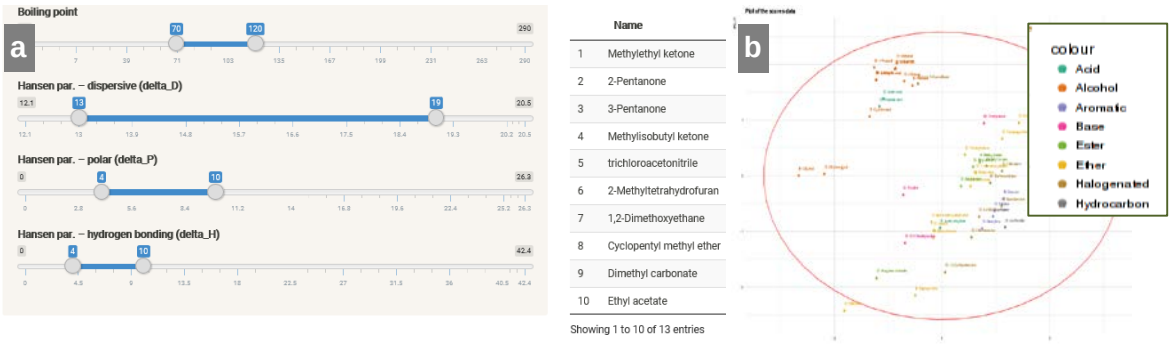

Figure 1. Screenshots of the matching (a) and PCA (b) tabs in the tool.

4. Conclusions

Different scientific specialisms lead to different languages and approaches. Tool development was found to be more intrinsically iterative than originally expected. While physical properties are a Rosetta stone for the meeting of chemists, engineers, and statisticians, progress required real usage cases. It was far easier to discuss mock-ups and share user stories than to write requirement specifications, leading to the mantra "show, don't tell". To remain meaningful to physical scientists, graphs and points required extensive labelling. Several concrete examples of use are documented in [7]. Possible improvements were continuously identified. Two important directions are: further incorporation of chemical theories; increased tool interactivity and filtering capability.

Highlights

- A concept for the online application of APC tools on plants in real time is proposed
- This concept utilizes an OPC UA standard for efficient data exchange
- The implementation of the concept is successfully demonstrated in a case study

1. Introduction

The structural implementation and application of model-based advanced process control tools based on methods such as data reconciliation, state estimation, sequential optimal experimental design or dynamic real-time optimization is a complicated and time-consuming task. It requires the development of a methodology for coupling of the tools with a process model, selection of a solver and implementation of a data-processing algorithms. The robust online application of these tools brings even more challenges for a developer. Solution must ensure that the APC tool can (i) read current and historical data from the plant in real-time, (ii) indicate relevant information to the plant operator, and (iii) influence the operation of the plant by manipulating variables, e.g. set points of the controllers.

This gap between the development of an APC tool and its efficient online implementation is being addressed in this contribution. The proposed data communication model is independent from the specific plant and APC tool and is based on the OPC UA standard [1], which fulfills all requirements for Industry 4.0 communication [2].

2. Methods

The data communication concept is shown in Fig.1. The connection between a plant and an APC tool is achieved via an intermediate aggregating OPC UA server, which is the main feature of the concept. It mirrors data from the real plant, stores it in a database and assures a bidirectional communication between the plant and the APC tool. Complex data types, provided by a server, specify a communication data model for APC tools allowing for a standardized data handling. The process model and the APC tool based on it are generated with the web-based modeling platform MOSAICmodeling [3]. The latter contains information about mapping of process variables (sensors, actuators, etc.) and model variables.

3. Case Study and Results

In order to check the applicability and potential of the developed concept, a case study has been conducted. Real-time plant operation is mimicked by the simulation of a dynamic model of a continuously stirred tank reactor with a chemical reaction of the second order. This simulation is connected to an aggregating OPC UA server, which constantly stores measurements in a database. This data is accessed by different APC tools, which are based on the same dynamic model: moving horizon state estimation, dynamic optimization of plant trajectories, and parameter estimation. The concept has been implemented in Python [4] and successfully tested. Simulation and state estimation have been running in parallel for twenty hours, while all the generated data has been stored in the database. No data has been lost during the experiment and no bottlenecks that hinder long lasting experiments were found. This allows for further investigations of the concept applicability on a real mini-plant for homogeneously catalyzed liquid multiphase reactions at TU Berlin operated by the SIMATIC PCS 7 distributed control system.

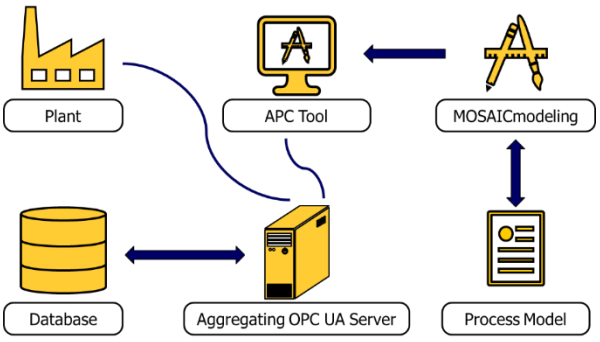

Figure 1. Proposed data communication concept.

4. Conclusions

Online implementation of APC tools is a complex task, which requires an efficient and easily applicable solution. On the one hand, this solution must be robust and secure, while on the other hand it must be easy in use and flexible. The concept presented in this contribution, fulfills these requirements. Based on results it is suggested that the OPC UA standard is to be used as a base layer for online application of APC tools, while the proposed concept and its Python implementation are a good example of a possible generalized solution of the highlighted challenge.

Generic Model-based Framework for Predictive Particle Monitoring using Advanced Image Analysis and Deep Learning

Rasmus Fjordbak Nielsen[1], Krist V. Gernaey[1], Seyed Soheil Mansouri[1]

[1]*Process and Systems Engineering Centre (PROSYS), Department of Chemical and Biochemical Engineering, Technical University of Denmark, Sølvtofts Plads, Building 229, DK-2800 Kgs. Lyngby, Denmark*

Highlights

- Generic modeling framework for particle processes using real time imaging
- Using raw images and deep neural network to estimate particle birth/growth rates
- Estimating particle size distribution measurement uncertainty
- Including measurement uncertainty to enhance model robustness

1. Introduction

Particle processes has gained significant importance in chemical and biochemical engineering in the last two decades. Especially within fermentation, flocculation, crystallization, there has been an increased industrial focus on optimizing and enhancing controllability of these processes. At the same time, both optics and image-analysis algorithms have improved significantly. It is now possible to analyze sample particle populations in real-time. This can be done by automatically sampling particle suspensions from the production tank to a mono-layer lab-on-a-chip device, where microscopy images are taken and analyzed using automatized advanced image analysis.

In this work, a deep neural network is used to estimate the birth and growth rates of the given particle process in real-time. Here we use the raw image, the results from the image analysis, and the measured and controlled process variables as inputs. When using deep neural networks, there is a greater risk of overfitting [1]. To accommodate this, it has previously been suggested to add random noise to the input data [2]. Here we utilize the prior knowledge on the inherent sampling error from the image analysis, and show how it is possible to reduce the risk of overfitting the neural network model. At the same time, we also account for the measurement uncertainty already during the model generation.

2. Methods

The suggested model structure can be seen in Figure 1. The network consists of a range of dense neural network layers, one generic population balance model and a loss function. Here we evaluate the performance of the model by calculating the mean absolute error (MAE) of the predicted relative size distribution. By adding Gaussian, zero-mean, random noise to the size-distribution data during training, with the same standard deviance as the known sampling error of the image analysis, the risk of overfitting can be reduced. At the same time, the uncertainties of the measurements are included in the process model during model generation, resulting in a more robust model. This will work for even crude errors, as long as the measurement uncertainty is correctly estimated.

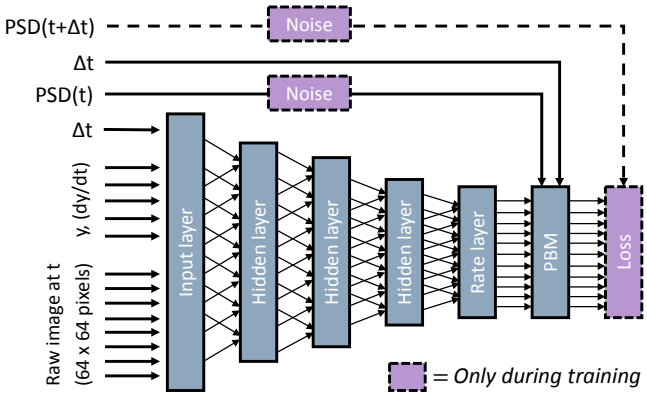

Figure 1. Modelling structure, where y represents measured and controlled variables. The time-derivative data of y is only supplied for controlled variables. The number based particle size distribution is abbreviated as PSD.

The sampling error of image analysis is here be estimated by assuming a random and unbiased sampling, where total sample size $\sum_i N_i$ (number of particles detected on the image) is much smaller than the total number of particles in process tank [3]: $\sigma = \sqrt{N_i \cdot (1 - N_i / \sum_i N_i)}$

3. Results and discussion

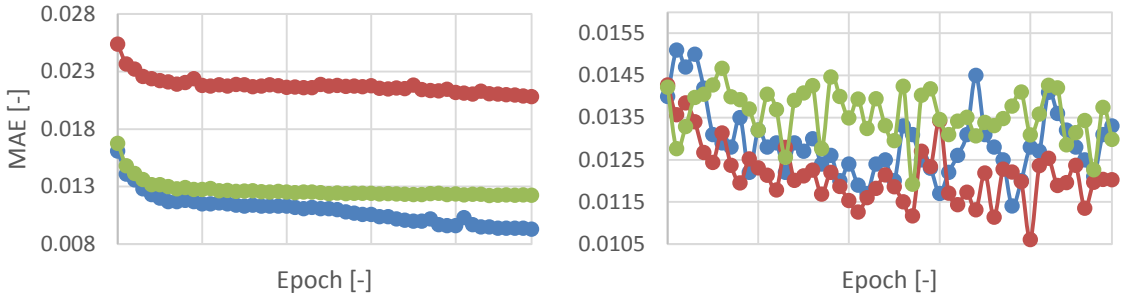

Figure 2. Training error (left) and validation error (right). ● Without noise ● Random noise ● Measurement specific noise

By applying the presented framework on a case study of lactose crystallization, where the temperature is the only measured and controlled process variable, it is here shown that the generated model is able to predict the evolution of the crystal size-distribution with high precision. As can be seen in Figure 2, by adding measurement-specific noise, compared to no noise addition and random noise, the model precision is increased. Furthermore, the tendency to overfitting is also shown to be reduced.

4. Conclusions

With the presented framework, it is shown possible to model a particle process using advanced image analysis and deep learning, giving accurate predictions of the size-distribution evolution. Here, the image analysis uncertainty is already taken into account during model training, showing to give even better predictions.

Development and validation of a model of the fructose metabolism across the liver sinusoid.

Yunjie Liao[1], David Bogle[1], Nathan Davies [2]

1 Department of Chemical Engineering, University College London, London, WC1E 7JE, United Kingdom;

2 Institute for Liver and Digestive Health, Division of Medicine, University College London, Royal Free Campus, London, NW3 2PF, United Kingdom

**Corresponding author: d.bogle@ucl.ac.uk*

Highlights

- Novel use of Process Systems Engineering techniques.
- A model of reaction mechanisms for fructose metabolism in the human liver.
- The model predicts the effects of novel therapeutic interventions.

1. Introduction

The liver is one of the most complicated processing organs in human body. It performs a broad range of biochemical functions for maintaining metabolic and energetic homeostasis of the whole body. Fructose, a daily dietary ingredient metabolised in the liver, had been proposed as a beneficial sweetener and recommended as a desired replacement for glucose for the obese and for diabetics. Yet both clinical and experimental studies recently have suggested a causal relationship between fructose over-consumption and damaged metabolism inducing hepatic steatosis [1-3]. However, neither animal models nor immortalised (HepG2) cell line studies have provided biologically accurate information relevant to human subjects due to species differences and the lipid build-up characteristics of HepG2 cells, respectively. Further, little is known on the effects of fructose on differential metabolic zones across the sinusoid. Therefore, a computational model based upon a systems biology approach is an attractive option to acquire a more comprehensive insight into the potential pathophysiological mechanisms of high fructose intake.

2. Methods

A kinetic model of hepatic fructose (± glucose/sucrose) metabolism was developed in MATLAB (Mathworks, MA, USA) based on modified Michaelis-Menten and Hill equations. The model includes literature identified biochemical components and reactions within distinct pathways, e.g. gluconeogenesis, *de novo* lipogenesis, beta-oxidation and triglyceride synthesis. The model parameters were determined and refined by comparison to literature values and also *in vitro* and *in vivo* studies (including a range of samples from healthy and diseased cases).

3. Results and discussion

In our *in silico* model, eight graded compartments including the fructose metabolism were constructed to represent hepatic heterogeneity along the periportal to perivenous axis. The simulations predicted increasing production of pyruvate, fatty acid and triglycerides on a 12-hour

periodic basis after fructose feeding, showing good association with published values [4,5]. The model also shows sensitivity at a number of control loci that may represent therapeutic intervention points such as fructokinase and peroxisome proliferator-activated receptors (PPARs).

4. Conclusions

We have adopted a systems engineering approach to investigate the fructose metabolism across the liver sinusoid and to determine the rate of pathophysiological consequences that develop as a result of an affected metabolism. The results suggest that the model is robust and reliably predicts the behaviour of the fructose metabolism, showing an accumulation of lipid within the hepatocyte as a direct consequence of fructose feeding. The model is further expected to predict the effects of novel therapeutic interventions based upon identified regulatory points which can then be corroborated by experimental studies.

We believe that organ modelling *in silico* model systems will have numerous applications in developing future therapeutic strategies and are a future growth area for Process Systems Engineers in collaboration with clinical colleagues.

Machine Learning in the context of the Modifier Adaptation Methodology for Real Time Optimization.

Daniel Navia[1], Felipe Moreno[1]

1 Universidad Técnica Federico Santa María, Av. Vicuña Mackenna 3939, Santiago de Chile, Chile

**Corresponding author: daniel.navia@usm.cl*

Highlights

- Machine learning implemented in the modifier adaptation method.
- Rejection of disturbances and modelling mismatch in real time optimization.
- Method allows tracking the optimum of an uncertain process in spite of disturbances.

1. Introduction

Real Time Optimization (RTO) with Modifier Adaptation method (MA) allows finding the optimum of a process ($\boldsymbol{u}_p^\star$) when the model of the process presents structural mismatch. To do so, MA updates the decision variables ($\boldsymbol{u}$), solving iteratively a modified model-based optimization problem, updated with first ($\boldsymbol{\lambda}$) and zeroth ($\boldsymbol{\varepsilon}$) order corrections in the objective function (J) and in the inequality constraints ($\boldsymbol{C}$). $\boldsymbol{\lambda}$ are calculated using process gradients with respect to $\boldsymbol{u}$ [1]. As the process is uncertain, the experimental gradients are calculated with historical data. In real processes unmeasured disturbances ($\boldsymbol{\xi}$) can affect the process outputs, i.e. $J_p(\boldsymbol{u},\boldsymbol{\xi})$ and $\boldsymbol{C}_p(\boldsymbol{u},\boldsymbol{\xi})$. Therefore, the process derivatives calculated only with past information of $\boldsymbol{u}$ can be erroneous, which implies that the MA may not find $\boldsymbol{u}_p^\star$ [2]. To avoid the estimation of the process gradients, MA has been reformulated as a nested optimization problem (NMA) [3]. NMA uses an upper optimization layer to update $\boldsymbol{\lambda}$, looking for the minimization of the Lagrangean of the process ($\mathcal{L}_p \coloneqq J_P(\boldsymbol{u},\boldsymbol{\xi}) + \boldsymbol{\mu}^T\boldsymbol{C_P}(\boldsymbol{u},\boldsymbol{\xi})$). As $\boldsymbol{\xi}$ can affect the outputs, it is expectable that $\boldsymbol{u_p^\star(\xi)}$**.** Machine Learning (ML) is a subset of artificial intelligence algorithms that uses statistical techniques to give computers the ability to learn with data. It allows overcoming the uncertainty related with the modeling-mismatch of a process building internal surrogated models based in statistical analysis. It relays in the idea of sequential queries to the real process, each of them calculated solving an optimization problem with the surrogated model. At each evaluation in the process, the model uses the gathered data to increase the knowledge of the uncertain system. The objective of this work is the implementation of algorithms based in ML in the upper layer of NMA (ML-NMA) to give the MA the ability to track the value of $\boldsymbol{u}_p^\star(\boldsymbol{\xi})$ in real time.

2. Methods

For a given steady state k, the upper layer proposes $\boldsymbol{\lambda}_{k+1}$ solving Eq.(1), where $f_{GP_k}(\cdot)$ is the available mapping of $\mathcal{L}_p$. f_{GP_k} is obtained with the Gaussian Process approach (GP). GP is a nonparametric regression method to find an approximation of $\mathcal{L}_P$ with the available data.

$$\min_{\boldsymbol{\lambda_{k+1}}} f_{GP_k}\left(\mathcal{L}_p\left(\boldsymbol{u}(\boldsymbol{\lambda_{k+1}}),\boldsymbol{\mu}(\boldsymbol{\lambda_{k+1}})\right)\right), s.t.: Eq.(2) \quad (1)$$

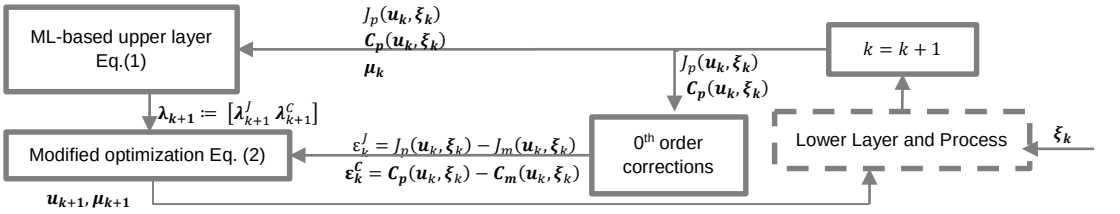

Figure 1. Developed algorithm of NMA with ML (ML-NMA).

The value of $\boldsymbol{\lambda}_{k+1}$ and $\boldsymbol{\varepsilon_{k+1}}$, are used to solve the modified optimization from Eq.(2). The outcome of Eq.(2) is implemented into the process. Once the steady state is reached, the outputs of the process are measured to update f_{GP_k} and solve Eq.(1). The update of f_{GP_k} gives the ML-NMA the ability to adapt the MA to the changing conditions of $\boldsymbol{\xi}$.

$$\min_{\boldsymbol{u}\in\boldsymbol{U}} J_m(\boldsymbol{u},\boldsymbol{\alpha}) + \left(\boldsymbol{\lambda}^J_{k+1}\right)^{\boldsymbol{T}}(\boldsymbol{u}-\boldsymbol{u}_k) + \varepsilon^J_{k+1}$$
$$s.t.: \boldsymbol{C}_m(\boldsymbol{u},\boldsymbol{\alpha}) + \left(\boldsymbol{\lambda}^C_{k+1}\right)^{\boldsymbol{T}}(\boldsymbol{u}-\boldsymbol{u}_k) + \boldsymbol{\varepsilon}^C_{k+1} \le 0 \qquad (2)$$

3. Results and discussion

The ML-NMA was tested in the Otto-Williams reactor. The process consisted of an isothermal CSTR working at a given temperature T_R with two influents (F_A and F_B). Inside the CSTR three chemical reactions are produced, while in the approximated model of the process only two of them are considered. The decision variables of the process are T_R and F_B. In this work we have considered F_A as an unmeasured disturbance changing over time. The RTO looks for F_B and T_R those optimize the economic benefit of the process inside a feasible region [4]. The main result of this work was that the evolution of F_B calculated with ML-NMA followed the trajectory of the optimum of the process closer than other MA approaches, while T_R was better estimated by the DUAL-MA SSKF (Figure 2). Nevertheless DUAL-MA SSKF depends on the accuracy in $\boldsymbol{\xi}$ estimation.

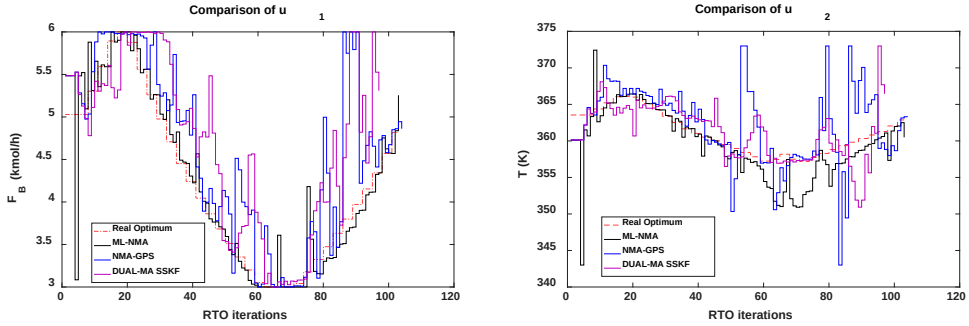

Figure 2. Evolution of F_B and T_R: ML-NMA (black solid line), real optimum of the process (red dotted line), NMA using Generalized Pattern Search (blue solid line), MA with dual approach and Steady-state Kalman Filter (magenta solid line)

4. Conclusions

It has been demonstrated that ML-NMA allows tracking the optimum of an uncertain process which is affected by unmeasured disturbances.

Synthesizing Temperature Control System for Binary Distillation Columns.

Lu Liu[1], Kejin Huang[2], Yang Yuan[3], Xing Qian[4], Haisheng Chen[5]

College of Information Science and Technology,
Beijing University of Chemical Technology, Beijing 100029, People's Republic of China

Highlights

- Sensitivity analysis and minimum deviation methods give inconsistent outcomes.
- The new method balances the static and dynamic behaviors of rectifying section.
- The new method suppresses sensitivities to pressure variations of stripping section.
- The new method renders better static and dynamic behaviors than the former two methods.

1. Introduction

Based on the sensitivity analysis and minimum deviation methods, the synthesis and design of temperature inferential control systems for three ethanol/butanol binary distillation columns with, respectively, low, intermediate, and high product purities are addressed in this work. The temperature inference control systems based on the sensitivity analysis method focusing on dynamic behaviors and the minimum deviation method focusing on static behaviors are difficult to give satisfactory control effects under high product purity conditions. Through in-depth analysis of the static and dynamic behaviors of the controlled stages in the rectifying section and the stripping section, we explain why these two methods fail to give consistent control effects at low, intermediate, and high product purities, followed by verification in closed loop control.

2. Methods

The controlled stages by the sensitivity analysis method usually exhibit quick dynamic responses but only in the case of low product purities can their temperatures display satisfactory corresponding relationships with product compositions. For the controlled stages by the minimum deviation method, their temperatures usually display satisfactory corresponding relationships with product compositions. In the case of high product purities, because the controlled stages are quite near in locations to the ends of the distillation column, degraded process dynamics is introduced in the rectifying section and great sensitivity to pressure variations occurs in the stripping section, both worsening the performance of the temperature inferential control system. Therefore, in order to achieve tight inferential control of product qualities, it is necessary to develop a new method that can compensate for changes in system characteristics. In order to compromise the static and dynamic behaviors in the rectifying section, the controlled stage should be selected between the top stage and the sensitive stage. The temperature difference between the two lowest stages in the stripping section should be used as the controlled variable to achieve the most effective compensation for pressure changes.

3. Results and discussion

Let us take the example of an ethanol/butanol binary distillation column with an intermediate product purity of 99%. The closed loop response processing a ±20% step change of feed composition and a ±20 % step change of feed flow rate is shown in Figures 1 and 2, respectively. The closed loop response based on the sensitivity analysis, minimum deviation and new methods are labeled as CS1, CS2 and CS3, respectively. The positive responses are represented by black curves and negative responses by gray curves. In Figure 1, although the CS2 greatly reduces the steady-state deviations compared to the CS1, its dynamic behaviors of the top and bottom products are deteriorated. In Figure 2, the CS2 not only has larger steady-state deviations than CS1 in the bottom product, but also deteriorated dynamic behaviors. Compared with CS1, CS3 not only reduces the steady-state deviation of the top product concentration, but also reduces the transient and steady-state deviations of the bottom product concentration. Although the CS3 has slightly larger steady-state deviations than CS2 processing ±20% step change in feed composition, its static and dynamic behaviors are balanced.

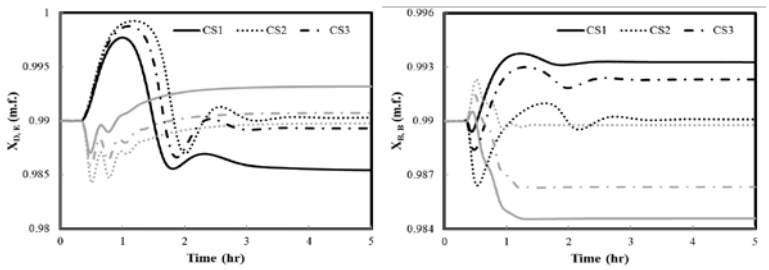

Figure 1. Closed-loop responses in case of a ±20% step change in feed composition.

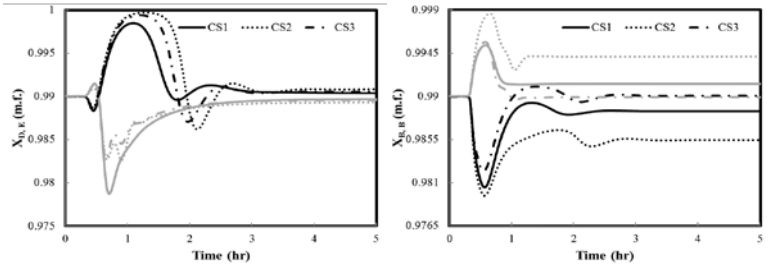

Figure 2. Closed-loop responses in case of a ±20% step change in feed flow rate.

4. Conclusions

Sensitivity analysis and minimum deviation methods give inconsistent outcomes. Therefore, we develop a systematic method that can not only compromise the static and dynamic behaviors of the rectifying section but also suppress the sensitivity to pressure variations in the stripping section. The obtained results have confirmed that the new method can render better static and dynamic behaviors than the sensitivity analysis and minimum deviation methods.

Highlights

- Multi-objective optimization
- Process simulation
- Scalarization methods
- Genetic algorithm

1. Introduction

The use of a variety of commercial process simulators is state of the art, offering the possibility for calculating mass transfer phenomena, thermodynamics and reaction kinetics of single processes, individual production plants and entire production sites. The last step in process simulation is the optimization of the design and/or operating parameters of the plant in view of economy, operational safety, environmental impacts and social aspects. As these aspects are often conflicting each other, this frequently implies a multi-objective optimization (MOO) problem, also called Pareto optimization. MOO problems always include two or more objectives, common examples for that are investment costs vs. operational costs and profitability vs. environmental aspects.

Popular process simulators, like Aspen Plus, Aspen HYSYS, CHEMCAD and gProms, include optimization modules, which are capable of performing only single objective optimization (SOO). To overcome this drawback, introducing MOO in process simulators is commonly realized by coupling the process simulator with an external application which runs the optimization algorithm. In general, there exist two groups of optimization algorithms: deterministic and stochastic algorithms.

Deterministic optimization algorithms require gradient information of the optimization problem, which makes them very fast compared to stochastic algorithms. Gradient information in process simulators is only available when they are running in equation orientated simulation mode via the equation set object, defined by the CAPE-OPEN standard. [1]

Stochastic optimization algorithms, on the other hand, require only information about the dependent variables (objectives or output of the system) and the independent variables (process parameters to be optimized). Therefore, they are suitable for optimizing black-box functions, such as process simulators running in sequential modular mode. Their main disadvantage is the

relatively slow convergence, due to many evaluations of the objective functions in the course of evaluation runs of the process simulator.

In this work, several approaches for applying MOO in process simulation are compared among their effort for realization and their suitability for optimization in process engineering. They are implemented in the framework of Wolfram Mathematica, which is coupled with KBC PetroSIM as a process simulator via a COM Interface.

2. Methods

Scalarization methods, which transform a MOO problem (vector) into a SOO problem (scalar) are very popular due to the fact that they are easy to implement and the broad availability of built-in SOO algorithms in nearly every mathematical program. [2] Therefore, as a first step, popular scalarization methods, such as the weighting method and ε-constraint method are implemented and their resulting SOO problems are solved by the built-in global SOO algorithms, i.e., simulated annealing, differential evolution and Nelder-Mead. [3]

As a second step, a genetic algorithm is implemented. Genetic algorithms are population based and a group of them is able to handle MOO problems directly. One of the most popular algorithms is the Non-dominated Sorting Genetic Algorithm II (NSGA-II). This standard-algorithm is implemented together with several adaptions for handling integer variables. Additionally, five different jumping-gene operators as well as the hyper-volume of the Pareto front as a convergence measure are implemented as extensions to NSGA-II. [2,4]

3. Application

To compare these different implementations and variations for MOO, they are applied to the example of a steam reformer located in a European refinery, optimizing the process in view of specific hydrogen production (kg H_2/kg natural gas) and HPS (high pressure steam) production. Using this example, strengths and weaknesses of the aforementioned approaches are analyzed and recommendations for their application are given.

3. Conclusion

The presented work demonstrates the workflow and efforts to enable MOO in process simulators with the example of optimizing a steam reformer in view of process flexibility. Beyond the typical application of MOO for economic optimization, it gives the possibility of evaluating the increasing demand of process flexibility and load-shift capability of plants and processes.

Highlights

- Global optimization of catalyst recovery in an extraction cascade.
- Complex LLE and catalyst distribution models replaced by artificial neural network.
- Implicit model formulation reduces the input dimension of the surrogate model.
- Surrogate model quality is improved by optimization based bound tightening during preprocessing.

1. Introduction

The aim of using renewable resources for chemical processes and improving their energy efficiency calls for the exploration of novel and integrated process concepts. Thermomorphic multiphase systems (TMS) enable favorable reaction conditions as well as efficient catalyst recycling for homogeneously catalyzed reactions. A TMS is homogeneous at reaction conditions and a subsequent decrease in temperature results in biphasic behavior: a catalyst-lean product phase and a catalyst-rich phase that is recycled back to the reactor. If the separation of catalyst from the product phase in one step is not sufficient, the process can be extended by additional extraction stages to further increase recovery of valuable catalyst.

Mathematical optimization can be used to find the economically most viable realization of such a process. For nonlinear models with continuous decision variables this leads to nonlinear programs (NLP), which are typically hard to solve and may possess multiple local minima. Therefore, deterministic global optimization is required to avoid suboptimal design decisions based on poor local solutions. Thermodynamic models employed to predict the phase equilibrium of TMS and the catalyst distribution are often computationally difficult to handle within optimization problems, even in the case of local optimization. Replacing thermodynamic models with suitable surrogates provides the means to trade model accuracy for better computational tractability.

As an example, the hydroformylation of long-chain aldehydes with homogeneous catalysts using a TMS for catalyst recovery is considered in [1]. In that work, the thermodynamic models are replaced by a Kriging model to avoid convergence problems within the local optimization of the overall hydroformylation process. However, the resulting surrogate model comprises a large number of relatively complex nonlinear terms, which renders it computationally unfavorable for deterministic global optimization.

To overcome this problem, we present modifications to the surrogate construction aimed at reducing the number of nonlinear expressions and thus the computational complexity of the model. Globally optimal solutions of the resulting model are identified using BARON [2].

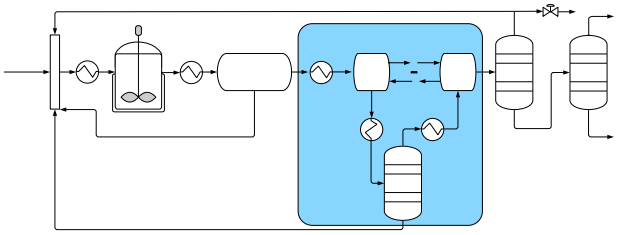

Figure 1. Flowsheet of the hydroformylation process considered in [1]. The highlighted area shows a multistage extraction cascade with solvent recycle.

The following methods are applicable for processes dealing with liquid-liquid-equilibria. However, we focus on a subprocess taken from [1], highlighted in Figure 1, as a case study. Catalyst is recovered from a product stream by an extraction solvent in a series of decanter units in a countercurrent setup. The extraction solvent is regenerated using a distillation column. As in [1], the reference data of the temperature dependent liquid-liquid equilibrium of a four-component mixture and distribution of catalyst between the separate phases is generated using a modified UNIFAC Dortmund model and COSMOtherm. The economic cost function comprises refrigeration, decanter units, catalyst loss, and costs for a short-cut distillation column.

2. Methods and results

A number of methods for data-driven surrogate modeling is available in the literature, see e.g. [3,4] for an overview. Based on testing with various Kriging formulations and artificial neural networks (ANN), an ANN with a single hidden layer and tangent hyperbolic activation function was selected to replace the thermodynamic reference models. The input dimension of the surrogate is reduced in comparison to [1] by choosing the position on the binodal curve as an input instead of the feed composition. This strategy, illustrated in Figure 2, results in an implicit model, but it simplifies the definition and modeling of valid input values. The quality of the ANN is further improved by reducing the range of input values with optimization based bound tightening in a preprocessing step. Error bounds for a least-squares fitted second order polynomial are chosen such that all available data points lie within the relaxed model. The polynomial surrogate model may have larger error bounds than an ANN, but computational effort is significantly lower. BARON is then utilized to calculate tighter bounds on the input variables based on the relaxed model.

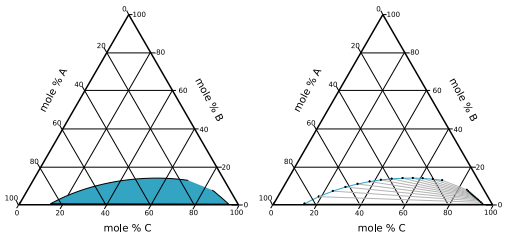

Figure 2. Ternary phase diagram with a two-phase region. Input space highlighted for explicit (left) and implicit (right) model formulation.

These combined methods reduce the computation time and increase the accuracy of global optimization with surrogate models in the considered case study. The global optimization results also verify the findings presented in [1]. Application to other processes will be tested in the future.

Highlights

- Conceptual design of reactive distillation (RD) processes
- Effect of boiling point orders on the applicability of RD
- Evaluation of the applicability of RD to quaternary systems

1. Introduction

Reactive distillation (RD) is an attractive process intensification unit as it offers multiple benefits, such as higher conversion, improved selectivity, energy savings and lower costs [1]. However, the number of its commercial applications was limited by the assessment of RD applicability and operation [2, 3]. To deal with this problem, we proposed a mapping method to comprehend and predict the applicability of RD [4]. The present work employs this method to determine the optimal feed locations of RD columns (lower energy usage) in quaternary systems (A + B ⇄ C +D) with different boiling point (T_b) rankings: 1) group I_p ($T_{b,C} < T_{b,A} < T_{b,B} < T_{b,D}$), 2) group III_p ($T_{b,C} < T_{b,A} < T_{b,D} < T_{b,B}$), and 3) group III_r ($T_{b,A} < T_{b,C} < T_{b,B} < T_{b,D}$). The group's naming convention follows the rules as set by Luyben and Yu [5]. Other boiling point rankings are not considered because they are not promising for the application of a single RD column [6]. To the best of our knowledge, this is the first study that provides essential insights into the optimal feed locations of RD considering the effect given by the boiling point rankings.

2. Methods

The main feature of the mapping method is the applicability graphs plotting the reflux ratio (RR) vs number of theoretical stages (NTS). They are produced from generic reactions under assumptions of ideal thermodynamics and constant key parameters, i.e. relative volatilities (α) and chemical equilibrium constant (K_{eq}). The lowest RR possible for each NTS forms a boundary line in each graph that splits applicable and not-applicable areas. To construct an applicability graph, the numbers of rectifying, reactive and stripping stages of any RD configurations are varied, while the feed locations of each reactant are always fixed at both end-sides of reactive zone. Afterwards, a representation of RD with the lowest RR and $NTS=2 \cdot NTS_{min}$ is selected and its feed locations are optimized to further reduce the reflux ratio (lowering energy requirement). All simulations in this work are carried out with Aspen Plus v8.6 software.

3. Results and discussion

Figure 1 depicts reflux ratios based on varied feed stages of both reactants. The optimization of feed locations decreases RRs by 15% in group I_p, 37% in group III_p and 23% in groups III_r. In group I_p, positioning both feed inlets close to the centre of the reactive zone is favorable. In group III_p, lower RRs are achieved by placing the feed inlets at the top of the reactive section. In contrast, for group III_r, it is more beneficial to set the feed stages at the bottom of the reactive zone.

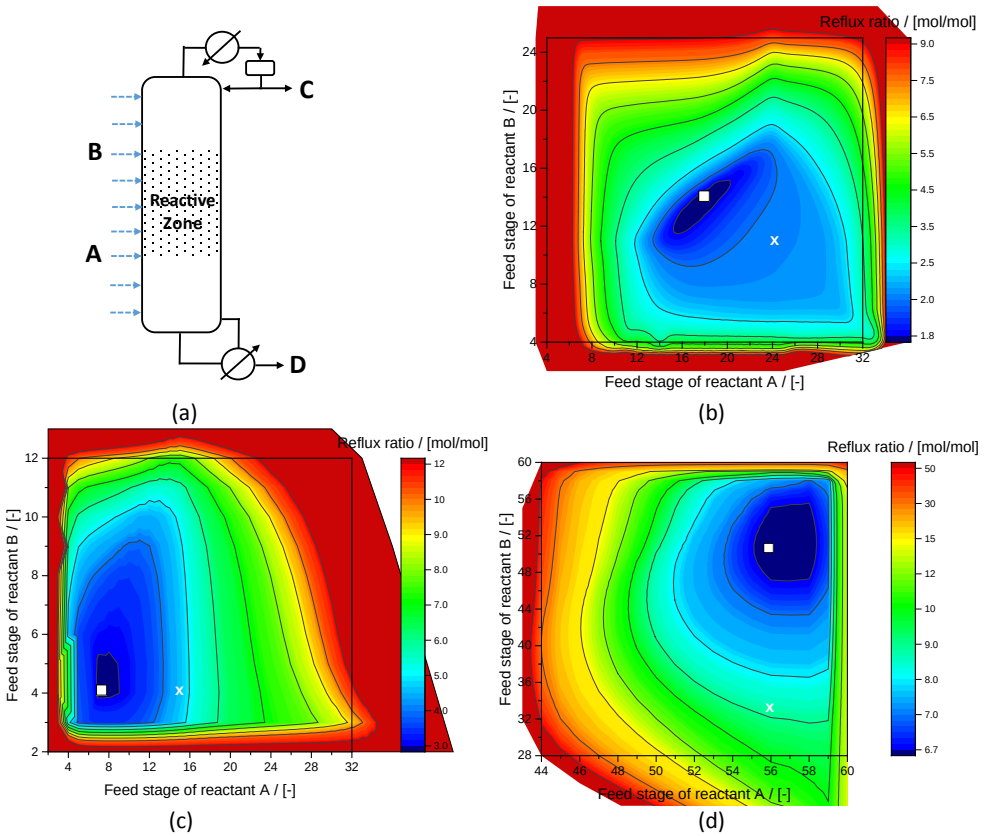

Figure 1. RD setup with varied feed locations (a). Contour plots of RRs in (b) group I_p, (c) group III_p and (d) group III_r with α_{AB}=2, α_{CD}=6 and K_{eq}=1. Cross and square marks indicate the feed locations before and after the optimization [7].

4. Conclusions

The boiling point rankings determine the location of the optimal feed stages of RD columns. The findings in this work suggest that positioning the feed inlets close to each other improves the RD performance (lowering reflux ratios), but placing both reactants at the same stage results in a competition between reaction and separation, which hinders an effective RD process.

Highlights

- First systematic and critical comparison of process synthesis strategies
- Rigorous coupling of module simulation and optimization is key
- Novel process designs are identified through process synthesis
- Guidelines for selection of the best process synthesis approach are proposed

1. Introduction

In the field of process synthesis (or process design), various methods have been proposed to select a set of equipment with their operational conditions and their interconnection in a process flowsheet. These methods may vary from empirical approaches (where the "process designer" proposes an architecture based on his/her expertise or using hierarchical decomposition methods and then uses a simulation tool to validate the proposed design by means of sensitivity analysis) to optimization-based approaches (where the process synthesis problem is posed as a mathematical problem) [1].

In this paper, it is proposed to compare several methods from the field of Process System Engineering (PSE) on a common process synthesis problem.

2. Methods

Three methods, developed by the paper's authors, are selected for the comparison (see Table 1).

Table 1. Process synthesis approaches and mathematical formulation chosen in this paper.

SYNTHESIS APPROACH	MATHEMATICAL FORMULATION	SOFTWARE TOOL	REF.
Superstructure-based	Global optimization NLP	AMPL + Knitro	[2]
Superstructure-based	MINLP solved by Ant Colony Optimization	Prosim + MIDACO	[3]
Ab-initio (no superstructure)	Evolutionary Programming	Dedicated	[4]

These approaches differs in the synthesis approaches (based or not on a superstructure, i.e. a virtual process including various structural alternatives) and mathematical formulations used to solved the optimization problem.

The comparison procedure is summarized as follows:

- Definition of the synthesis problem (all): available components, unit operations, associated degrees of freedom and their range, objectives and constraints.
- Problem formulation (approach-specific) to fit the method's requirements.
- Calibration (all): check that the physico-chemical models for unit operation and process simulation give the same results by performing parametric screening (crucial step).

- Optimization (approach-specific): run each algorithm and isolate optimal solutions.
- Validation (all): simulation of the optimal solutions within a process simulator.

The results can be then compared on the basis of various criteria such as: best solutions, exclusivity of solutions (process structure and parameters), computational time, ease of use for a process engineer, etc.

3. Case study: O_2/N_2 separation

A case study of N_2 production from air using membranes is chosen for the comparison. Results are analysed from both structural (number of stages and recycles) and design/operational parameters (membrane surfaces, pressure ratio) points of view. The design is performed using an economic objective function considering capital costs (turbomachineries, membranes, heat exchanger) and operational and maintenance costs (energy, membrane replacement, operation), together with technological constraints and minimal levels of purity for produced N_2 from 90% up to 99.9%.

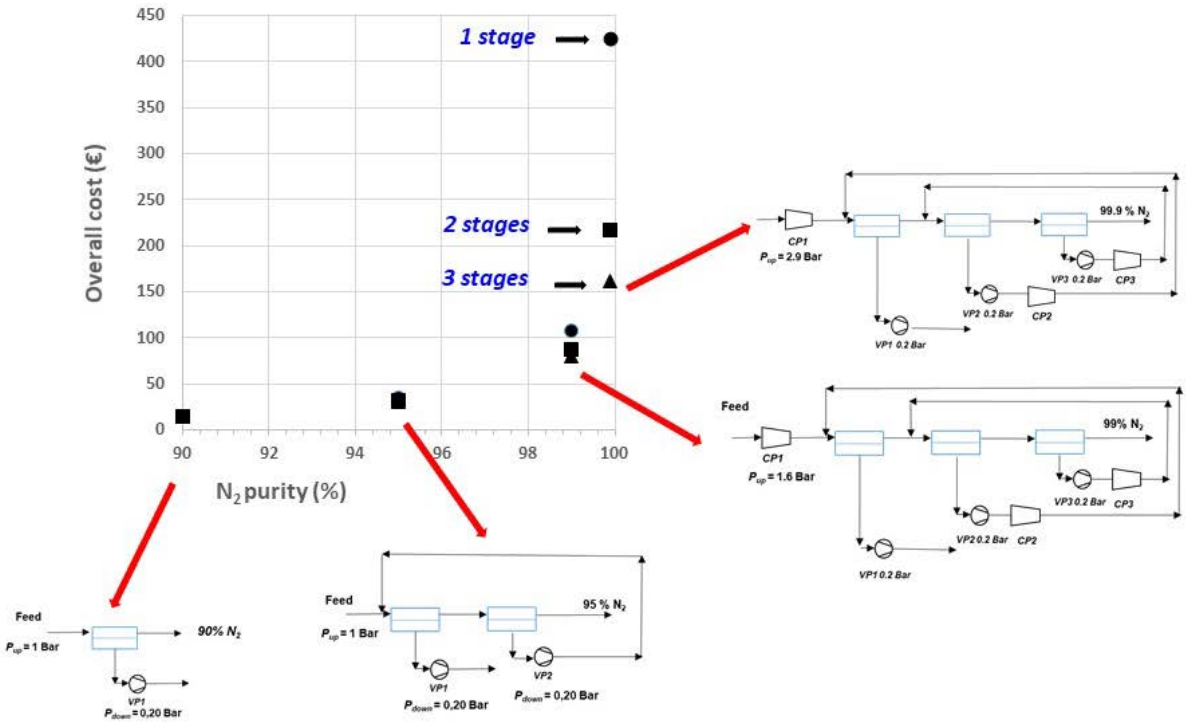

Figure 1. Example of configurations for O_2/N_2 separation for several recoveries and purities [2].

Comparison of sequential and simultaneous draining in periodic cycled separation columns

Jess Rasmussen, Seyed Mansouri, Jens Abildskov, Jakob Huusom*

PROSYS, Department of Chemical and Biochemical Engineering, Technical University of Denmark, Søltofts Plads, Building 229, 2800 Kgs. Lyngby, Denmark

Highlights

- Development of models for sequential and simultaneous drained cyclic distillation
- Comparison of tray efficiency for different draining methods
- Comparison of developed models with theoretical expectations

1. Introduction

Periodic (or cyclic) distillation is an intensified distillation process first proposed in the 1960's [1], where the liquid and the vapor phase flows are divided in two separate periods [2,3]. The two periods are a vapor flow period (VFP) and a liquid flow period (LFP). During the VFP, the liquid holdup(s) on the trays are in fixed positions, while vapor flows through the column. During the LFP, the liquid is drained from one tray to the tray below, followed by a new VFP and so forth. By operating a distillation in cyclic mode, the separation efficiency has been shown to be higher than for conventional distillation [3]. When replacing a conventional distillation column with a cyclic distillation column, a smaller column with fewer trays is needed for the same separation [1]. Depending upon the design, energy consumption may also be reduced. This expands the range of options for designs [2,3].

The theory of cyclic distillation was developed during the 20th century. However, industrial applications are only slowly coming along [3]. A serious problem with the first generation of realizations was the need for improved liquid flow control. This problem was solved in different ways during the 1980s. In recent years, new trays [4] have made it possible to operate any size column in periodic mode and thus making cyclic distillation feasible in large scale. With this tray design there is still an issue regarding the need for interrupting the vapor flow during LFPs. This can cause significant pressure dynamics. An alternative tray design has been developed that implies draining of the trays occur sequentially instead of simultaneously [5].

The currently available models are relatively simple. These models are often based on mass balances and neglect effects of pressure drop, energy transfer and variations of the point efficiency. Furthermore, it is only the more recent models that allows multi-component mixtures and non-linear phase equilibrium. In addition to this, (nearly) all existing models address simultaneous draining, which means there is a need for models that describes the sequential draining for comparison

2. Methods

Simple linear phase equilibrium models for binary mixtures are developed for both the sequential and the simultaneous draining method. These simple models are suitable for describing stripping, absorption and high-purity distillation and are convenient for analysis.

With the developed models, the efficiencies for the two draining methods are compared to each other and to theoretical expectations.

3. Results and discussion

With the developed models, the two draining methods presented for cyclic distillation have been compared to each other and theory. There are currently no comparisons available in the literature. The comparisons are focused on the tray and the overall separation efficiencies.

The difference in draining methods is expected to have an effect on the separation efficiency. When a column is drained sequentially, there is an empty tray at greater fractions of time. This will affect the overall tray efficiency. On the other hand, the rest of the trays still undergo VFP when another tray is being drained, which could be an advantage. Our analysis will investigate these conflicting effects.

4. Conclusions

Cyclic distillation is an intensified process that increases the separation efficiency compared to conventional distillation. There are two liquid draining methods available, sequential and simultaneous draining, which each have its own advantages and disadvantages. Simple models have been developed to describe a cyclic distillation process with either sequential or simultaneous draining. The developed models for the two draining methods are compared to each other and to the theoretical expectations.

Highlights

- Global optimization using Aspen Plus flowsheet simulations
- Memetic algorithm
- Flexible customizable cost function
- Reduction of the total cost compared to expert solution

1. Introduction

The decisions taken during process development are critical for the economic success of process engineering projects. The design engineer needs to screen, develop and evaluate a large number of process alternatives. Even when sophisticated software tools are applied for modelling and analysis, iteratively carrying out the design usually requires month to years. Due to the strong involvement of human work force, high personnel costs are incurred and the results depend on the experience of the developers. Obviously, also the risk of human errors e.g. by prematurely ruling out alternative solutions is always present.

Marking a breakthrough in boosting the efficiency of process development a novel process optimization tool has been established in a joint project between divis, SUPREN and TU Dortmund. Starting from an existing simulation flowsheet that was created by a design engineer, a memetic algorithm is applied to investigate, globally optimize and assess alternative process configurations and conditions in an automated fashion. The tool supplements the process understanding and creativity of an engineer with the reliability and efficiency of optimization. Replacing human labor by computations, the repetitive work in the course of process development is accelerated while the related costs decrease.

2. Methods

This contribution presents the results of the application of our computer-aided optimization procedure to the production of methyl tert-butyl ether (MTBE) (world production volume 18 Mtons/year in 2005) that is inspired by the Oxeno-technology [1]. A memetic algorithm is applied because of its capabilities to act as a global solver and to handle integer design variables. The memetic algorithm used combines an evolutionary algorithm, e.g. an evolution strategy (ES), with a local solver. At the beginning of the optimization procedure the ES gen erates a population (a set of individuals) with integer design variables and continuous operation parameters within given bounds. For this first population, using the widely used simulation tool Aspen Plus, process

simulations are performed. The results are evaluated automatically with regard to customizable – often economic – objective functions. Based on the results of the ES, the memetic algorithm generates new individuals (offspring) by the recombination and mutation of two of the afore-investigated individuals. This procedure is repeated until the convergence criteria are met. [2]

The optimization problem discussed includes 22 continuous and 7 integer design variables and 3 process constraints. Based upon objective functions that are available in the library of the tool along with problem-specific information, the economics of the process alternatives are assessed.

3. Results and discussion

Commencing from a previously optimized solution created by an experienced engineer for an industrial client, the optimizer achieves a further improvement of 1.2% of the overall costs. Exploiting the simulation file present from the manual investigation, about 2 hours of time are needed to define the optimization problem. Afterwards, without interaction with an expensive design engineer, 3 days of computation time are required to reach the results presented in Figure 1. Multiple runs of the stochastic optimization establish the uniqueness of the result.

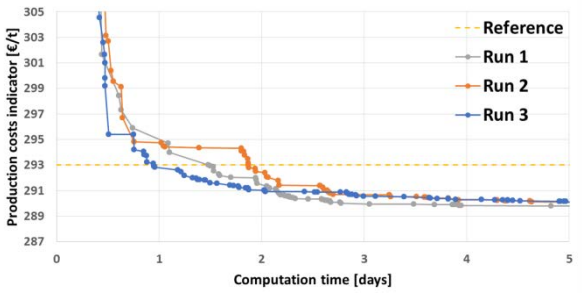

Figure 1: Improvements of the economic cost function with the expert solution as reference.

Due to the use of a commercial simulation environment the required computation time is high, but the advantage is the flexibility of the approach. Changes to the flowsheet such as the introduction of additional process equipment can be performed easily and fast. For the current case, modifications of the model were tested and realized in timespans of well under 30 minutes of human work and 3 days of calculation time. Thanks to a fully automated documentation, the results of the optimization run are summarized in the form of easily accessible spreadsheets and the corresponding Aspen simulation files are stored. Based on this information, each individual solution or the optimization run can be analyzed in detail with regard to the identified operation and design parameters as well as to the objective functions.

4. Conclusions

The presented approach is capable of enhancing the process development workflow using the reliable and efficient memetic algorithm in combination with the creativity and knowledge of the process engineer. Due to the use of a commercially available simulation tool, industrially trusted results are generated. In summary, the application of the tool leads to overall better process designs involving the engineer primarily in the creative development process rather than in repetitive and tedious elements of the workflow.

Highlights

- Under perturbated conditions the flexibility analysis assesses the system performance.
- The price of an higher flexibility is a system oversizing.
- The total cost vs flexibility trend helps the engineer decision making.

1. Introduction

In process engineering the leading separation process is distillation. The standard procedure for distillation columns design is based on the economic and operational aspects. However, this optimal design is strictly related to the operating conditions, i.e. perturbations, when present, can seriously turn the tables.

Flexibility analysis is an important part of process design seldom included in the standard procedure. Even if sometimes a sensitivity analysis is performed afterwards, there are some differences between the two that can't be neglected.

The flexibility, for a chemical plant, is defined as the ability of the system to cope with any change of the operating conditions. To achieve higher values of flexibility it is necessary to perform a structured analysis. The analysis can be applied to existing plants and to plants in the design phase [1]. These higher values guarantee a reduction of the risk of money losses and of the stand-by period.

2. Methods

From the available literature about this topic it is clear that the flexibility analysis has been deeply studied and well defined as well as the resulting economic considerations.

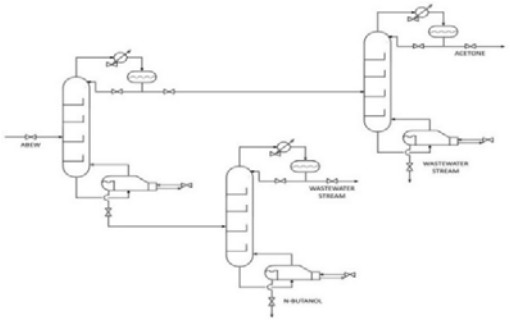

Figure 1: Distillation columns in a midsplit configuration

The mathematical procedure used to assess the flexibility of the selected case study system is the one developed by Saboo and Morari [2], i.e. the Resilience Index (RI). It is assessed by calculating the largest total disturbance load, independent from the direction of disturbance, a system is able to withstand without becoming unfeasible. The RI is then defined as the lowest of the aforementioned withstood perturbations so that every parameter value can change within the +/- RI range without compromising the system operation. This index has been applied to a complex system made of three distillation columns in a midsplit configuration, used to separate a water, ethanol, n-butanol and acetone mixture. Figure 1 shows the system under study.

3. Results and discussion

The flexibility analysis has been carried out and the maximum withstood load for each variable has been assessed. The most constraining parameters result to be water (8%) and butanol (13%), while ethanol and acetone flexibility limits can be neglected, since they are 32% and 45%. The price for a higher flexibility is linked to a system oversizing (column diameter, condenser and reboiler exchanger surface). The economic assessment has been performed and the corresponding total cost vs flexibility trend is plotted in Figure 2 as suggested by Di Pretoro et al (2019) [3].

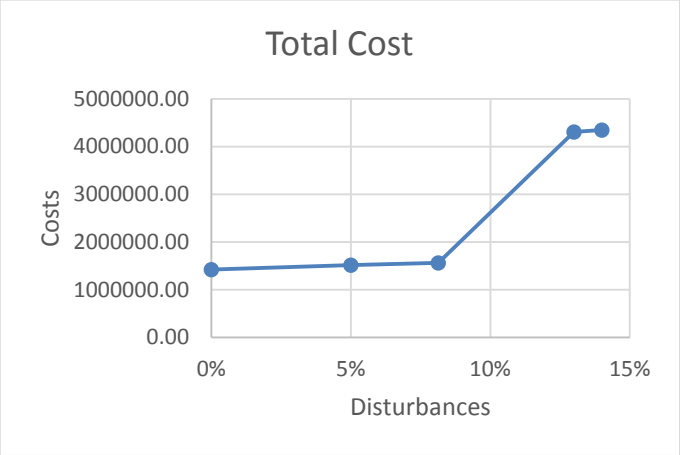

Figure 2. Total Cost

4. Conclusions

The article shows that an a priori flexibility analysis can lead the designer engineer to the optimal compromise between a flexible plant and an affordable investment.

Highlights

- Evaluation of energy consumption of hybrid membrane separation-distillation processes
- Energy consumption of the hybrid process is 83% less than that of distillation process
- Capital cost divided by the payback time of membrane separation unit was estimated

1. Introduction

Energy-saving of separation process is a problem in order to reduce greenhouse gas emission, because the separation process accounts for about half of the energy consumption in the chemical industry [1]. In the chemical industry, diversification of raw materials is proceeding. An as example, in propylene production, the propylene content in the mixture fed to the propylene purification column is 98% for the ethylene center, whereas it is 90% for the propane dehydration process. Although distillation is widely used for these separations, reduction of the propylene content leads to increase of energy consumption. Therefore, it is necessary to develop an alternative energy-efficiency separation process. As an energy-efficiency separation process, membrane separation has attracted attention [1]. However, since membrane separation is not suitable for high throughput, it is difficult to replace the distillation process of propylene separation with membrane separation. To solve this problem, there is hybridization of membrane separation and distillation as one of the candidates. In the design of hybrid process, it is necessary not only to clarify the configuration that can reduce the energy consumption but also to achieve cost reduction. This study clarifies the influence of the configuration of the hybrid process on energy consumption for separation of propylene/propane mixture and discusses the cost of the separation membrane unit.

2. Simulation model

For a case study, the propylene content in the feed was set as 90 mol%, and the feed flow rate was constant at 1433 kmol/h. As the product specifications, the propylene content was 99.5 mol%, and the recovery ratio of propylene was 99.5%. The thermodynamic properties were estimated using the Peng-Robinson model. **Figure 1** shows the schematic diagrams of hybrid membrane separation-distillation processes. The hybrid process consists of one distillation column and one membrane separation unit. The stage numbers of the distillation column was fixed at 230 stages. The pressure of the distillation column was 2040 kPa. As membrane separation performances, the propylene

permeability was 1×10^{-6} mol/($m^2 \cdot s \cdot Pa$), and the propylene selectivity was 100. The pressures of permeate and feed side were 2040 and 200 kPa. All simulation were performed by Pro/II (ver. 9.4).

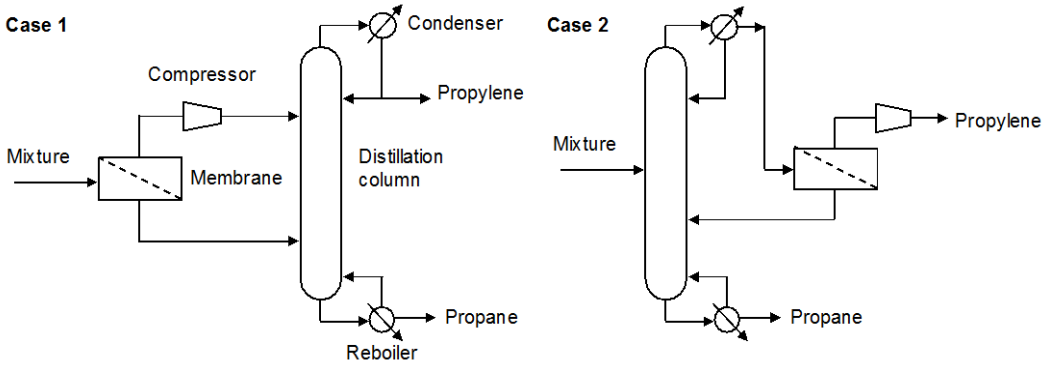

Figure 1. Schematic diagrams of hybrid membrane separation-distillation processes.

3. Results and discussion

The energy consumptions including duties of reboiler and compressor of Case 1 and 2 were minimized when the membrane areas were 355 and 413 m^2, respectively. The energy consumption of Case 1 and Case 2 were 50.5 and 48.1 GJ/h. There results correspond to energy saving of approximately 82 and 83% compared to the distillation process. Based on the results, this study estimated the cost reduction by reducing energy consumption. Here, the costs of the steam and the electricity was assumed to be 13.28 and 16.8 $/GJ [2]. The operating time per year was set to be 8322 hours [2]. As a result, the annual operating costs for the distillation process, Case 1 and 2 were 3.09×10^7, 6.12×10^6, and 5.87×10^6 $, respectively. If the difference of operating cost between the distillation and the hybrid process is greater than the equipment cost divided by the payback time, total annual cost (TAC) of the hybrid process is reduced. Therefore, the upper limit of the equipment cost divided by payback time for Case 1 and 2 are 2.48×10^7 and 2.50×10^7 $.

4. Conclusions

This study evaluated the energy consumptions for the hybrid processes of Case 1 and 2, and found that energy savings of 82 and 83% can be achieved in Case 1 and 2, respectively. Based on the results, this study estimated the upper limit of the equipment cost divided by the payback time of the membrane separation unit.

Highlights

- Microemulsion systems as enabler for homogeneous catalysis of long-chained substrates
- Soft sensor implementation to access immeasurable states
- Long-term mini-plant operation
- Moving horizon state estimation and dynamic optimization

1. Introduction

Homogeneous catalysis provides highly desirable reaction performance features, such as high chemo- and regio-selectivities and is thus widely applied in process industry[1]. To allow for recycling, applied valuable catalysts are often reallocated to an aqueous phase via ligand modification. However, for the conversion of long-chained substrates this triggers contradicting design features of the reaction system. On the one hand, perfect miscibility of substrate and catalyst phase is required for the reaction. On the other hand, perfect separability for downstreaming and catalyst recycling is desired. To this end, surfactant containing multiphase system can be applied to overcome this hurdle. Surfactants are used as phase transfer agents to enable efficient conversion of nonpolar substrates. Moreover, the specific phase separation behavior of these microemulsion systems can be exploited for catalyst recovery and product separation. Due to their complexity, such novel process concepts pose a variety of operational challenges and reliable plant operation is only possible by applying model-based advanced process control. Especially for microemulsion systems, profound theoretical descriptions are absent and thus a detailed experimental investigation is inevitable to obtain suitable models to aid process operation. Regarding this, we present a systematic approach for the efficient identification and operability analysis of such systems to enable the fast track development of semi-empiric models to be used in process control.

2. Methods

As a case study, the hydroformylation of 1-dodecene in a microemulsion system formed with an aliphatic nonionic surfactant is applied and tested in a fully automatized mini-plant, holding a high-pressure reactor-settler setup and 3 individual recycles[2]. The systematic system identification and analysis firstly focusses on the reaction itself. Here, a mechanistic microkinetic model is adapted regarding relevant influences of the component system on reaction performance. Secondly, the dynamic phase separation behavior of the microemulsion is systematically studied to identify the relevant set of influencing factors and suitable operation regions for plant operation. Additionally, the controllability of the system regarding monitoring of relevant states is analyzed. From this, an

updated experimental series is conducted gaining the relevant results for the modeling the three phasic separation of the microemulsion system. This information is merged into a fully dynamic mini-plant model and used within optimal control strategies comprising moving horizon state estimation and dynamic real-time optimization.

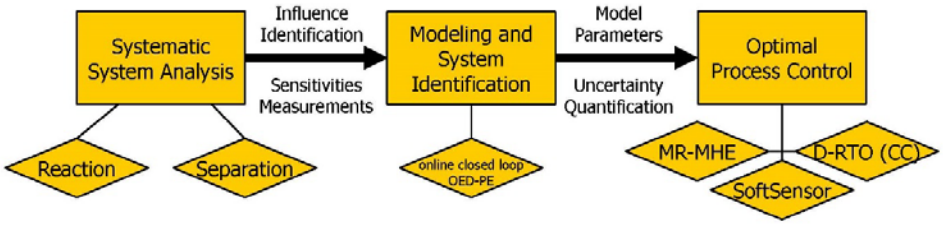

Figure 1. Workflow for systematic system analysis and development of advanced process control strategies for reactions in microemulsion systems

3. Results and Discussion

The systematic system analysis was successfully applied. A new macrokinetic model was derived and parameterized, which is able to describe undesired byproduct formation induced by local concentration changes in the microemulsion system. Furthermore, the analysis of the phase separation system revealed that the surfactant concentration, the most sensitive influence factor on the separation state, is immeasurable and a stable process operation is not possible. To cope with this, a model-bases soft-sensor was developed, which is based on optical observation of the phase evolution in the microemulsion system. The applicability of developed optimal process control strategies was then tested in long-term continuous mini-plant campaigns of up to 200 h. Control of the critical phase separation step was tested for different operation modes and overall good oil phase purities of up to 99,5 % (amount of oily components in the separated oil phase) were observed. The reaction performance was validated against preliminary lab-scale investigations, wherein a product yield of 40 % and an overall selectivity of 95 % were achieved.

4. Conclusions

Within this contribution, a procedure for the systematic system identification and operability analysis of surfactant containing multiphase systems has been proposed. Based on this, semi-empiric models have been formulated to describe the system dynamics and applicable operation regions. Especially, the identification of immeasurable states has been enabled by a model-based soft sensor. From the application of developed models for state estimation and the calculation of plant trajectories from a dynamic optimization a stable mini-plant operation with successful reaction and separation was achieved.

Critical CO_2 Carnot Engine for Industrial Waste Heat Recovery and Utilization

Sarah Makuc[1], Eldred Chimowitz[2]

1,2 University of Rochester Chemical Engineering Department, Rochester, NY

Highlights

- Critical CO_2 Carnot cycle maximizes low-grade heat harnessing and utilization
- Small (~1.5 L) engines can utilize waste heat, generating power
- Increased energy savings, decreased energy bills, and environmental emissions

1. Introduction

Industrial processes regularly discard large volumes of low-grade waste heat to the environment. Harnessing this heat and transforming it into usable power would be environmentally and economically advantageous for industries. An overlooked solution to utilizing this waste heat is the use of a Carnot cycle to generate work with supercritical CO_2 as the working fluid. Supercritical CO_2 is a novel working fluid for a Carnot engine as its critical temperature (31.1°C) is much lower than the boiling point of water. This allows for the lower isotherm of the Carnot cycle to be constructed at the critical temperature, resulting in a sizable Carnot cycle with a near flat lower isotherm and upper isotherm just below the temperature of the low-grade heat. Thus, this type of Carnot cycle encompasses a larger area on a P-V diagram than any other thermodynamic conditions, thereby optimizing the amount of work that can be converted to power using a relatively small engine. We describe this approach of waste heat harnessing and illustrate ideas for utilizing the waste heat from an industrial toluene process. The impact of compression ratio, upper isotherm temperature, and pressure in the engine are investigated. Resulting savings amount to hundreds of thousands of kWh/year, thereby reducing cooler loads, electricity bills, and environmental emissions.

2. Methods

The developed and validated Excel program can analytically calculate the work of the Carnot cycle using the following equations derived from the Van der Waals equation of state and the critical parameters for CO_2. The calculated work is then used to find the size/frequency of an engine necessary to harness all of the available work and transform it to usable power.

$$Q_H = \int_{V_1}^{V_B} \frac{RT_H}{V-b} = RT_H ln(\frac{V_B - 1}{V_1 - b}) \text{ where } b = \frac{1}{8}\frac{RT_c}{P_c} \quad \textbf{Equation 1}$$

$$W = Q_H(1 - \frac{T_C}{T_H}) \quad \textbf{Equation 2}$$

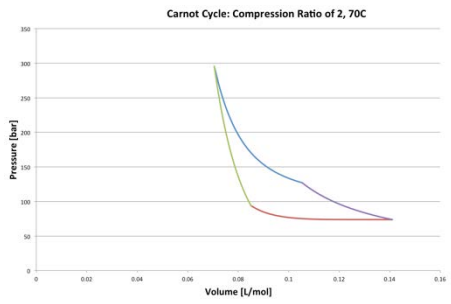

Figure 1. Typical Carnot Cycle Program Output

Required program inputs include cooler size, isotherm temperatures, compression ratio, frequency, and starting volume. Outputs include work available, engine size,

pressure, and, if applicable, the necessary cooler size still required. An alternative program takes in the engine size and outputs the required frequency. Reversible adiabatic and isothermal steps have been assumed.

3. Results and discussion

Program outputs for specific examples found in the disproportionation of toluene process indicate a large potential for utilizing waste heat. With a decrease in upper isotherm temperature, the work available, and thus power, increases and engine size decreases, but the analogous increase in pressure is a limiting factor. With the increase in engine size, the required frequency of the engine, measured in Hertz, decreases. Process specific findings include the ability to harness 135.49kW from one stream in the toluene process, cooling it roughly 39°C. This leads to a net annual production of 975,528 kWh of energy, amounting to over $50,000/year in cost savings.

Upper Isotherm (°C)	Work (J/mol)	Power (kW/mol)	Maximum Volume (L/mol)	Engine Size (L)	Pressure (bar)
60	224.14	11.21	0.141	2.01	266
70	264.00	13.20	0.141	1.45	296
100	270.56	13.53	0.141	0.644	386

Table 1. Data for a 135.48 kW Power Production.

Electricity Source	Price [*U.S. EIA estimates]	Cost Savings per Year ($)
U.S. National Average	$0.0724/kWh	70,628
Conventional Coal	$98.7/MWh	96,285
Biomass	$95.3/MWh	92,968
Onshore Wind	$48/MWh	46,825
Solar Thermal	$126.6/MWh	123,502

Table 2. Annual Energy Savings from a 135.49 kW Engine

4. Conclusions

It is found that with a relatively small engine and frequency, on the order of 1.5 L and 50 Hz, moderate upper isotherm temperature, and a compression ratio of 2, almost 1 million kWh can be saved each year from the integration of a single Carnot cycle into the disproportionation of toluene process. Considering various electricity sources, the production of 1 million kWh of electricity can save the industrial plant over $50,000/year and decrease environmental emissions. Carnot cycles therefore represent an underutilized resource to harness low grade waste heat present in numerous industrial processes.

Highlights

- Circular Economy (CE) can be a solution to resource degradation and scarcity.
- To achieve CE a system's engineering approach is needed for optimal decision making.
- A system's engineering framework towards CE is developed and presented.
- Case studies indicate that the approach can supply optimal solutions towards a CE.

1. Introduction

Natural resources play a critical role in the development and wealth of societies. They are vital for the provision of energy, food, shelter, transport and all basic functions of our societies. Population growth, welfare growth and the constant need of an increasing standard of living, means that more natural resources are used, leading to resource degradation, increased landfill wastes caused be the increased consumption, and negative environmental impact caused by the production and consumption of resources.

Circular Economy (CE) can be a solution to this resource challenge. CE is an economy that is restorative and regenerative by design and aims to keep products, components, and materials at their highest utility and value at all times [1]. CE operates at three levels, the micro level (products, companies, consumers), meso level (eco-industrial parks) and macro level (city, region, nation and beyond) [2]. To achieve such an economy, four actions have been suggested: reuse, repair, remanufacturing, and recycling (Figure 1) [3, 4]. These actions close loops and connect different stages of the supply chain of a product that in a linear economy are discreate. These interconnections along with the players and stakeholders connected with them make decision making for CE supply chains very challenging. A holistic systems engineering approach is thus clearly needed to navigate the multi-scale, multi-faceted and interconnected CE supply chain, identify opportunities for synergistic benefits and systematically explore interactions and trade-offs.

2. Methods

We present the foundations of a systems engineering framework and quantitative decision-making tools for the analysis and trade-off optimization of interconnected resource networks to achieve a CE. The framework combines data analytics and mixed-integer modelling and optimization methods to establish (i) the interconnections between different stages of the supply chain, (ii) the potentially

competing interests amongst various stakeholders, and (iii) policy, regulation and societal issues. A multi-objective optimization strategy is followed for the analysis of the trade-offs empowered by the introduction of composite metrics for CE that include waste, energy and resource use minimization, as means to facilitate decision making and compare alternative process and technological options. The versatility, potential and applicability of the proposed framework will be demonstrated through a case study on the supply chains of coffee [6].

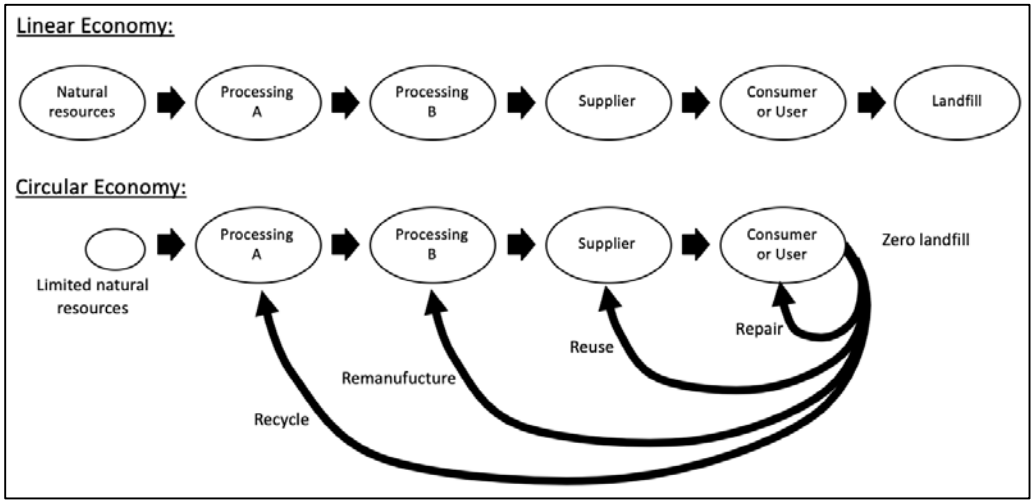

Figure 1. Linear and Circular Supply Chain

3. Results and discussion

Computational results of the two case studies indicate that the proposed approach is capable of supplying the decision makers with different optimal trade-off solutions and pathways towards a CE supply chain.

4. Conclusions

CE supply chain systems call for a systematic methodology that considers conflicting objectives, multiple scales and stakeholders for optimal decision making. This work presents a system's engineering framework for the analysis and trade-off optimization of supply chains towards a CE.

Green Solvent Selection and Early Stage Process Design for the Homogeneously Catalyzed Reductive Amination of Long-chain Aldehydes

Steffen Linke[1,*], Kevin McBride[2], Karsten Hans Georg Rätze[1] Kai Sundmacher[1,2]

1 Otto-von-Guericke University Magdeburg, Chair for Process Systems Engineering, Universitätsplatz 2, 39106 Magdeburg, Germany; 2 Max Planck Institute for Dynamics of Complex Technical Systems, Process Systems Engineering, Sandtorstraße 1, 39106 Magdeburg, Germany

**Corresponding author: linke@mpi-magdeburg.mpg.de*

Highlights

- Integrated computer-aided solvent selection and process design.
- Performance evaluation in terms of thermodynamic and environmental criteria.
- Application of the methodology to a challenging, complex reaction.

1. Introduction

One of the major challenges facing chemical engineering today is the transition from fossil-based resources towards renewable alternatives. In pursuit of this goal, difficulties arise connected to the conversion of biomass into useful substrates. Not only this, but there are additional questions regarding how to efficiently use the long chained molecules gained from such biomass conversions [1]. This leads to the need for new process concepts. One such promising approach for the functionalization of long chained molecules is homogeneous catalysis. The use of homogeneous catalysts enables mild reaction conditions, higher selectivities with respect to the target products, and high reaction rates. However, the most critical step in homogenously catalyzed processes is usually the recovery of the often expensive transition metal catalysts (e.g. Rhodium). Liquid extraction can efficiently solve this separation problem using a suitable solvent as extraction agent [2]. In most cases, the choice of the solvent is made on the basis on expert's knowledge and predictive tools, like the Hansen parameters or COSMO-RS that explore the direct functionality of the solvent without consideration of the efficiency of the entire process.

In this work, we present a new approach to compare systematically the performance of different solvents – determined by computer-aided solvent screening – on the process level, and exemplify it for the reductive amination of long chained aldehydes [3]. Besides thermodynamic properties, our approach includes environmental, health and safety criteria (EHS) in order to select a green solvent, and it estimates the technological-economic process performance of green solvents.

2. Methods

For the generation of possible solvent candidates, screening of approx. 7800 molecules using COSMO-RS was performed, thereby taking into account the boiling point, the solubility of the Rhodium-based catalyst and the size of the liquid-liquid miscibility gap wherein liquid-liquid extraction of the catalyst can be performed. For the evaluation of the EHS criteria, we took various QSAR models found in the VEGA toolbox [4] and created from these several ensemble models to

represent each predicted characteristic. Finally, the ensemble model results were compressed into a single, overall green solvent index in order to efficiently rank solvents. EHS end-points considered are carcinogenicity, mutagenicity, fish toxicity, biodegradability, persistence, among others. After identifying a set of suitable solvents, process design based around these candidate solvents is performed. The separation task is defined by the composition formed after the reaction; there may be one or two liquid phases depending on the solvent used in the reaction. For the downstream process, we consider liquid-liquid and vapor-liquid separations. The split factor for each separation step is calculated with COSMO-RS due to the lack of experimental data at this design stage.

3. Results and discussion

In figure 1, the general design methodology is illustrated starting with the thermodynamic and EHS solvent screening, and ending with the process design.

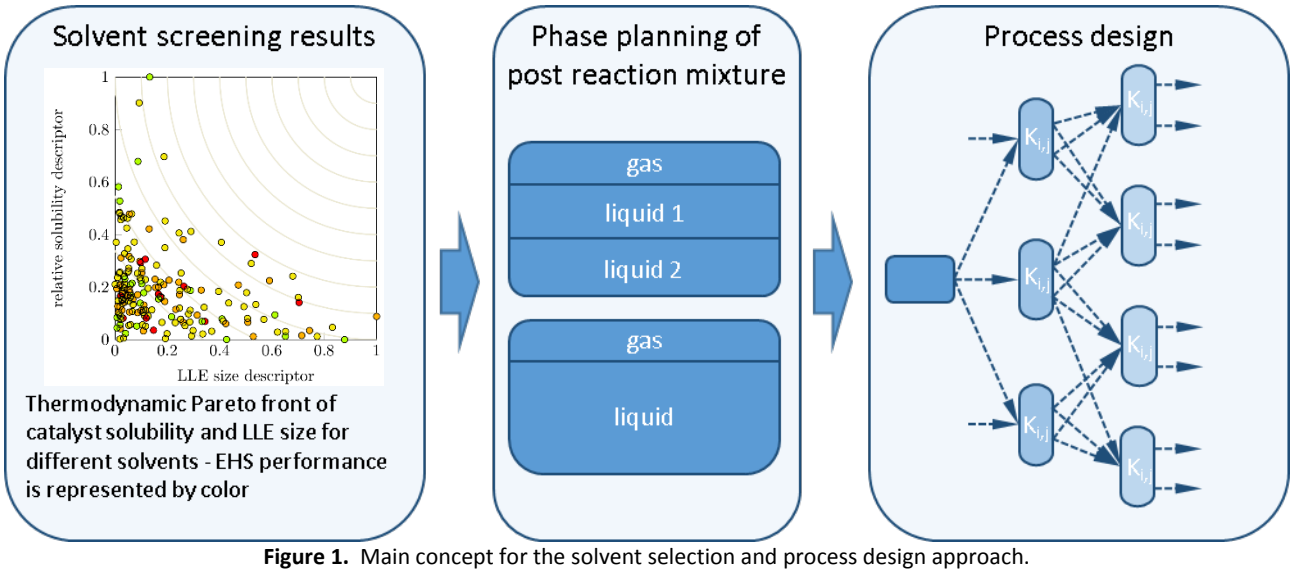

Figure 1. Main concept for the solvent selection and process design approach.

4. Conclusions

We present a combined solvent-process design approach for homogeneously catalyzed reactions and discuss the benefit of early stage process design compared to simple solvent screening methodologies. Simultaneously, the performance potential of green solvents is evaluated.

Multi-step Automated Heat Exchanger Network Retrofit Planning

Timothy G. Walmsley[1], Nathan Lal[2], Petar S. Varbanov[1], Jiří J. Klemeš[1]

1 Sustainable Process Integration Laboratory – SPIL, NETME Centre, Faculty of Mechanical Engineering, Brno University of Technology, Brno, Czech Republic; 2 Energy Research Group, School of Engineering, University of Waikato, Hamilton, New Zealand

**Corresponding author: walmsley@fme.vutbr.cz*

Highlights

- Heat Exchanger Network retrofitting is becoming increasingly more urgent
- The Automated Retrofit Targeting algorithm is further developed
- A petrochemical example is analysed, developing many retrofit investment plans
- The best three-step retrofit option saved 7.3 MW with a profit of 1.3 M EUR/y

1. Introduction

Ever-rising energy costs and environmental concern drives a cycle of continuous process energy improvement in the chemical and process industries. To remain competitive, industrial companies and sites need to retrofit and revamp their technology to keep pace with more energy-efficient new plants. Such options include disruptive projects – e.g. new reactor installation – and incremental improvement – e.g. new heat exchangers [1]. Due to the capital intensity of disruptive change, most companies favour incremental, low-risk retrofit. Recent efforts have focused on graphical retrofit techniques based on individual process stream mapping [2] and the Energy Transfer Diagram [3] as well as mathematical optimization techniques [4].

This paper presents an extension to the recently developed Automated Retrofit Targeting – ART algorithm [5]. A unique feature of the algorithm is the comprehensive search function that systematically looks at all practicable pathways for energy retrofits. This algorithm is now extended in this work to a multi-step approach, exponentially increasing the number of retrofit options while providing a long-term investment guide for energy projects. To help counteract the increase in complexity, the extended ART determines the Pareto optimal solutions, together with logical and thermodynamic constraints [6], reducing the search space to a manageable size.

2. Methods

The ART algorithm was previously developed and explained by Walmsley et al. [5] and further refined by Lal et al. [6]. To main brevity, please refer to these works for method details. Two changes are proposed in this work. First, the extension implements an outer iterative loop to obtain multi-step retrofit solution, detailing the retrofit action required at each step. Second, the extension finds the Pareto optimal solutions using

$$\max \quad \left\{ k\frac{Q_i}{Q_{max}} + j\frac{(Q/A)_i}{(Q/A)_{max}} + (1-j-k)\frac{(Q/n)_i}{(Q/n)_{max}} \right\}, \quad 0 \le j \le 1, \quad 0 \le k \le 1, \quad j+k \le 1 \tag{1}$$

by varying values of *k* and *j* at steps of 0.1. In Eq. 1, *Q* is the heat savings, *A* is the required new heat transfer area, and *n* is the number of new heat exchanger units (modifications). The approach intentionally relied on non-economic results that are key dimensions that affect economics.

3. Results and discussion

This work re-examines the petrochemical case study of Walmsley et al. [5]. The number of retrofit "steps" was limited to 3. Figure 1 presents the results with the various colours representing each of the sequential steps with the "best" solution (i.e. the most profitable). The algorithm selected the retrofit option with the shortest payback (1.1 y) as the first step. The 48 possible first retrofit steps are not shown due to provide better clarity. Figure 1A shows the general trend that as successive retrofit steps are taken, the ratio Q/A decreases, i.e. diminishing returns with the additional area.

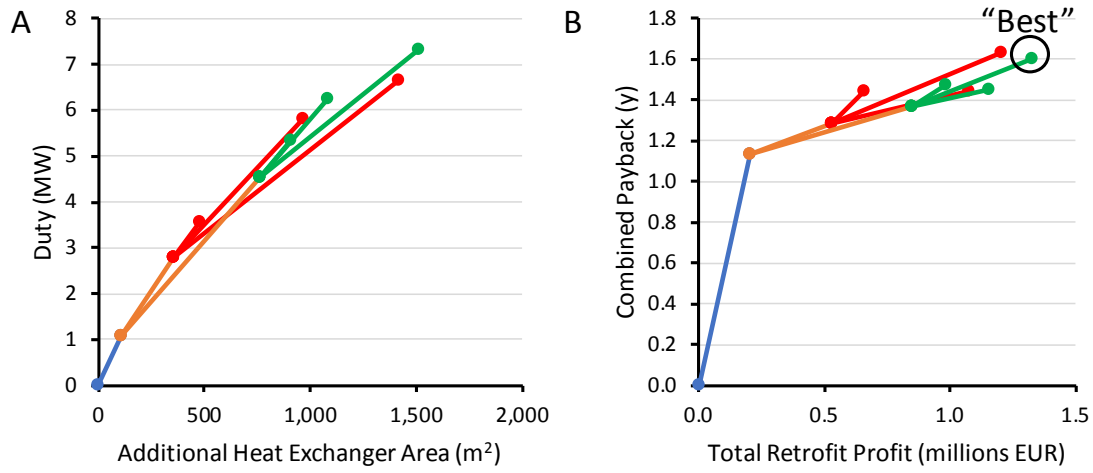

Figure 1. Pareto front of Heat Exchanger Network retrofit options - (A) Trade-off between area and heat recovery duty. (B) Economic performance.

4. Conclusions

The extended multi-step Automated Retrofit Targeting algorithm, combined with the identification of the Pareto front, has enabled a new tool for retrofit investment planning. A petrochemical plant example is solved, providing multiple options for investment in Heat Exchanger Network retrofit with an estimated final profit of 1.3 M EUR/y and a payback of 1.6 y for the best solution. With a heat savings of 7.3 MW, the estimated greenhouse gas emission reduction is 11,800 t/y.

The new Automated Retrofit Targeting algorithm has many facets that will continue to be developed in future work. Some directions include heat pump integration, lifecycle analysis, detailed heat exchanger design, and network simulation.

- The investing in BIGCC is superior to the conventional IGCC power plant.

1. Introduction

Recently, the IGCC power plants were combined with the clean coal technologies which were used to reduce CO_2 emissions and remove other pollutant emissions such as sulfur dioxide (SO_2) and nitrogen oxides (NOx). The oxy-fuel combustion with the aid of the air separation unit (ASU) could effectively reduce NOx and increase the concentration of CO_2 in the flue gas, but the high cost and the high energy penalty of ASU would obviously enhance the levelized cost of electricity (LCOE) [1]. To improve the overall efficiency of the IGCC system, an elevated-pressure ASU had significant potential option [2]. Regarding the reduction of energy penalty of ASU, a new technology based on coal gasification integrated with the syngas chemical looping (SCL) was validated to reduce the energy penalty as well as the capital cost of the cryogenic air separation unit (CASU). This work show a few results (i) a heat-integrated IGCC polygeneration plant using SCL is presented, (ii) the SCL contributes to generate electricity, H_2, and CO_2-rich gas, (iii) the net energy efficiency of the proposed design can achieve about 60% if ASU and CCS are removed, (iv) the BIGCC using 20% biomass in place of coal can reduce the yields of hydrogen and methanol by 8.3% and 10.7%, respectively.

2. Methods

The proposed BIGCC power plant connecting the syngas chemical-looping (SCL) shown in Fig. 1 is carried out the process simulations in the Aspen Plus environment.

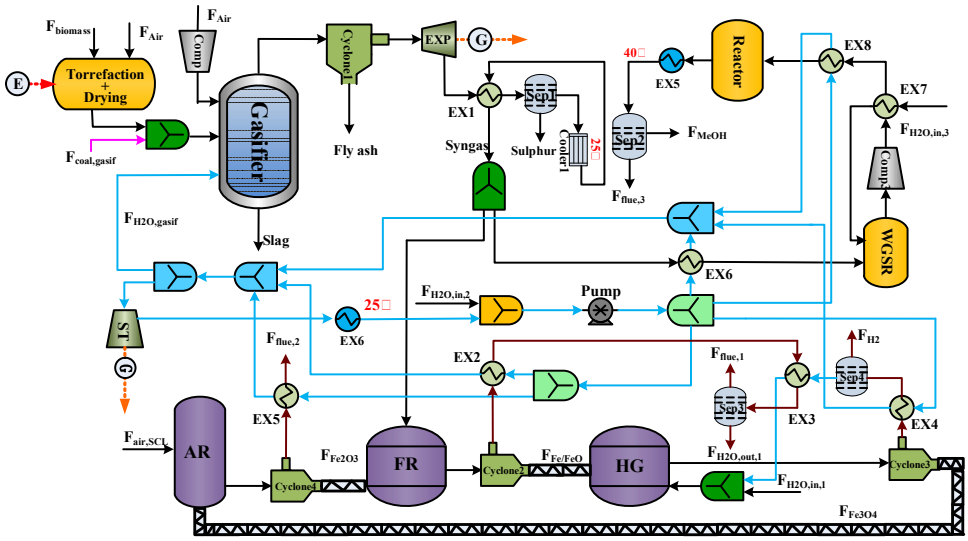

Figure 1. Schematic of BIGCC power plant connecting the syngas chemical-looping (SCL)

3. Results and discussion

This study is emphasized on the reactor design in the chemical looping, where the fast fluidized bed reactor and the moving bed reactor can be validated by some experiments. Through the system integration, the new polygeneration processes with biomass gasification is proposed and its performance in terms of hydrogen yield, hydrogen thermal efficiency, net power efficiency, and the overall system efficiency is evaluated. Based on the prescribed economic model with different scenarios and conditions, the economic indicators such as the levelized cost of electricity, net present value, and internal rate of return carry out the complete economic assessment. Finally, it is expected that the BIGCC has a few economic benefits. In the research, the integration of Aspen Plus® and Matlab® is used to execute the simulation task.

4. Conclusions

To remove the high energy duty of the air separation unit such as CASU are investigated, the BIGCC polygeneration plant connecting can increase the net energy efficiency output since it connects the syngas chemical looping to generate electricity and hydrogen simultaneously. The corresponding net efficiency would be up to 60% if the heating values of fuels of hydrogen and methanol are taken into account.

A Simulation-based Support System for the Planning and Design of Modular Logistics in Chemical Production Processes.

Christian Sonntag[1,*], Dominik Wolff[1], Markus Zajac[2]

1 INOSIM Consulting GmbH, Joseph-von-Fraunhofer-Str. 20, 44227 Dortmund, Germany
2 Fraunhofer-Institut für Materialfluss und Logistik, Joseph-von-Fr.-Str. 2-4, 44227 Dortmund, Germany
**Corresponding author: christian.sonntag@inosim.com*

Highlights

- Modular plant logistics are essential to realize the full potential of modularization.
- A new planning support tool enables efficient design of modular logistic systems.
- Material flow simulation quickly provides quantitative KPIs for decision support.

1. Introduction

In process industries, there is a constantly growing trend towards increasing product differentiation, shorter product life cycles, and increasing market volatility [1]. The reason for that lies in increasing market uncertainty: While in the past, usually only a few products were demanded constantly over long periods, nowadays markets require permanent innovation. This enforces raised industrial standards in production planning and logistics. To address these uncertainties, modular production concepts are receiving wide-spread attention since they allow industry to adjust their production processes quickly to changing market environments and enable a reduction in reconfiguration and adjustment times [2]. To realize the full potential of modularization, it must be extended beyond production itself to include the process logistics, including e.g. the plant supply chain, packaging, and shipping.

The increased flexibility that is provided by modular logistics systems requires new approaches for planning, engineering, and validation. In the scope of the research and innovation project LEGOLAS [3], we are developing a new planning support system for the simulation-based design of such modular logistics systems. This talk provides an overview of this system and illustrates its features on a challenging case study, the filling/packaging section of an herbicide/fungicide production plant.

2. The Planning Support System for Modular Production Logistics

The planning support system provides an environment to quickly design and validate modular logistics systems, covering scenarios such as from-scratch design, re-configuration, disturbance and fault analysis, and turnaround management.

Fig. 1 provides an overview of the iterative workflow that is supported by the planning support system. First, the user creates a set of system alternatives in a graphical drag-and-drop environment. These alternatives are then transformed into material flow models and analyzed using the INOSIM process simulation software to generate quantitative KPIs that the user then uses to choose a process alternative that fulfills all requirements or, if all alternatives are discarded, to return to the system design step to create more alternatives.

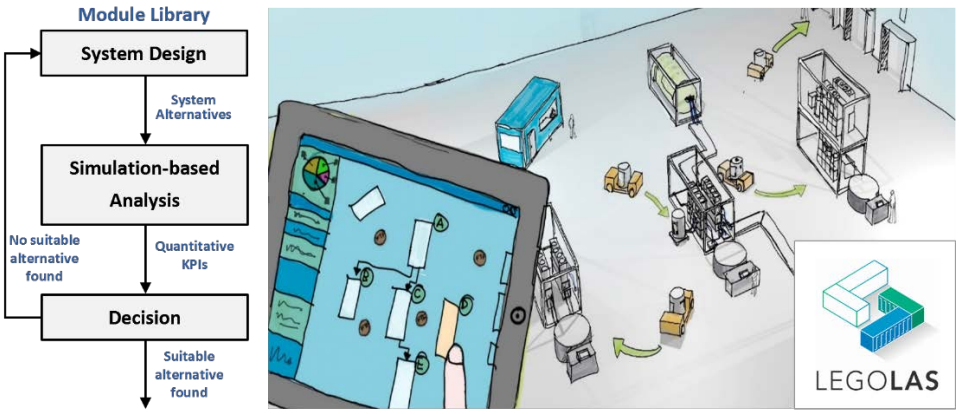

Figure 1. Conceptual workflow supported by the LEGOLAS planning support system.

3. Decision Support based on Material Flow Simulation

To illustrate the features of the planning support system, it has been applied to a challenging case study, the modular filling/packaging section of an herbicide/fungicide plant (see Fig. 2) by the German logistics provider Imperial Logistics. In this talk, the demonstration focuses on the simulation-based decision support step which is based on the dynamic simulation of modular logistics systems using the INOSIM process simulator and its new packaged-goods simulation engine, enabling the user to model complex batch and mixed processing plants and their logistical elements seamlessly within the same environment.

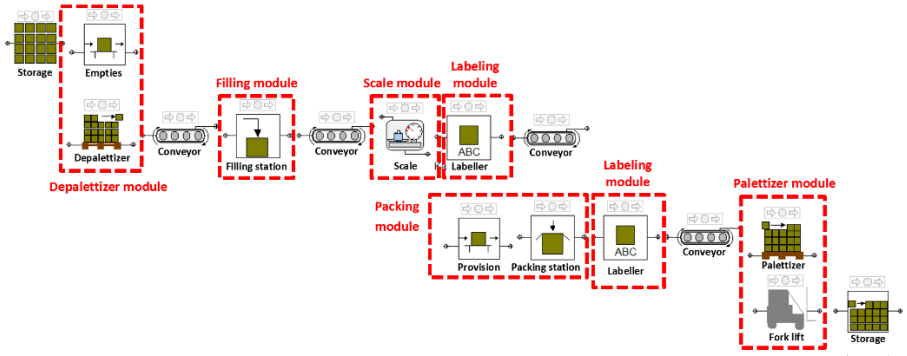

Figure 2. Flowsheet of a modular filling/packaging section of an herbicide/fungicide plant in the INOSIM process simulator.

4. Conclusions

The LEGOLAS planning support tool enables the efficient engineering of modular logistics systems based on material flow simulation for quantitative decision support. The next step is to validate it and illustrate its potential on a number of other challenging case studies.

Benefits of Using Macrokinetic Bioreactor Models in Rigorous Flowsheet Simulators

Jan C. Schöneberger[1*], Armin Fricke[1], M. Nicolas Cruz Bournazou[2]

1 Chemstations Europe GmbH, Berlin, Germany; 2 Department of Chemistry and Applied Biosciences, ETH Zürich, Swizerland

**Corresponding author: js@chemstations.eu*

Highlights

- Simulation of coupled up- and downstream processes
- Rigorous First-Principal modelling of biotechnological processes
- Economic analysis and optimization of complete biotechnological processes

1. Introduction

The number of biotechnological processes that are realized in large-scale dimensions is steadily increasing. In addition to food technology applications such as breweries or biofuel applications like biogas and bioethanol plants, biorefineries for the production of basic and specialty chemicals are becoming more important. In classical EPC business, flowsheet simulators are used to solve the mass and energy balances of the processes taking into account the laws of thermodynamics. The results from the simulation form the basis for equipment dimensioning and plant wide process optimization.

The apparatus models used in biotechnology differ from the apparatus models used in classical chemical processes. Reactors or fermenters in biotechnological processes are often operated discontinuously. Downstream processes can be operated batch wise, but depending on the amount of product, a continuous process is often the more economical solution.

In the modeling of bioreactors, the high number and complexity of biochemical intracellular reactions makes it difficult to accurately describe the dynamic behavior of the reactor. In addition, the properties of the microorganisms are subject to constant change. Macrokinetic models can be used to describe these reactions at least for a certain time period or a specific state of the bacteria's life cycle. However, these models commonly need to be adjusted and model parameters must be updated regularly.

2. Methods

In this work two approaches are presented for including macrokinetic models in a flowsheet simulator, a mass-balance based approach and a mole-balance based approach. The different simulation results of these approaches are discussed in detail by means of a simple example from Fogler [1]. The mole-balanced approach is then applied to an Escherichia coli based production process for 1,3-Propanediol (PDO). Therefore, a more complex macrokinetic is used, similar to the one published by Anane et al. [2]. The PDO process is modelled in CHEMCAD as a combination of

four batch fermenters and a continuous downstream process with filtration section, ion exchanger, and distillation section. The flowsheet is depicted in Figure 1.

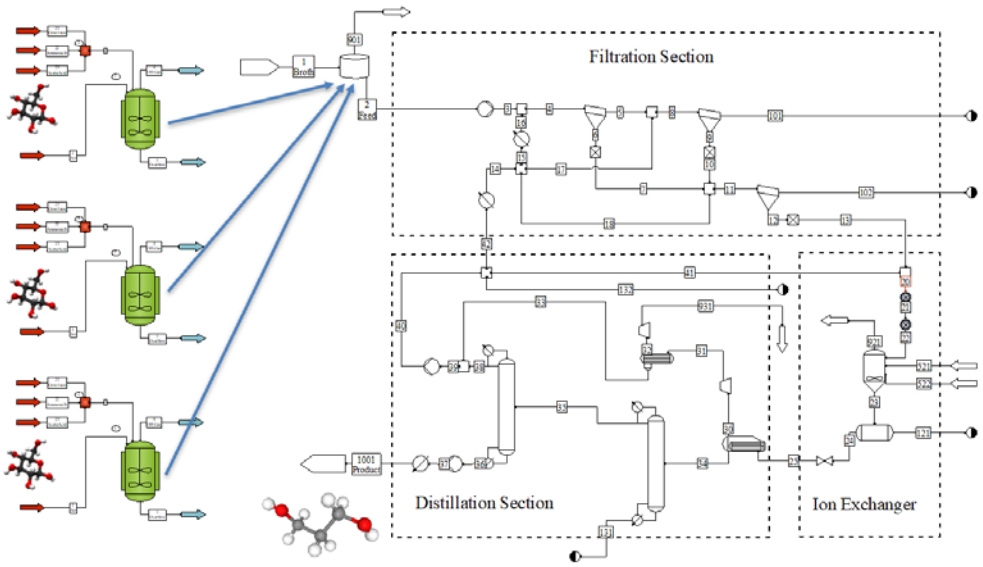

Figure 1. Simulation flowsheet of a bacteria based PDO production process.

3. Results and discussion

The simulation of the complete production chain from cane juice to PDO allows a detailed estimation of the operational expenditures (OPEX), considering the costs of the feed (cane juice, ammonia, and acetic acid), the utilities (electricity, steam, and cooling water), chemicals (caustic soda and sulfuric acid), and the revenues gained with the produced PDO as a function of the final product quality. Such calculations enable an economic optimization of the production process.

The maximization of the PDO plant's benefit was the task of the Process Simulation Cup 2018 [3], where students from all over the world were allowed to change predefined design variables. Table 1 shows the development of the calculated profit by enabling over the one year's runtime of the cup the design variables of the different sections.

Table 1. Achieved profit of the PDO plant during the different stages of the PSC2018.

Initial Solution	Optimization of the distillation section	Optimization of the distillation section and the recycle flows	Optimization of the substrate flows with fixed downstream	Optimization of the substrate flows + air flow with fixed downstream	Optimization of the coupled process
-387 $/h	191 $/h	422 $/h	695 $/h	1.192 $/h	1.408 $/h

4. Conclusions

The results given it Table 1 demonstrate impressively, how the usage of microkinetic bioreactor models in rigorous flowsheet simulators help to find optimal or at least improved operation parameters for biorefineries.

Chemical Engineering Education in Botswana

Paul Serban Agachi[1]

1 Botswana International University of Science and Technology

**Paul Serban Agachi: agachip@biust.ac.bw*

Highlights

- Education and Higher Education in Botswana
- Chemical Engineering Education in Southern Africa.
- Botswana International University of Science and Technology. Chemical Engineering Department in Botswana.
- Challenges and successes

1. Higher Education in Botswana

Botswana is newly formed country, gaining its independence in 1966. Previously, the former state organizational form was Bechuanaland Protectorate under British rule, established in 1885 in the arid Kalahari Desert. Since it was a very poor territory (the diamonds were not discovered) there was practically no interest for development. Until 1982, Botswana did not have its own, autonomous HE institution. In 1964 the common University of Botswana, Lesotho and Swaziland (UBLS) was established and operated until 1974, with its headquarters in Lesotho. Then, the University of Botswana and Swaziland (UBS) functioned in Swaziland between 1975 and 1976. In 1982, the University of Botswana (UB), the first autonomous institution of HE in the country, was established and was totally focused on the "education of educators". At the time of liberation, there were only 677 qualified primary school teachers. And that was all teachers' body in Botswana. It is touching how UB was established through public donations: each family donated as much as it could from their household: a cow, a goat … Only in 1991, the next professional technical university was established, the present Botswana University of Agriculture and Natural Resources and, long time after, in 2005 (but practically operating from 2012), Botswana International University of Science and Technology [1].

2. Chemical Engineering Education in Southern Africa.

Southern Africa is the southernmost region of Africa, comprising Botswana, Lesotho, Namibia, South Africa and Swaziland. There are 9 Bachelor's Degree programs of Chemical Engineering/ Chemistry and Chemical Engineering/ Physical Metallurgy in South Africa only, plus one program in Namibia and one in Botswana. It is somehow unnatural that these countries with such luxury of minerals to remain exporters of small value added materials.

3. Botswana International University of Science and Technology. Chemical Engineering Department in Botswana.

The conception of the Botswana International University of Science and Technology (BIUST) can be traced to the national strategic shift that came with the Revised National Policy on Education (RNPE)

of 1994. Unlike the country's first Education Policy of 1977 dubbed 'Education for Kagisano' whose thrust was 'access and equity', the RNPE shifted focus to 'quality' and emphasized an education system geared at the world of work [2].

RNPE recognised Science and Technology as the driving engines in transforming the country from a pre-dominantly agro-based economy to an industrial economy, hence the subsequent establishment of a National Science and Technology Policy in 1998.

The first program of Chemical Engineering in Botswana was a logic consequence of the Botswana Economic Development Plan and was established in 2015 [3]. To build it from scratch was a real struggle.

4. Challenges and successes

Although it was a struggle to build the results are promising: next year 20 Batswana students graduate in this field. The curriculum had to be adapted at what Botswana needs most. There are plans of research and real research projects which are supposed to bring real benefit for the country.

Influence of Different CO_2 Concentrations in Aeration Air During Thermophilic Fermentation Of *Bacillus Caldolyticus.*

Milan K. Popovic[1], Larissa Skelac[1], Sandra Wewetzer[1], Axel Karschöldgen[2], Johannes Bader[1]

1 Beuth University of Applied Science Berlin, Germany; 2) Kreienbaum Wissenschaftliche Messsysteme, Langenfeld, Germany

Highlights

- Optical dissolved CO_2-probe at 70 °C
- Fermentation of thermophilic bacterium
- Beneficial effect of increased CO_2 concentrations
- Increased yield by reduced aeration rate

1. Introduction

In fermentation processes, the concentration of CO_2 is a relevant parameter for the control of the metabolic function of microorganisms in the bioreactor. In most cases, CO_2 is determined in the exhaust-gas-stream as a sum parameter of the metabolic activity in the bioreactor. In large scale bioreactor inhomogenities exist, which can influence product yield and product quality. Whereas small amounts of dissolved CO_2 have advantageous effects on the production of amylase and proteases (Popovic *et al*., 2009 [1]; Bader *et al*., 2015 [2]), increased CO_2 concentrations result in a decreased pH value in the cells followed by altered metabolic activity. Hence, it is beneficial to measure directly in the fermentation broth, instead of using the exhaust-gas-analysis. A slight increase of CO_2-concentration can be achieved by a reduction of the aeration rate combined with a pressurized fermentation. Hence, aeration costs may be reduced and the yield can be increased simultaneously (Popovic et al. 2014 [3]).

2. Methods

Fermentation of *Bacillus caldolyticus* DSM 405 was performed in stirred tank reactor Biostat E (Sartorius AG, Germany) at 70 °C in batch mode. Amylase and protease activities were determined according to Manning and Campbell (1961) [4] and Strydom *et al.* (1986) [5]. The amount of dissolved carbon dioxide was calculated by the exhaust air composition (Sidor, Sick Maihack GmbH, Reute, Germany). CO_2 measurement by in-situ probe was carried out by using YSI 8500 CO2 Monitor (YSI Inc., Yellow Springs, USA).

3. Results and discussion

In the Biostat E bioreactors a congruent response of in-situ probe and exhaust gas analysis could be observed (Figure 1).

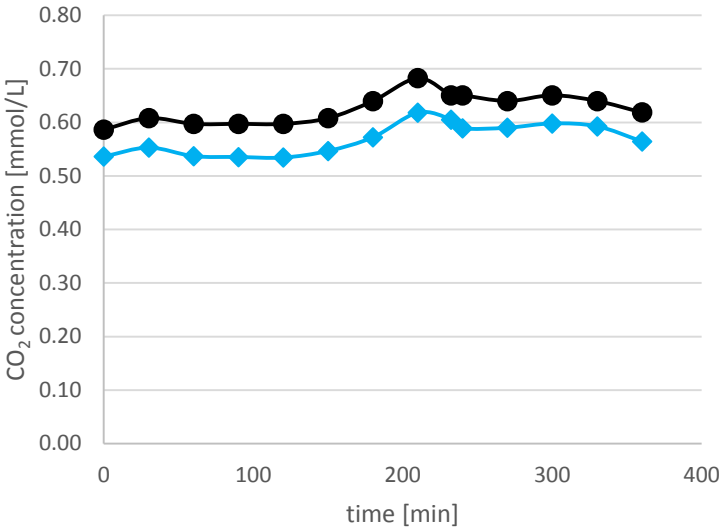

Figure 1. Comparison of the CO_2-quantification by in-situ probe (black dot) and exhaust gas measurement (blue diamond) (Bader *et al.*, 2015) [2])

At atmospheric CO_2 concentration, an amylase concentration of 5.5 U/mL was observed after 300 minutes whereas the increase in CO_2 concentration to 5% (v/v) resulted in a maximal amylase concentration of 6 U/mL after only 180 min. Comparable effects of the increased CO2 concentration were observed for the protease production. Without increased CO_2 concentration, 1.2 U/ml of protease were observed. At 5% (v/v) CO_2, 2 U/ml were secreted after 210 min.

These results indicate to importance of reliable CO_2 measurement during fermentation processes. Especially in large scale bioreactors these effects have to be taken into account due to high hydrostatic pressure and known inhomogenities.

4. Conclusion

In the presented work, the reliability of an optical dissolved CO_2-probe was evaluated during the fermentation of the thermophilic microorganism *Bacillus caldolyticus* at a temperature of 70 °C over a period of 10 hours. The results were compared with exhaust-gas-analysis measurement. The applied optical dissolved CO_2-probe showed comparable and reliable results during the whole fermentation process. This indicated the possibility of using this in-situ measurement even under high temperatures.

The Quality Monitoring of Vinyl Chloride Polymerization by Soft Sensor and OPC Technology.

Haitian Pan[1*], Pengfei Zhu[2], Mengfei Zhou[1], Luyue Xia[1]

1 College of Chemical Engineering, Zhejiang University of Technology, Hangzhou, Zhejiang 310014, PR China;
2 Zhejiang Longsheng Chemical Research Co. Ltd., Shaoxing, Zhejiang 312368, PR China

**Corresponding author: htpan@zjut.edu.cn*

Highlights

- A multi-model fusion modeling method
- A soft sensor application scheme by OPC technology
- The operation load of the entire monitoring system is light and stable

1. Introduction

In the vinyl chloride polymerization process, it is essential to monitor the polymerization rate and the conversion rate online for the sake of product quality, process optimization and safety [1]. Traditional off-line measurement methods cannot meet the real-time control requirements. A soft sensor method with multi-model is used for the polymerization process monitoring by OLE for Process Control (OPC) technology.

2. Methods

The development of modern control theory and artificial intelligence enriches the soft sensor technology [2,3]. According to the characteristics of vinyl chloride polymerization, a multi-model fusion modeling method, based on an improved Kalman filter algorithm, is proposed, as shown in Figure 1.

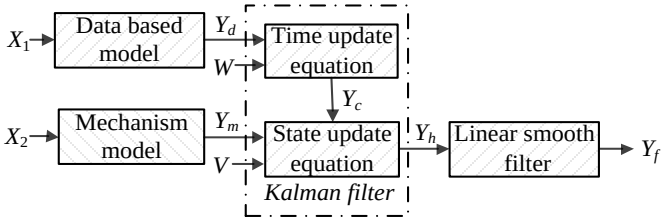

Figure 1. Multi-model fusion modeling structure

where， X_1, Y_d, X_2, Y_m are inputs and outputs. The update equations are as follows:

$$Y_t=Y_{t-1}+(Y_{d,t}-Y_{d,t-1})+w_{t-1} \quad (1)$$

$$Z_t=Y_{m,t}=HY_t+v_t \quad (2)$$

where t is the time, Y is the state variable, Z is the observation variable, H is the gain of state variable to observation value, w, v are the process noise and the measurement noise respectively, and the corresponding variances are W and V. In the recursive framework of the Kalman filtering algorithm, the combined weights are automatically adjusted online. The predictive value of combination model Y_h is obtained. Moreover, a linear sliding smoothing filter is applied to stabilize Y_h and the final prediction value Y_f is obtained. However, the application of the method takes much computing resource if this program is run in the control system. Thus, a soft sensor application scheme by OPC technology is proposed, the structure is shown in Figure 2. The server station and the operation station constitute the communication network through the industrial Ethernet. The real-time process parameters of DCS control system are sent by OPC server. The server computer runs soft

sensor module program. The target variables are sent back to the control system. The monitoring software obtains the data by the OPC client.

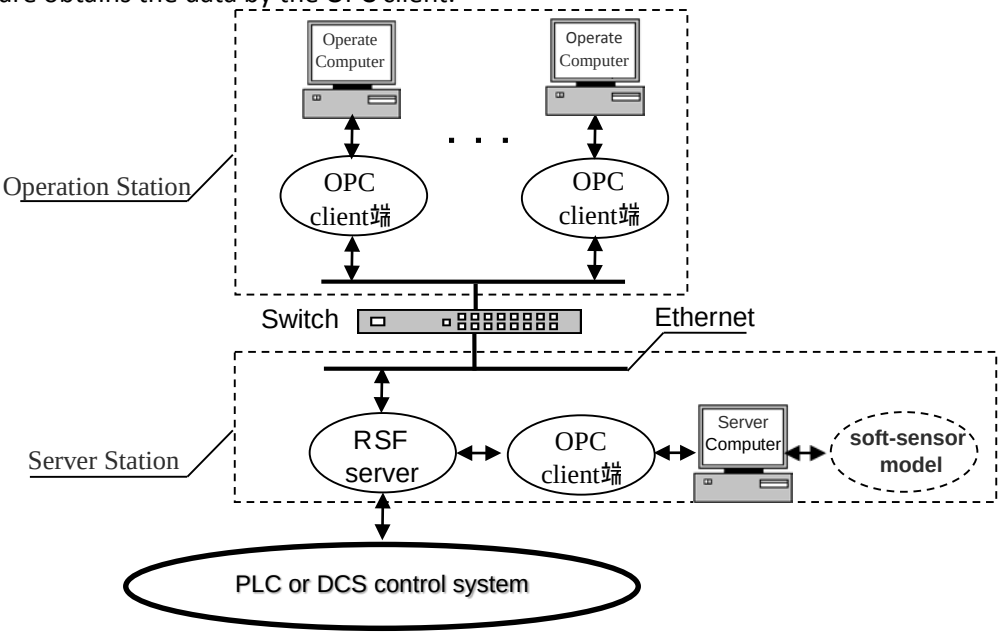

Figure 2. Structure of a soft sensor application scheme by OPC technology

3. Results and discussion

The multi-model fusion modeling method and OPC technology are applied to the soft-sensing of the polymerization rate in vinyl chloride polymerization. First, a data-driven modeling method is used by combining mixtures of Kernels Principal Component Analysis (K_2PCA) with Artificial Neural Network (ANN). The input variables are polymerization time *t*, polymerization temperature T_r, inlet and outlet temperature of jacket cooling water T_{Ji} and T_{Jo}, flow rate of jacket cooling water F_J. The output variable is polymerization rate. Second, a mechanism model based on the heat balance model of the reactor is proposed by calculating the thermal equilibrium parameters. The thermodynamic mechanism model is as follows:

$$Y_m = \frac{dx}{dt} = \frac{F_J \rho_w c_{p,w}(T_{Jo} - T_{Ji}) + F_w \rho_w c_{p,w}(T_r - T_{in})}{(-\Delta H_r) m_m} \tag{3}$$

The final value *of* polymerization rate Y_f is obtained through a series of mentioned techniques. Then, the polymerization conversion *X* can be obtained by integral.

$$X = \int_0^t Y_f \, dt \tag{4}$$

4. Conclusions

The OPC application result is satisfactory. The soft sensor technology solves the problem of online monitoring of the polymerization quality. The OPC technology solves the data switching problem between different software and hardware. The application in the vinyl chloride polymerization process proves the stability and reliability of the method.

Application of Iterative Real-time Optimization in an Intensified Continuous Plant at Pilot Plant Scale.

Anwesh Reddy Gottu Mukkula[1*], Sebastian Engell[1]

1 Process Dynamics and Operations Group, Technische Universität Dortmund, Germany

**Corresponding author: anweshreddy.gottumukkula@tu-dortmund.de*

Highlights

- A lithiation process performed in an intensified tubular reactor is optimized.
- Modifier adaptation with quadratic approximation (MAWQA) is used.
- MAWQA identifies the plant optimum in the presence of plant-model mismatch.
- Concentrations are measured using an online NMR developed by BAM, Berlin.

1. Introduction

It is always of great interest to identify the optimal point of a plant and to operate it at this point. Usually, the optimal operating point of a plant is identified by solving a model-based optimization problem. Developing an accurate mathematical model and estimating its parameters require a large amount of time and effort. Sometimes it may not be possible at all to develop an accurate model due to the complex phenomena that take place in the plant. Modifier adaptation with quadratic approximation (MAWQA) [1] is an iterative optimization scheme which uses measurements from the plant to drive the plant to its true optimum in spite of the presence of significant plant-model mismatch.

2. Methods

In MAWQA, the iterative gradient-modification optimization (IGMO) method is combined with a derivative free optimization (DFO) method to estimate the plant gradients along with an additional surrogate model. We refer to [1] for a detailed description of the MAWQA algorithm. The process under consideration is a lithiation reaction that takes place in a tubular reactor in a containerized pilot plant. The pilot plant setup has been developed in the European project F3-Factory [2]. The reaction mechanism and its kinetic parameters are not precisely known. The overall reaction is depicted in Figure 1.

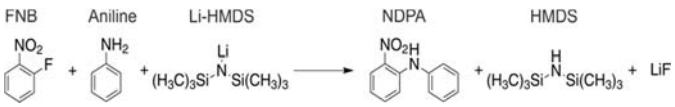

Figure 1: Overall lithiation reaction scheme

Due to the unavailability of the complete reaction information, the mathematical model of the process is incomplete and does not represent the behavior of the plant accurately.

The aim of the controller is to operate the process at its economically optimal operating point. This is enabled by real-time concentration measurements from a novel online NMR device that was developed by BAM, Berlin [3], in the context of the EU-funded project CONSENS [4].

The maximized plant profit function is: $\text{profit} = \frac{M_4 C_4 w_4}{\rho} \sum_i^3 u_i - \sum_i^3 w_i u_i$. M_4, C_4 are molar mass $[\frac{kg}{mol}]$ and concentration $[\frac{mol}{m^3}]$ of Li-NDPA. u_1, u_2, u_3 are feed flowrates $[\frac{kg}{h}]$ of Aniline, Li-HMDS and FNB. w_1, w_2, w_3, w_4 are relative costs of reactants Aniline, Li-HMDS and FNB and product Li-NDPA. ρ is the density $[\frac{kg}{m^3}]$ of the reaction mixture.

3. Results and discussion

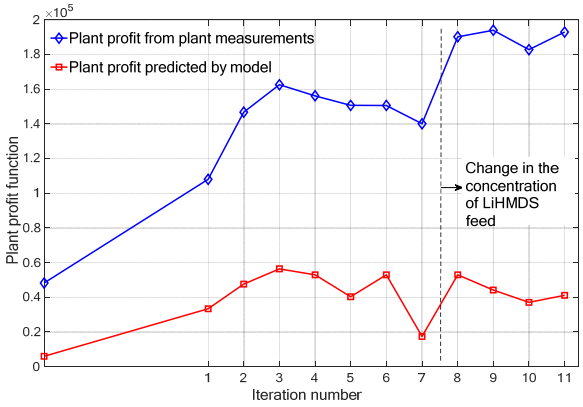

Figure 2: Plant cost over MAWQA iterations in the validation experiment performed at the pilot plant in INVITE, Leverkusen

The evolution of the plant profit during the iterative optimization using the NMR measurements is shown in Figure 2. The blue line indicates the real plant profit as computed from the measurements whereas red line represents the plant profit as computed from the nominal model which has both structural and parametric plant-model mismatch. After an unknown change of the feed concentration of Li-HMDS, the algorithm managed to improve the plant profit (blue line) significantly. In contrast, the plant profit function that was predicted by the model drops as a fixed value for the feed concentration is assumed.

4. Conclusions

In summary, it was validated that the combination of the NMR measurements with the iterative optimization algorithm MAWQA could drive the plant to an optimal operation despite significant deviations between the plant model and the true plant behavior. MAWQA reacted quickly to changes in the process conditions and responded by making input moves to identify the true process optimum. Measurement delays caused by low sample flow rates and long piping between the reactor and the NMR device can be compensated using the methods proposed in [5].

Highlights

- Perform modeling and pinch analysis for water removal process of natural gas.
- Process improvement in consideration of energy and economy in the water removal process of natural gas

1. Introduction

Many energy plants using processing system are trying to improve its efficiency and lessen the production of greenhouse gasses. In this study, the pinch analysis of the water removal process using triethylene glycol (TEG-$C_6H_{14}O_4$) was performed for the water removal process of the LNG plant. From the results of this study, the improvement factors of the heat flow were identified, and the applicability was evaluated by optimizing the pinch point on the composite diagram.

2. Methods

The economic feasibility was examined using the results of energy targeting using the pinch analysis. Energy costs were evaluated by using the following equation.

$$\mathrm{E \cdot C} = \sum\left(C_h \times Q_{h,min}\right) + \sum\left(C_c \times Q_{c,min}\right) \qquad (1)$$

C_h and $\mathrm{C_c}$ are utility costs of hot and cold temperatures, respectively. Also $\mathrm{Q}_{h,min}$ and $\mathrm{Q}_{c,min}$ are target energy values (kW) of hot and cold temperatures, respectively. Equation 2 was used to calculate the initial installation cost (C.C) of optimized heat exchanger network that can supply the minimum heat and cold utility values corresponding to energy target temperature (ΔT_{min}).

$$\mathrm{C \cdot C} = \mathrm{a} + \mathrm{b} \times \left(\frac{Area}{Shells}\right)^{C} \times Shells \qquad (2)$$

Finally, the total annual cost(TAC) is calculated from Eq(3) [1].

$$\mathrm{A \cdot C} = \mathrm{A} \times \left(\sum C \cdot C\right) + E \cdot C \qquad (3)$$

$$A = \frac{(1+ROR/100)^{PL}}{PL} \qquad (4)$$

Rate of return (ROR) is fixed at 10% as investment-return rate. In addition, the heat exchanger network plant life was assumed to be 15 years.

3. Results and discussion

The static process model for the water removal process and utility system is shown in Fig. 1.

Furthermore, an attempt was made to see whether it is viable to replace high-pressure steam to either mid (175 ℃, 1,500 kPa) or low (125 ℃, 500 kPa) pressure steam. We set 8.5 ℃ as the lowest allowable temperature and applied various steam pressures to create balance composite curve and utility composite curve as seen in Figs. 2 and 3. As a result, it was possible to replace with 102.9 MJ/h (61%) of low pressure steam and 21 MJ/h (13%) of mid pressure steam, which account for 74% of overall heat supply in the plant.

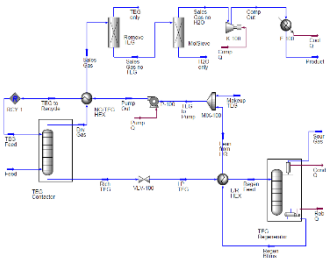

Fig. 1. The process flow diagram of the hydration process.

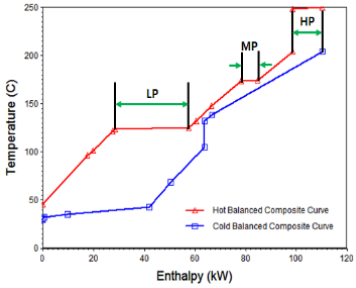

Fig. 2 Balanced composite curve with 3 utility.

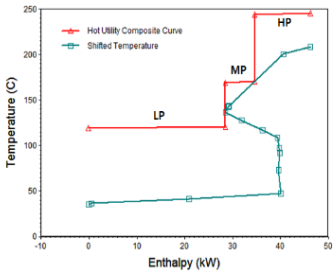

Fig. 3 Utility composite curve with 3 utility.

4. Conclusions

Defining hot and cold stream utilities during the dehydration process was in order, followed by carrying out static process modeling in the utility system. The data resulted from these steps allowed producing composite curves of various utility usage levels, which can be helpful in planning a reduction strategy of the heat exchange temperature in the dehydration process.

Highlights

- Development of an MILP model for Industrial Demand Side Management.
- Approximation of Multi-stage problems as a series of two-stage problems.
- Novel aggregated formulation for power contract optimization.
- Application of risk measures to an industrial-size power plant.

1. Introduction

Integrated production sites in the chemical industry typically consist of many large-scale plants which are highly interconnected through material (e.g. base chemicals or intermediates) and utility networks [1]. A power plant is of major significance, as it provides utilities to the plants, e.g. electricity and process steam. Furthermore, power plants are able to collect off-gases from other plants and use them as fuels. The importance of power plants is also acknowledged by the European Union with the CHP Directive (Directive 2004/8/EC, 2004) that sets a framework to promote growth of cogeneration plants.

In this work we address the integrated electricity procurement and operation of a power plant that supplies steam and power to a chemical process and interacts with the power grid. Adopting a stochastic mixed-integer programming formulation, the aim of this work is to optimally determine for a planning horizon of one week:

- the amount of electricity purchased from power contracts;
- a daily day-ahead commitment with hourly discretization to purchase electricity from the day-ahead market under time-sensitive prices;
- the hourly production levels of steam and electricity;
- the amount of fuels stored and the off-gases incinerated.

2. Methods

To integrate electricity procurement and operation of the power plant, we adopted a multi-stage stochastic mixed-integer programming approach taking into account day-ahead electricity price uncertainty [2, 3]. To overcome the large computational effort needed to solve an industrial-size multi-stage stochastic program, we adopt an approximation strategy that solves a series of two-stage stochastic programs within a rolling-horizon framework. The rolling horizon framework not only reduces the problem size but also makes it possible to react to new information available

regarding the amount of off-gases to be incinerated. The proposed approximation strategy drastically reduces the computational burden and renders possible the application of multi-stage programs to industrial-size optimization problems.

Considering even a low probability of large losses as not acceptable, we integrate the concept of risk into the optimization problem adopting the Conditional-Value at Risk measure.

3. Results and discussion

Fig.1 shows the electricity purchase profiles and the electricity produced by the power plant obtained solving the proposed multi-stage stochastic program with the described approximation strategy. The risk-averse solution follows the time-sensitive electricity price and purchases electricity from the power contracts when the price variation is higher to reduce the risk measure. The computation of a positive Value of the Stochastic Solution estimates the savings that the power plant could obtain adopting a stochastic formulation instead of a deterministic one.

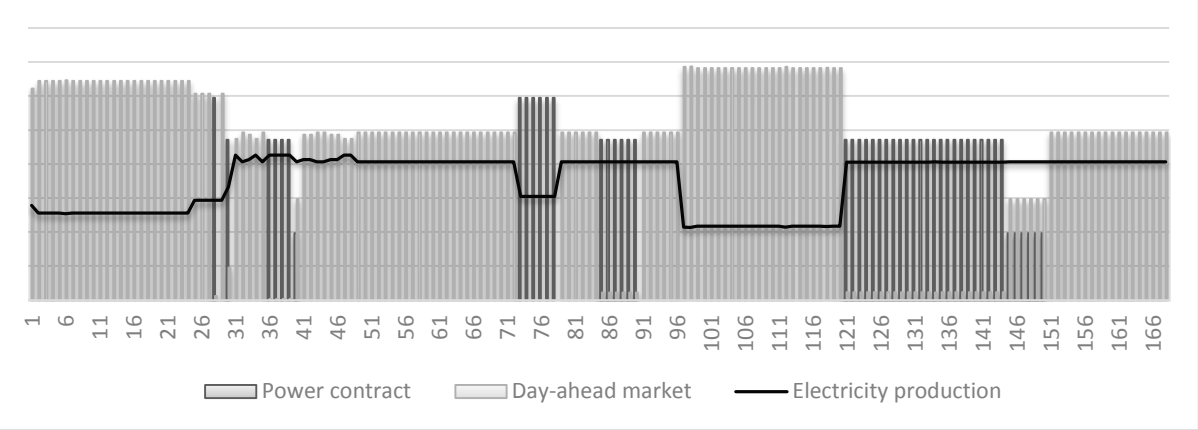

Figure 1. Optimal electricity procurement.

4. Conclusions

This work addresses the integrated electricity procurement and operation for an industrial-size power plant. A multi-stage mixed-integer stochastic program is proposed to model electricity commitments taking into account electricity price uncertainty. An approximation strategy is proposed to solve efficiently industrial size optimization problems.

Price-based coordination of shared resources with external suppliers

Christian Klanke[1*], Lukas S. Maxeiner[1], Sebastian Engell[1]

1 Process Dynamics and Operations Group, Department of Biochemical- and Chemical Engineering, TU Dortmund University, 44221 Dortmund

**Corresponding author: Christian.klanke@tu-dortmund.de*

Highlights

- Ecological and economical savings via coordination of plants at chemical production sites
- Incorporation of access to global commodity markets
- Confidentiality in case of competing enterprises by employing a distributed coordination scheme

1. Introduction

Worldwide, chemical production sites are significant consumers of energy and resources and improving their efficiency has been pursued continuously over the past decades. Optimizing plant operations is an economically attractive way of improving their efficiency because the investments are relatively low, and the duration of the projects is not overly long. In large chemical sites, the plants are interconnected by networks of raw and intermediate materials and of carriers of energy, especially steam at different pressure levels. Coordinating the production and consumption of these shared resources provides an impactful lever towards a more efficient production.

While the site-wide optimization of the operation of the interconnected plants is theoretically feasible, practically it is desirable to perform a distributed optimization with some central coordination. One strong argument in favour of such schemes is that information on the internals of the individual plants, e.g. their demands, revenues and profit functions does not have to be shared so that such schemes can also be applied if the plants are operated by different business units. This can be achieved by so-called *price-based coordination* schemes in which a central coordinator balances the networks by adapting the transfer prices, which enter in the individual cost functions [1].

A limitation that the previously proposed coordination schemes suffer from is that many of the shared resources produced and/or consumed on the site are also available via external suppliers on short notice or can be sold on the spot market.

Such exchanges of materials and carriers of energy are subject of medium- or long-term contractual agreements. What we propose here is a scheme that determines dynamic transfer prices in the context of such agreements without providing the parties involved access to sensitive data, thus improving flexibility and enhancing fairness. This is an essential agreement of the practical implementation of industrial symbiosis.

2. Methods

A dual decomposition-based method entitled *price-based coordination* forms the core approach within this work [2]. Mathematically speaking, it is based on dual decomposition, interpreting the Lagrange multipliers as correct transfer prices of the resources and utilities under consideration [3]. As a result of applying dual decomposition the mass balances that govern the connecting networks are transformed into economical incentives for the individual plants. This way the network balances are satisfied and confidentiality is guaranteed [4].
The scheme uses a gradient-based update step that computes the equilibrium prices in an iterative procedure. At these equilibrium prices, the network balances are satisfied.

3. Results and discussion

Based upon an industrial case study, existing *price-based coordination* schemes have been extended to deal with complex pricing structures that are imposed by suppliers on external commodity markets. The investigated pricing structure covers two resources, where the purchase price of one resource depends on the purchase amount of both resources and vice versa.
Despite of this coupling of the purchase prices, it is possible to derive a distributed coordination algorithm, which finds the optimum of the resulting mixed-integer problem. The algorithm reliably converges to equilibrium prices, as can be seen in Figure 1 right. At the equilibrium price, the supplies and demands of all resources match, as shown in Figure 1 on the left. At the same time, optimal amounts of external purchases of both resources are determined.

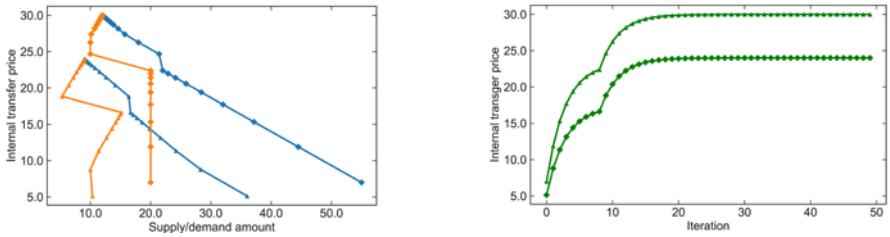

Figure 1. Supply (/) and demand (/) curves of two resources depending on the internal transfer price (left). Internal transfer price (/) plotted against iteration number for both resources (right).

4. Conclusions

By characterizing the solution structure of the centralized solutions to the coordination problem taking access to external markets into account, it is possible to find operating conditions and purchases at which the site operates optimally. Future work will include how to distribute the savings between the participating units on the site.

**Corresponding author: limyi@hknu.ac.kr*

Highlights

- A CFD model was proposed for CO_2 methanation in bubbling fluidized-bed (BFB).
- An internal helical heat exchanger was employed to the BFB reactor.
- Heterogeneous reaction kinetics and multiphase heat transfer were applied.
- Temperature, solid holdup, gas composition and reaction heat were analyzed.

1. Introduction

Power-to-gas (PtG) processes are being considered as one of the most promise alternatives to integrate renewable energy resources into a current energy grid [1] via CO_2 methanation process. Computational fluid dynamics (CFD) has become a suitable tool for design and hydrodynamics evaluation of chemical processes [2,3]. Kopyscinski et al., [4] did the first attempt to apply the fluidization technology for CO methanation. Recently, Sun et al., [5] evaluated the full-loop circulating fluidized-bed using CFD for CO methanation. However, few CFD studies on bubbling fluidized-bed (BFB) reactor have been done for CO_2 methanation with H_2.

This study focuses on the design of an internally-cooled BFB (IC-BFB) reactor for CO_2 methanation with H_2 using CFD model. A heterogeneous reaction kinetics from the literature and gas-solid heat transfer model are employed to the CO_2 methanation with a Ni-based catalyst. The CFD model results on pressure, velocity, temperature, solid volume fraction, CH_4 composition, and reaction heat are presented.

2. CFD model and boundary condition

The IC-BFB includes the two domains: (1) fluidized-bed reactor with diameter of 80 mm and height of 500 mm, where the catalyst bed height is about 250 mm; (2) helical coil heat exchanger (HCHE) with a tube diameter of 6 mm and a center diameter of two coils of 30 and 60 mm, respectively.

A commercial CFD code ANSYS Fluent R19 (ANSYS Inc., USA) was used, the reaction kinetics from Xu and Froment [6] was employed via a user-defined function. The material properties and boundary conditions are summarized in Table 1. The 2D CFD domains were discretized into 39,000 cells. The time step of the unsteady-state gas-solid Eulerian two-fluid flow model was set to 1×10^{-4} s. The CFD domains and mesh structure are shown in Figure 1a.

Table 1. Material properties and boundary conditions.

Material type	Properties					
	Diameter [μm]	ρ [kg/m³]	λ [W/m/K]	C_p [J/kg/K]	Diff. [m²/s]	Viscosity [kg/m/s]
Catalyst	100	2350 kg/m³	0.67	880	-	1.789e-5
Gas mixture	-	SRK real gas	Ideal-gas mixing-law	Mixing law	Kinetic-theory	Ideal-gas mixing-law
BC name	Boundary conditions					
	BC type	T [K]	HTC [W/m²/K]	P [Pa]	Velocity [m/s]	$CO_2/H_2/N_2$ [mole %]
Inlet	Velocity inlet	673	-	5e5	0.13 m/s	0.2/0.8/0
Outlet	Pressure outlet	673	-	5e5	-	0/0/1
Reactor wall	Wall	353	0.3	-	-	-
Coil wall	Wall	470	135	-	-	-

3. Results and discussion

The snapshots at t = 60 s for the contours of pressure, velocity, solid volume fraction, temperature, CH_4 mole fraction, and heterogeneous reaction heat are displayed in Figure 1b, c, d, e, f and g. Reactions are more intensive at the core of the reactor, while gas-solid mixing is enhanced by HCHE to become almost even distribution of temperature in the whole catalyst bed. The product dry gas compositions of $CO_2/H_2/CH_4$ = 0.079/0.329/0.592 are similar to literature [7].

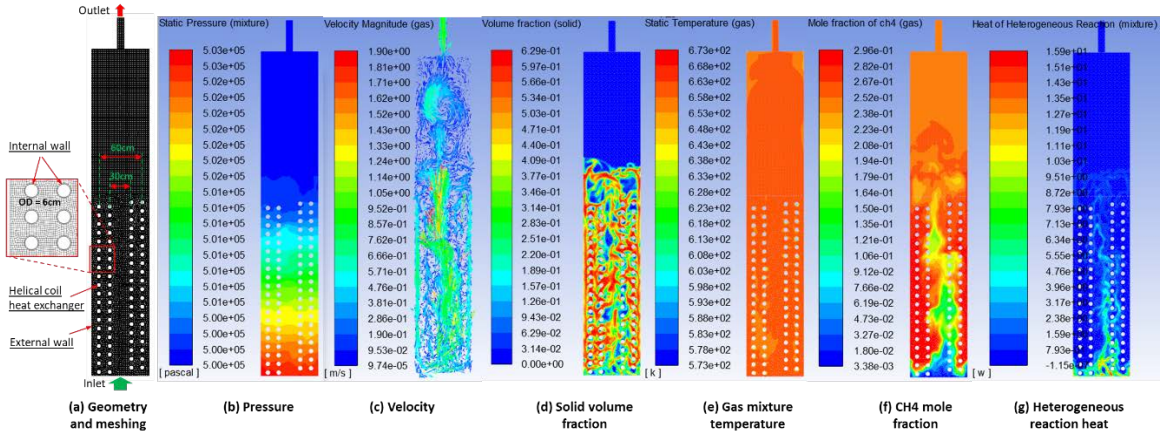

Figure 1. CFD domain and meshing, and CFD results.

4. Conclusions

An IC-BFB was modeled using a 2D Eulerian two-fluid CFD model for CO_2 methanation. The CFD model demonstrated the excellent heat and mass transfer capability of the IC-BFB reactor.

Optimization of water mist system in refinery process

Hyundo Park[1, 2], Junghwan Kim[1,*]

1 Green Materials & Processes Group, Korea Institute of Industrial Technology, Ulsan, Republic of Korea

2 Department of Chemical and Biomolecular Engineering, Seoul National University of Science and Technology, Seoul, Republic of Korea

**Corresponding author: kjh31@kitech.re.kr*

Highlights

- Development of CFD model and pilot plant based on the actual refinery process.
- Optimization of flow rate, number of nozzles and mist size.
- Reduction of the number of nozzles (20%) or amount of water (25%).

1. Introduction

At the CCR/Platforming process, which is operated by commercial refinery company, heat exchange is performed using an air-cooled heat exchanger. Unlike a water-cooled heat exchanger, an air-cooled heat exchanger uses air for heat exchange. Therefore, it is affected by ambient air temperature. Especially in the summer, when the temperature is high, a problem occurs that the heat exchange efficiency is reduced.

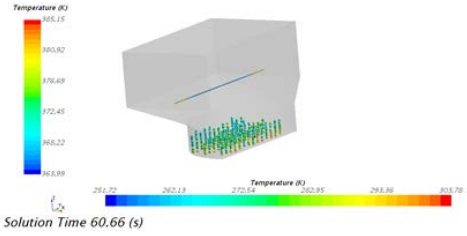
To solve this problem, many refinery companies are using water mist system. Water mist system is that sprays water finely to absorb heat in the ambient air. However, there is a problem with this system. That is, the corrosion of refinery device because of spraying excessive water.

In this study, we developed the CFD model to find out variables that affect water mist system and optimize the water mist system to solve the problem.

2. Methods

2.1 CFD modeling

The flow analysis model was developed based on the actual operational process using computational fluid dynamics (CFD). In this model, Lagrangian analysis and unsteady state flow conditions are simulated. There are 8 fans (2 fans/1 set) and 640 nozzles (80 nozzles/a fan) in the actual process. The CFD model is develop with 1/2 fan and 40 nozzles.



Simulator	Star CCM+ v12.04.011
Analysis time	60 seconds
Computational time	144hours/case (CPU 2.1GHz 64GB RAM)

Figure 1. CFD model of water mist system.

2.2 Pilot plant configuration

We made a pilot plant to observe the cooling effect of water mist system. The size of pilot plant is 2165mm (length) x 1670mm (width) x 2543mm (height).

3. Results and discussion

3.1 CFD simulation results

Table 1 shows two results. First, when the number of nozzles is decreased by 20%, the cooling effect increases by 6%. Second, when the total flow rate is increased by 16.7%, the cooling effect increases by 23.1%.

Table 1. Result of CFD simulation.

Case	Number of nozzles	Flow rate per nozzle	Total flow rate	Cooling effect [K]
1	64	15L/hr	960L/hr	-9.31
2	80	12L/hr	960L/hr	-8.78
3		14L/hr	1120L/hr	-10.81

3.2 Pilot plant test results

Table 2 shows no difference between nozzle A and B of cooling effect. Although the total flow rate of nozzle B is about 75% of nozzle A, they have almost same cooling effect. Because water mist size and distribution of nozzle B is smaller and better than nozzle A.

Table 2. Cooling effect by operating pressure.

	Input [K]	Output [ΔK, 30bar]	Output [ΔK, 40bar]	Output [ΔK, 50bar]	Output [ΔK, 60bar]
Nozzle A	387.15	45	45	45	45
Nozzle B		45	45	45	46

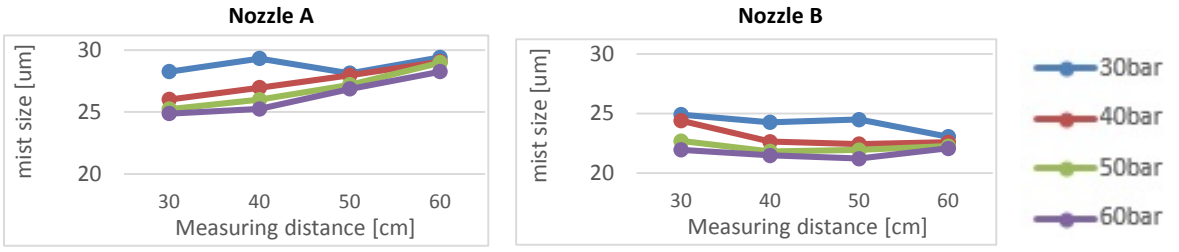


Figure 2. Water mist size by pressure.

4. Conclusions

We developed CFD model and optimized water mist system in refinery process. Pilot scale experiment for water mist system is conducted to find out mist size distribution and cooling effect depending on the nozzle A and B. Finally, we reduce the number of nozzles by 20% or amount of water by 25% to optimize the water mist system.

Immobilization of lipase onto micro tubular reactor for efficient production of (S)-ibuprofen.

Masakazu Naya*, Yuri Ikazaki, Katsuto Otake, Atsushi Shono

Department of Industrial Chemistry, Faculty of Engineering, Tokyo University of Science, Kagurazaka 1-3, Shinjuku-ku, Tokyo,162-8601, Japan

**Corresponding author: m.naya@ci.kagu.tus.ac.jp*

Highlights

- The activity of lipase on (S)-ibuprofen was confirmed by batch system.
- The immobilized lipase onto micro tubular has been prepared by multi-layer deposition.
- The reactivity of immobilized lipase was well conserved during repeated uses.

1. Introduction

Ibuprofen is an important drug material of NSAIDs and is sold as a racemate in the market. (S)-Ibuprofen has been reported to be 160 times more reactive than the (R)-ibuprofen. Currently established (S)-ibuprofen production methods involve complex organic synthesis. Lipases have been paid attention to lipid modifications [1]. They catalyzed hydrolysis, alcoholysis, acidolysis, amidolysis, and esterification in food and pharmaceutical industry. Some studies reported lipase reactivity for enantio synthesis of (S)-ibuprofen from racemate [2]. In spite of interesting performance of lipases, their application in industrial level is limited because of their cost and requires reuse of lipase for a practical process. We focused on immobilizing lipase onto micro tube and aimed to develop the reactivity of lipase for (S)-ibuprofen producing.

2. Methods

The polydopamine layer was used as a primer layer in polytetrafluoroethylene (PTFE) micro tube to provide inner surface of micro tube reactable groups. Polyethylenimine and *Candida rugosa* lipase were adsorbed on the PTFE surface by the layer-by-layer method. (S)-Ibuprofen production was initiated to introduce ibuprofen ester racemate as substrate into PTFE micro tubular reactor (Fig.1). The (S)-ibuprofen produced was analyzed quantitatively with HPLC.

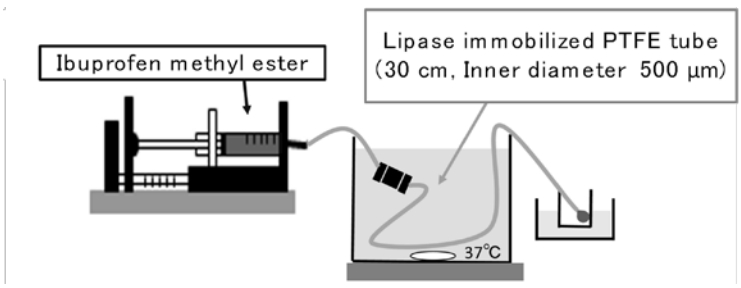

Figure 1. The experimental apparatus of (S)-ibuprofen production by immobilized lipase.

3. Results and discussion

The amount of loading lipase kept increasing as the number of layers increased by the 8th layer (Fig.2). The production yield of immobilized lipase on micro tubular reactor was developed than the yield prediction of batch system. The reactivity of immobilized lipase on tubular reactor (loading 3400 μg lipase) was determined by repeated reactions. The reactivity was well conserved during 8th repeated uses. It retained almost 80% of that of first reaction. The results successfully demonstrated that the immobilized lipase on PTFE inner surface was stable throughout the repeated uses.

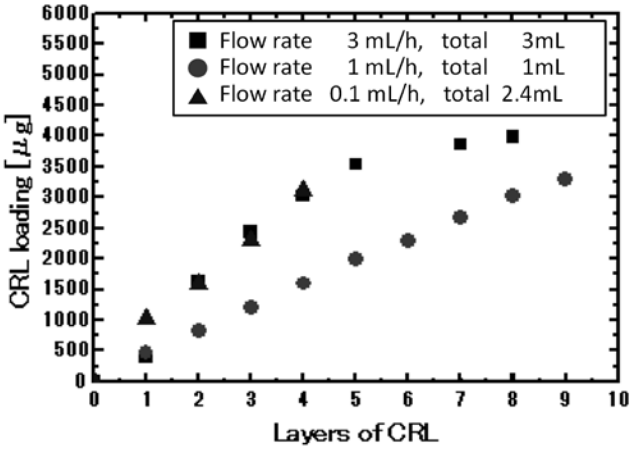

Figure 2. The amount of loading lipase by the multi-layer deposition on PTFE. The lipase loading kept increasing as the number of layers increased by the 8th layer.

4. Conclusions

The immobilized lipase onto micro tubular reactor has been successfully prepared by multi-layer deposition. Efficient performance of immobilized micro tubular reactor for production of (S)-ibuprofen was developed.

Integration of power-to-gas concepts with biomass gasification in the Swedish electricity grid

Johan M Ahlström[1*], Viktor Johansson[1], Lisa Göransson[1], Stavros Papadokonstantakis[1]

[1] *Chalmers University of Technology, 412 96 Gothenburg, Sweden*

Highlights

- A gasifier combined with an electrolyser implemented in an energy systems model
- The value of process flexibility is compared to hydrogen storage
- Results highlight the benefits of a flexible biomass gasification process

1. Introduction

The variability of wind and solar electricity generation will demand a flexible electricity system in the future. Simultaneously, increased demand for fuels and chemicals produced from biomass is expected in the future in response to climate change mitigation goals [1]. A power-to-gas concept, which produces H_2 and O_2 can contribute to balancing the electricity grid while increasing the output of biofuel production processes [2]. In the present study we suggest a concept where generated H_2 is utilized to increase the output of methane from a biomass gasification plant by converting CO_2 effluent from the gasification cold gas, using the Sabatier process. The purpose is to evaluate the value of having a direct, oxygen blown, gasification process that can use H_2 to increase production when it is economical, in relation to a process with constant H_2 demand.

2. Methods

In a previous study, four process configurations were assessed for the upgrading of the produced gas to biomethane [3]. The considered configurations differ in terms of how CO_2 separation and H_2 separation are placed in relation to the Sabatier reactor in the flowsheet. Here, two gasification processes are considered, a flexible gasification process which can utilize H_2 to increase production if it is beneficial from an economical perspective, and a non-flexible process that requires a constant feed of H_2. Data generated from a sensitivity analysis over model parameters is used to create a linear surrogate model for CAPEX, OPEX and biomethane production as a function of CO_2 recirculation and H_2 addition (applying the partial least squares method). The equations are implemented in a cost-minimizing regional electricity system model [4]. Actual wind, solar and load data from Sweden is applied. The model optimizes the cost of the total electricity system and can produce biomethane with or without H_2 addition; the biomass supply is limited to 100 TWh/year.

3. Results and discussion

Figure 1 shows the total H_2 production and the electricity price over one year for the two types of gasifiers, the flexible one that can use H_2 to enhance production of biomethane, and the one which requires a constant feed of H_2 to generate biomethane of sufficient quality. For both cases, the model produced biomethane using all available biomass. In the flexible case, H_2 is injected at 44% of the hours of the year, for the second case it is constantly required. The gasifier configuration

with an adjustable hydrogen demand (Fig. 1 a)) uses electricity for hydrogen production at an average price of 4.5 €/MWh. The electrolysers in the adjustable gasification process are dimensioned to meet the maximal hydrogen demand from the process. To avoid electricity generation in gas turbines, the electrolysers are used with a storage to produce fuel for fuel cells if the biomethane price is above 70€/MWh. Implying, that it becomes cheaper to generate electricity at peak-load with fuel cells rather than using biomethane as fuel in gas turbines.

For the configuration with a constant demand for process hydrogen (Fig. 1 b)), the average electricity price for hydrogen production is 47 €/MWh. When high priced electricity is used for H_2 production the value increases and there is an incentive to store hydrogen. Therefore, the optimized electrolyser is dimensioned with approximately 10% higher capacity than the maximum H_2 input. Both the adjustable process and the process with constant demand increase the value of wind power contra the value of thermal generation techniques.

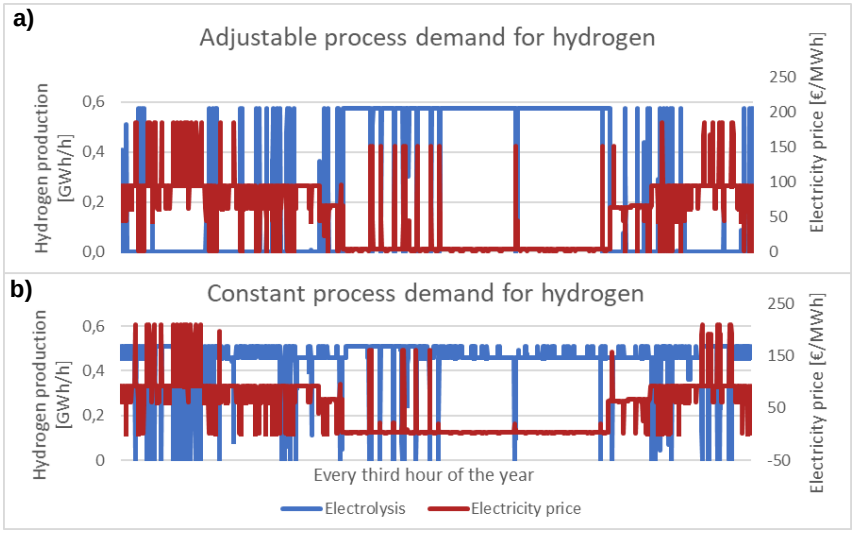

Figure 1. Hydrogen production and electricity price with a three-hour time resolution over 1 year. a) is a process configuration that can use H_2 flexibly, b) is a process configuration that need constant feed of H_2 to operate.

4. Conclusions

The adjustable gasification process uses low-priced electricity to increase methane production and the process with a constant H_2 demand avoids H_2 generation at the hours with highest electricity price by using storage. Both a static and flexible H_2 demand increases the economic benefits of constructing variable electricity generation. Thus, there is economic incentive to combine electrolysers with biomass gasification from a process perspective while it constitutes a driving force to increase wind power capacity. Future work will include analysis of the possibilities to include CCS in the gasification process and sensitivity analysis on important economic parameters, e.g. biomass price.

Highlights

- Superstructures for RSR loop and membrane reactor are optimized for maximal yield
- Dimensionless numbers (Da, Pe) are explored to define optimality domains of structures
- Discrimination criteria are built to delimit the optimality zone of membrane reactors

1. Introduction

The development of a sustainable industry for a successful energetic transition requires rethinking existing processes and/or designing innovative processes by applying Process System Engineering methodologies. Intensified devices and multifunctional units have been extensively studied in the last decades and have demonstrated their interest for cost minimization and plant optimization. Unfortunately, they are not systematically considered in conventional design approaches[1,2], whereas the early steps in process design are critical to define the technologies, utilities, control strategy, etc. and to assess the OPEX and CAPEX of a project.

The main objective of this work is to define quantitative criteria to choose the most interesting combination between a reaction step and a membrane separation unit, even at the early phases of the process synthesis. To do so, two cases are studied, optimized and compared: (i) a membrane separator in a Reactor-Separator-Recycle loop (RSR) and (ii) its integrated equivalent, a membrane reactor.

2. Methods

Two superstructures have been designed including either a reactor and a membrane unit, or an integrated membrane reactor (Figure 1). Both superstructures are parameterized by 4 and 2 split factors respectively, and characterized by physical data, such as the reaction stoichiometry and kinetics, reactor volume, membrane area, permeability and pressures. Numerical resolution of the mass balances gives access to all flow rates, compositions and performance criteria such as the overall yield of both processes. For a given chemical system, the split factors of each structure are optimized to maximize the yield. The single-pass conversion and two separation efficiencies are calculated for further comparison and criteria definition. Particular attention is drawn to multiple solutions and, if equivalent, the simplest solution in terms of structure is favored.

To generalize the investigation, the set of parameters is made dimensionless by introducing the permselectivity, the pressure ratio, the Damköhler number and the Péclet number: these

numbers enable to easily compare the reaction time, the space time and a characteristic time of the separation[3,4].

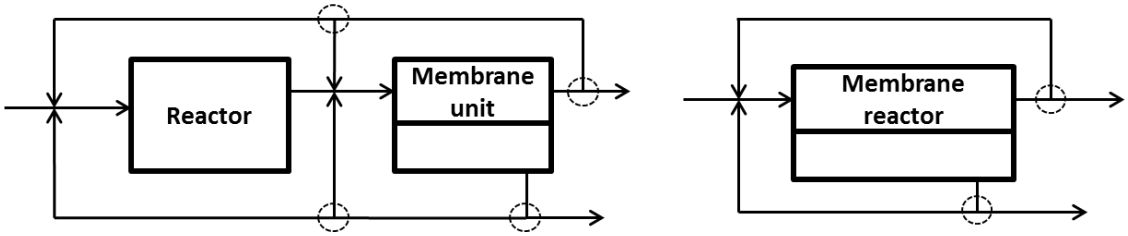

Figure 1. Superstructures studied for the RSR loop (left) and the membrane reactor (right). Dashed circles indicate the positions of split factors.

3. Results and discussion

Concerning the RSR superstructure, for a given chemical system, only a few non-trivial recycle schemes (among 49 possibilities) are optimal with respect to the overall yield: these optimal substructures can be directly related to the local efficiencies and can be discriminated by a simple criterion that describes the frontiers between their optimality domains.

Comparison of both structures confirms the technical superiority of the membrane reactor with respect to the overall yield for all studied cases: the multifunctional unit systematically exhibits a higher criterion than the RSR structure. Nevertheless, the possible gain is not significant over the whole range of dimensionless numbers: both optimized structures may exhibit very similar yields depending on the dimensionless numbers.

For definition of appropriate discrimination criteria, the existence of trivial and multiple optimal solutions requires exploring only a relevant part of the dimensionless space: the Da number should be large enough to enable sufficient single-pass conversion, the permselectivity and pressure ratio should be coherent with typical values, etc. On this basis, the zone of significant superiority of the membrane reactor can be circumscribed.

4. Conclusions

Two superstructures and corresponding balance equations describing the overall efficiency of a RSR loop and a membrane reactor have been studied, enabling to determine the maximum attainable yield and the associated optimal structure to solve a generic reaction separation problem. Exploration of the parameter space enabled to define discrimination criteria and optimality domains, with respect to this technical criterion.

Even if the overall efficiency described in this work is an important parameter in the decision-making procedure for process design, further works should focus on including economic aspects as main criteria for decision-making between uncoupled and multifunctional units.

Investigation of control and on-line optimisation opportunities of a wastewater treatment plant

Harry Laing[1 *], Chris O'Malley[1], Mark J. Willis[1], Anthony Browne[2]

1 Newcastle University, School of Engineering, Merz Court, Newcastle University, Newcastle upon Tyne, NE1 7RU, United Kingdom; 2 Northumbrian Water, Boldon House, Wheatlands Way, Pity Me, Durham, DH1 5FA

**Corresponding author: h.j.laing@ncl.ac.uk*

Highlights

- A Mixed Integer Linear Programming approach is applied to Biogas Production
- Retrospective Optimisation reveals potential annual savings of over 11%
- An optimal operational strategy is provided for plant operators

1. Introduction

Northumbrian Water (NW) anaerobically digests up to 40,000 tonnes of sewage sludge (dry solids) annually at their plant on Tyneside, producing renewable Biogas. Typically, Biogas produced on a wastewater Anaerobic Digestion (AD) plant in the UK is used to generate electricity only. Many sites are looking to upgrade to produce Biomethane for injection into the National Gas grid to take advantage of the government's Renewable Heat Incentive [1]. The Tyneside Advanced Anaerobic Digestion (AAD) plant is a rare case in that it has three possible uses for Biogas produced on site: upgrade for injection into the national gas grid; burning it in Combined Heat and Power (CHP) Engines; or burning it in Steam Boilers for the thermal hydrolysis plant. There are three CHP Engines, three Steam Boilers and one Gas Upgrade/Injection plant on site. If required, the plant may flare excess biogas. In addition, to ensure overall sludge processing remains unimpeded the plant may draw Natural Gas from the national gas grid to be used in the CHP Engines or Steam boilers.

Currently, there is no model on site to advise the optimal distribution of Biogas produced or how much Natural Gas is required to be purchased to ensure optimal cost and sludge processing performance. This work develops an optimal site gas distribution strategy, to enable operators to validate and make improved decisions.

2. Methods

Each unit is able to process a maximum volume of Biogas or Natural Gas on a daily basis. These processing limits were determined thorough retrospective analysis of plant operational data and are different for Biogas and Natural Gas volumes. Work reported in [2] was adapted to apply a Mixed Integer Linear Programming (MILP) approach to minimise total plant operational cost, T_C:

$$T_c = \sum_{t=1}^{H_t}(C_b\, B_{CHP}\, z_i) + \left(C_n N_{CHP}(1-z_i)\right) + \sum_{t=1}^{H_t}(C_b\, B_S\, z_i) + \left(C_n N_S(1-z_i)\right) + \sum_{t=1}^{H_t}(C_I\, B_I\ + \sum_{t=1}^{H_t}(C_f\, B_f)$$

C_b C_n C_I and C_f is the cost of burning Biogas, Natural Gas, Biomethane Injection and flaring Biogas retrospectively, B_{CHP} B_S B_I and B_f are biogas volume to CHP Engines, Steam Boilers, Injection and

Flaring respectively, N_{CHP} and N_S are Natural Gas to CHP Engines and Steam Boilers respectively, and z_i is a binary variable used to ensure only one of each gas type is used by each unit, subject to $z_i \in \{0,1\}$, $(\forall\, t = 1 \ldots H_t)$, where H_t is the operation horizon in one day intervals.

The optimiser was implemented using MATLAB's *intlinprog* function to minimise plant costs.

3. Results and discussion

The optimiser takes total daily biogas production on site and optimises the overall gas distribution, providing the operator with a visual operation strategy (Figure 1). Each daily optimisation also has an associated operational cost, which is used to perform Retrospective Optimisation (RO) of plant operations.

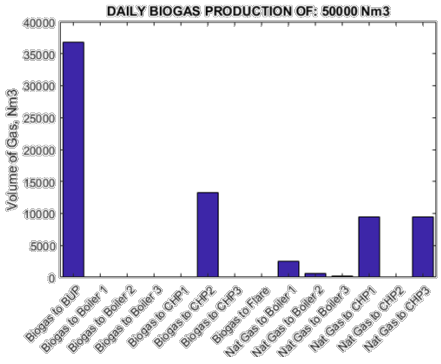

Figure 1. Optimal Gas Distribution on site for daily production of 50,000 Nm3 of Biogas

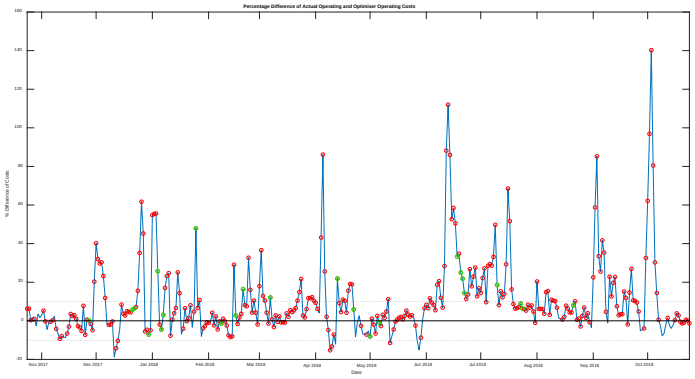

Figure 2. Daily RO result over 12 month period. 0% Difference is optimal. Red dots indicate days where flaring occurred but was unnecessary. Green dots indicate optimal performance.

RO of the daily optimal operational cost compared to the actual historical operational cost was performed for the 12 month period Nov 2017 to Oct 2018 (Figure 2). Initial RO results indicate potential annual operational cost savings >11% (>£0.5m). At times the plant operates more efficiently than the optimiser predicts. This is due to the static nature of model parameters that are an average of overall annual performance, and will be rectified in future work.

4. Conclusions

Our work indicates there are potential annual savings of over 11% to operational costs that could be achieved through improved operational strategies; the daily optimal operation strategy is provided to the operators in visual form, though weekly strategies are also possible if required. Further work is to be carried out to provide operators with a full sludge processing optimisation model, including a biogas production model to allow for improved operational forecasting.

**Jamal HAMDANI: jamal.hamdani@um6p.ma*

1. Introduction

Biological processes such as classical activated sludge treatment or membrane bioreactors (MBR) are the process the most used for the treatment of wastewater within the last decades. In recent years however, we are witness to an increase of global inflows entering wastewater treatment plants (WWTP), whereas authorized levels of pollutants in the outflows get more and more reduced. To face this context, WWTP new units have to become more and more efficient and a great attention is now paid to the optimization of treatment processes of both wastewater and excess wastewater sludge. In the present work, rheological approach is investigated to optimize wastewater treatment plan using a bench test device specially developed for the purpose of this work.

2. Methods

The rheological bench used consists in a bioreactor equipped with a double helical ribbon impeller fixed on a motor (HRI system) and a recirculation loop in which the sludge flows in pipes (pipe system) of 2 different diameters used to measure the "in situ" rheological behavior of activated sludge. The pipe system is equipped with two differential pressure transmitters and a flow meter to measure the pressure drop and the volumetric flow rate. This permit to draw the rheograms of sludge in pipes. For each solid concentration (TSS) studied, the parameters (τ0, K and n) of the Herschel-Bulkley model are determined based on the reference rheograms measured by the Couette rheometer (AR550). These rheograms are then compared to the one obtained with the different in situ configurations (HRI and pipes).

3. Results and discussion

HRI rheograms always show a good agreement with the reference one. On the contrary, pipes rheograms do not always match the reference. Wall slips phenomena are observed for each TSS concentrations, notably depending on the pipe diameter. At low concentration, slip is only observed for the pipe with the smaller diameter whereas at high concentration slip is present with both pipe configurations. Slip phenomena have been taken into account using slip correction calculations. Plotting the slip velocity curves as a function of the wall shear stress, we can distinguished two types

of phenomena responsible for wall slip: the static depletion and the particle migration. The occurrence of each mechanism is dependent on interparticles interactions via the TSS concentration.

Root cause diagnosis of multiple process faults: Integrating pattern matching with active simulation

Weijun Li[1], Xiangping Zhang[2], Sai Gu[1], Tao Chen[1]*

[1] Department of Chemical and Process Engineering, University of Surrey, Guildford GU2 7XH, United Kingdom; [2] Beijing Key Laboratory of Ionic Liquids Clean Process, Institute of Process Engineering, Chinese Academy of Sciences, Beijing 100190, China

*Corresponding author: t.chen@surrey.ac.uk

Highlights

- A novel and effective framework for root cause diagnosis.
- Applicable to both single fault and multiple faults.
- Integrating mechanistic model, pattern matching and optimisation.

1. Introduction

With increasing demand on process safety, fault detection and diagnosis (FDD) has attracted considerable attentions [1]. Despite the significant success in fault detection and isolation, root cause analysis remains a challenge for data-driven methods [2]. On the other hand, dynamic process simulations, based on mechanistic models, encapsulate a large amount of process knowledge especially the causal information, thus could be an effective tool in root cause diagnosis. Although hybrid mechanistic-empirical modelling is well known, its application in FDD for medium-to-large scale industrial processes has not been well explored. In this work, a generic root cause analysis method applicable to both single and multiple faults is developed by use of mechanistic model and pattern matching technique. Case study with the Tennessee Eastman (TE) process [3] is conducted to demonstrate its effectiveness, and the current limitations and potential solutions are discussed.

2. Methods

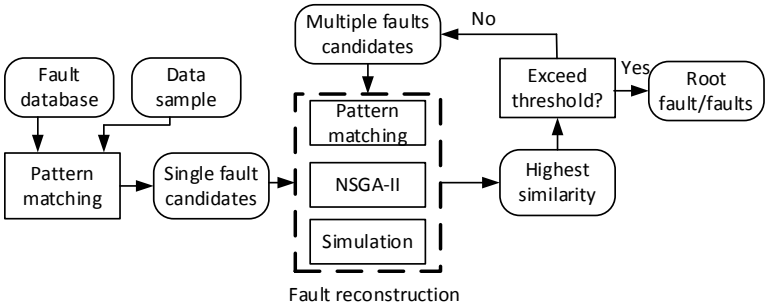

Figure 1. Flowchart of the proposed root cause analysis method.

The proposed strategy is summarised in Figure 1. Firstly, a fault database is built by simulating process faults at different magnitudes offline. Then, the operational data sample is compared with the database to screen fault candidates. From the candidates, the root cause is further confirmed

by use of an optimisation based fault reconstruction method, in which a multi-objective optimisaiton algorithm (NSGA-II: Non-dominated Sorting Generic Algorithm II [4]) is used to search for the root cause of the fault based on pattern matching [5] and process simulations. Two similarity metrics are employed in the pattern matching, i.e. PCA similarity (Spca) and Mahalanobis distance similarity (Sdist). Spca measures the similarity between datasets by relative angles between their principle components while Sdist by the distance between their centers.

3. Results and discussion

Figure 2(a) and 2(b) show the results in diagnosing single fault (caused by IDV1) and multiple faults (caused by IDV1+IDV7), respectively, in which IDV indicates the disturbances as described in [3]. Similarities (Spca and Sdist) displayed in Figure 2 represent the average values over individuals at each iterations in the optimisation. Figure 2(a) successfully identifies IDV1 as root cause of the single fault due to its much improved similarity values after optimisation. In Figure 2(b), the similarities of all the candidates are still low (symbols connected by solid line) after optimisation. Considering multiple faults scenario, we further evaluate candidate combinations and identify IDV1+IDV7 (the red dotted line) as the root cause due to its much improved similarities.

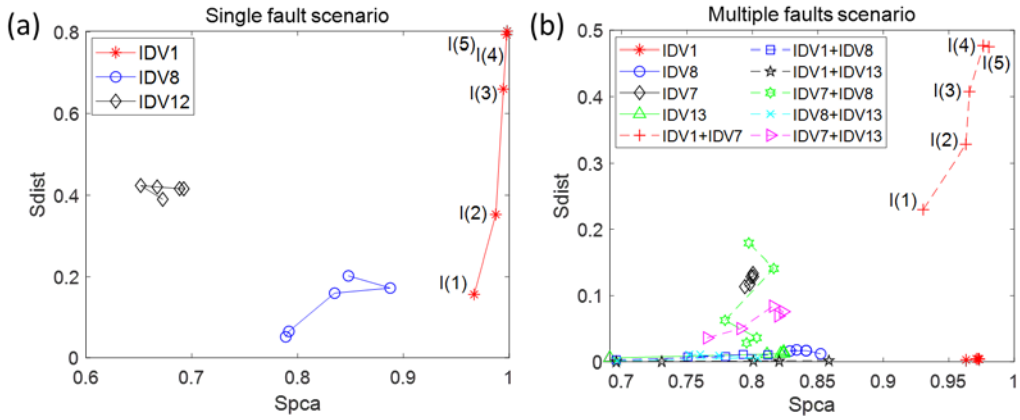

Figure 2 Similarity of candidates after fault reconstruction; I(i) indicates the i-th iteration during the optimisation.

4. Conclusions

This work proposes a novel root cause diagnosis method and demonstrated its effectiveness with the TE process. It is worthy to note its effectiveness depends largely on two aspect: 1) real-time model update technique to lessen model-plant mismatch; 2) pattern matching method effectively extracts similar features between operational and simulated dataset.

Optimization Study to Maximizing Heavy Naphtha Draw from a Condensate Distillation Unit

Mohammad Shamsuzzoha*, Mohammad Abdur Rakib, Mohamed Al-Musharfy

Research Centre Division, ADNOC Refining, Post Box: 3593, Abu Dhabi, UAE

**Corresponding author:* mshamsuzzoha@adnoc.ae

Highlights

- A rigorous simulation model has been developed in rating mode for an existing condensate distillation column to obtain the optimal condition.
- The calibrated model has been run for different cases to obtain the optimal seniors to maximize the deep cut naphtha.

1. Introduction

Steady-state process simulations provide powerful insights into the plant behaviour which can be used to enhance designs, safety and operations of oil refinery units. The process simulation model can be utilized in several ways from design stage to operation in oil refinery i.e., efficient and profitable designs, achieve consistent product quality, analyse plant operations, monitor & optimize operations and real-time optimization etc.

In order to explore sources of increased demand of heavy naphtha for increasing the throughput of heavy naphtha reformer for an additional heavy naphtha reformer, a rigorous simulation model was developed in process simulation software for an existing condensate distillation column. The model was tuned using test run data. Assays information for various sources of the condensate feed mix were studied, and implemented in the feed definitions to see the impact of different feed mix ratios. Since monitoring the benzene precursors for the downstream section is an important requirement, special attention was given to include detailed naphtha component analysis while defining the assays for the different condensates. A Peng-Robinson (PR) Equation of State was utilized while developing the rigorous tray-to-tray model. The model captures detailed heat exchanger networks with heat recovery from the column pump arounds. Hence the model was capable of evaluating different scenarios and studying the equipment limitations, especially the heat exchangers. An optimum scenario was thereby proposed to maximize heavy naphtha yield with details of benzene precursors for the downstream heavy naphtha reformer.

2. Methods

The calibrated model has been run for different cases to obtain the optimal seniors to maximize the deep cut naphtha. The heat duty of the overhead section of the main fractionation column has been main constraint in the column. The column overhead section constitutes both the air and trim cooler to achieve required reflux temperature.

3. Results and discussion

Therefore, in last three cases, the limiting overhead duty of 40 Gcal/hr has been restraint to keep draw adequacy and limitation of the unit overhead section.

Case 1: Calibrated model with plant data.
Case 2: Deep cut heavy naphtha 100-180°**C** EP.
Case 3: Heavy naphtha flow rate of 175 m^3/hr.
Case 4: Heavy naphtha flow rate of 155 m^3/hr, limiting overhead duty of 40 Gcal/hr.
Case 5: Heavy naphtha flow rate of 165 m^3/hr, limiting overhead duty of 40 Gcal/hr.
Case 6: Heavy naphtha flow rate of 175 m^3/hr limiting overhead duty of 40 Gcal/hr.

4. Conclusions

One the basis of the equipment adequacy and limitations, Case 5 has been selected for the design purposes. This case has heavy naphtha draw rate of 165 m^3/hr and limiting overhead duty of 40 Gcal/hr. The predicted results have been compared with the plant data, for yields and different other properties e.g, SG, flash point, freezing point and pour point. The products qualities show that the results are in line with expectation as.

Conceptual study on coal power plant transformation to metal power plant; A look into the future

P. Awad[1*], R.G. Baltazar[1], I.D. Garcia[1], E. Dijkman[1], P.L.J. Swinkels

TU Delft, Chemical Engineering Department, Van der Maasweg 9, 2629 HZ Delft, Netherlands

Highlights

- Iron oxide power plant conceptual design
- Reduced carbon emission power plant
- Reduction of iron oxide with carbon monoxide from dry methane reforming

1. Introduction

Greenhouse gases have been exhibiting a rapid increase recently. Coupled with the will to ensure security of energy supply, governments are trying to change the source of energy to other fuels, reducing the production and emission of these gases. As part of these efforts the Dutch government decided in May 2017 to stop using coal for electricity generation in the very near future.

The objective of this work is to assess the feasibility of a swift shift from coal-fired power plants to metal fuels power plants. A preliminary conceptual design is performed taking as a reference the existent Uniper's coal power plant in Rotterdam, the Netherlands.

2. Methods

For this project the Delft Design Map method is used [1]. The general approach of this method is to explore a wide range of options hierarchically. It consists of different design levels, from which the following are used in this work: Project Framing, Costumer Wants, Input-Output Structure, Subprocesses, Task Network, Unit Network and Process Integration.

Regarding the design itself, current assets of the existing coal plant was maximized. Preliminary and shortcut design methods were used whenever appropriate and preliminary cost estimations (±35%) were applied. Three main critical design decisions characterize the project outline, reflecting the final process design and the respective economic evaluation.

1- Input-output structure.

Process options are examined using input-output diagrams to decide on metal fuel type(s), regeneration need, extent and percentage of regeneration. Low cost of iron ore (mainly FeO), coupled with its oxidation stability and geographic availability are the main reasons for selecting it as the main raw material. It was also decided to use regeneration to FeO instead of reduction to pure Fe after some high-level mass balance and cost analysis calculations. Iron Oxide regeneration allows for a significant reduction of both required metal fuel needed as well as the waste stream.

A number of reducing agents and methods for regenerating the Fe_2O_3 combustion product were evaluated: hydrogen, carbon monoxide, iron electrolysis, micro-organisms and biomass. Then, carbon monoxide produced from dry methane reforming was selected due to the advanced

development stage of the reduction reaction and low investment. The production of CO is advantageous since it uses carbon dioxide to produce carbon monoxide, with hydrogen as by-product. A cyclic process was designed in order to minimize CO_2 emissions and introduce a flexibility of using CH_4 potentially from a bio source as a supplementary fuel to the process.

2- Process thermodynamics

Introduction of the Brayton cycle to the current existing Rankine cycle was another important decision. Furthermore, using exhaust gases from the furnace to heat the medium pressure steam results in a higher energy produced per raw material consumed. The absence of any carbon source creates an opportunity to use a turbine in this stream due to higher density providing higher separation efficiency upstream of the turbine. The combination of these two factors result in an increase in efficiency from 47% to 60%, primarily caused by the steam temperature upgrade.

3- Waste treatment

The purge stream from the iron cycle is considered as an added-value stream to the steel industry. Compared to the conventional inlet iron ore stream, produced iron oxide waste (Fe_2O_3) from this process is richer in oxygen and has a lower impurity content. Therefore, it can be sold at an interesting price to the steel industry. Furthermore, this reduces the demand for mining in the steel industry.

3. Results and discussion

Preliminary design and cost evaluation for this conceptual design resulted in a -1300 M€ NPV which is unacceptable for an investment. Raw material demand proved to be the largest cost driver. However, the project was initiated with future scenario's in mind. It was already known at the start that currently it is not yet economically feasible. The question was how far from economic feasibility it actually is, and what needs to change before it will become economically feasible, and when this is expected to take place. Carbon tax used in this work was set around €50/ton but it is uncertain when this will shift to higher values. A significant reduction on the raw material price would change NPV drastically. This can be achieved by researching other sources for the raw material, such as metal scraps from the car industry.

4. Conclusions

A metal fuel power plant as a replacement for a coal-fired power plant proved to be economically infeasible under the current circumstances and market values. However, when compared to conventional coal power plant, of which NPV is zero for €72/ton carbon tax, it reaches the same (negative) NPV once carbon tax is €103/ton. Figure 1 shows the relationship between NPV values and carbon tax values for both a conventional coal power plant and metal fuel one.

Highlights

- Precipitation process of particles generated from electrochemical Cr(VI) removal process is studied.
- The effect of the average velocity gradient on the sedimentation velocity was evaluated.
- The produced sludge form the Cr(VI) reduction was characterized.
- The sludge from the electrochemical process has chromite, which have potential reuse.

1. Introduction

Wastewaters from the chromate conversion coating have high concentrations of Cr(VI), which is a high toxic substance. Electrochemical process has been applied to remove the Cr(VI) from the industrial wastewaters [1]. During the process Fe(II) ions are released from a sacrifice iron electrode. These ions reduce the Cr(VI) to Cr(III) and the Fe(II) is oxidized to Fe(III) form. Both, Cr(III) and Fe(III) are precipitated at basic pH. There are no studies to evaluate the effect of the hydrodynamic conditions on the precipitation process of particles generated from electrochemical Cr(VI) removal process, which is important to reduce the sludge volumetric index (SVI) and optimize the coagulation and flocculation conditions, such as the reagents use, the agitation velocity and the precipitation pH. During flocculation the hydrodynamic behavior have important effects on the flocs characteristics. The velocity gradient is an important parameter that affects the flocs characteristics, because its size depends on the balance between the flocs agglomeration due to de mixing and the breaking of them because the energy kinetic dissipated [2]. Both effects depend on the agitation power supplied. To characterize the performance of agitated tanks used in fluctuation process, the average velocity gradient in the vessel (G_{ave}), is used (equitation 1).

$$G_{ave} = \left(\frac{\varepsilon_{ave}}{\nu}\right)^{1/2} = \left(\frac{N_p N^3 D^5}{V\nu}\right)^{1/2} \quad (1)$$

where: μ_{ave} = average energy dissipation rate, ½= kinematic viscosity, N_P = power number, $\acute{A}$ = density of liquid, N = rotational speed of impeller, D = impeller diameter.

In this work, the effect of the G_{ave} on the precipitation process of particles generated from electrochemical Cr(VI) removal process is studied. In addition, the sludge obtained was characterized.

2. Methods

The experimental tests were performed in a jar test apparatus with square transparent vessel of 2 L of capacity, with paddles of 7.6 cm of diameter. The sample was taken from a laboratory electrochemical reactor used to remove the Cr(VI) from wastewater. The wastewater was prepared with $K_2Cr_2O_7$. The pH was increased with NaOH 8M. During the tests, a rapid mixing at 200 or 100 rpm during 60s was applied, followed of a slow mixing at 50 or 25 rpm during a flocculation time (t_f). The t_f tested were 5,10, 20 and 30 minutes. After this, the sedimentation velocity (V_s) was evaluated. The sludge obtained was characterized by Raman spectroscopy.

3. Results and discussion

Figure 1a, shows the results obtained of the V_s variation as a function of the accumulated G_{ave} (G_{ave}·t_f). As can be seen, as G_{ave}·t_f (is reduced until about 200 the V_s drops, but it increases linearly until values of accumulated G_{ave} of 75, reaching a V_s = 0,42ms^{-1}, where after this value the V_s is almost the same (0.45ms^{-1}) at lower G_{ave}·t_f, which means that the agglomeration and breaking flocs forces are in equilibrium [2]. On the other hand, figure 1b, shows the results of the characterization of the produced sludge form the Cr(VI) reduction electrochemical process.

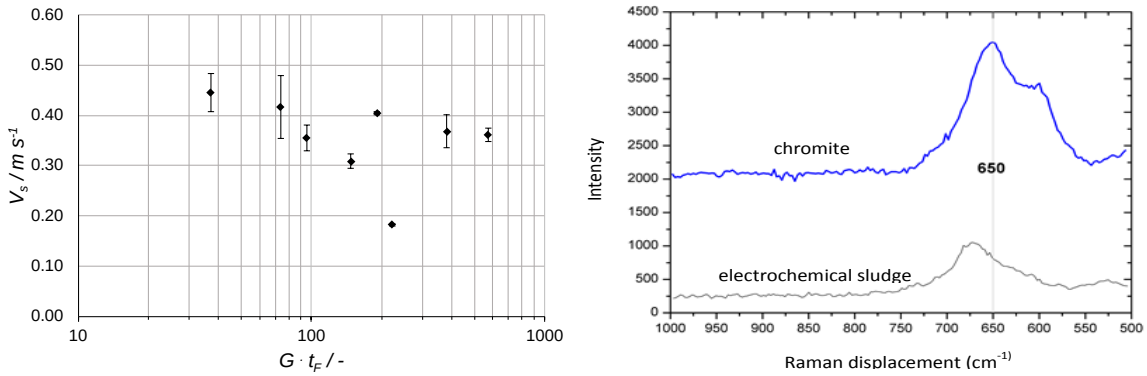

Figure 1. a) V_s variation as a function of the accumulated G_{ave} (G_{ave}·t_f), b) characterization of the produced sludge.

As it is shown, the sludge has chromite, which have potential reuse.

4. Conclusions

Based on the results, the G_{ave} to operate satisfactorily the flocculation process were obtained. The sludge produced during the electrochemical process has chromate which can be reused.

Simulation of methanol production from different point sources of CO_2

Tina Kegl[1], Blaž Likozar[2], Anita Kovač Kralj[1], Rok Gomilšek[3], Gregor Kravanja[1], Lidija Čuček[1]

1 Faculty of Chemistry and Chemical Engineering, University of Maribor, Smetanova 17, Maribor, Slovenia; 2 National Institute of Chemistry, Hajdrihova 19, Ljubljana, Slovenia; 3 Talum Inštitut d.o.o., Tovarniška cesta 10, Kidričevo, Slovenia

**Corresponding author: lidija.cucek@um.si*

Highlights

- Methanol production is a promising option for significant CO_2 emission reduction
- Influences of impurities and concentrations from point sources of CO_2 are studied
- Various catalysts and the dynamics of catalyst deactivation are analyzed
- Sensitivity analysis is performed to obtain simple economic bound of alternatives

1. Introduction

Human activities have led to an increased concentration of greenhouse gas emissions in the atmosphere, mainly by burning of fossil fuels [Vooradi et al., 2018]. Since the beginning of the industrial revolution the concentrations of CO_2, the principal greenhouse gas, has risen from 280 ppm to 400 ppm [Zhang and Huisingh, 2017]. In order to stabilize the global CO_2 concentration in the atmosphere, carbon capture and sequestration are estimated to play a major role in the reduction of CO_2 emissions [Kravanja et al., 2018]. However, more sustainable and economically-promising option for greenhouse gas emission reduction is CO_2 utilization [Roh et al., 2016], which is also in line with industrial ecology and circular economy. Captured CO_2 at different large point sources [Meylan et al., 2015] could be converted by chemical pathways [Rafiee et al., 2018] into commercial products such as syngas, methane, methanol, ethanol, organic acids and many other fuels and chemicals [Norhasyima and Mahlia, 2018]. It could also be used directly (by physical pathway) [Rafiee et al., 2018] in carbonated beverages, fire extinguishers, as a refrigerant, extractant, in enhanced oil and gas recovery, in algae farms and other applications [European Commission, 2018]. CO_2 emission reduction opportunities from point sources are shown in Figure **1**.

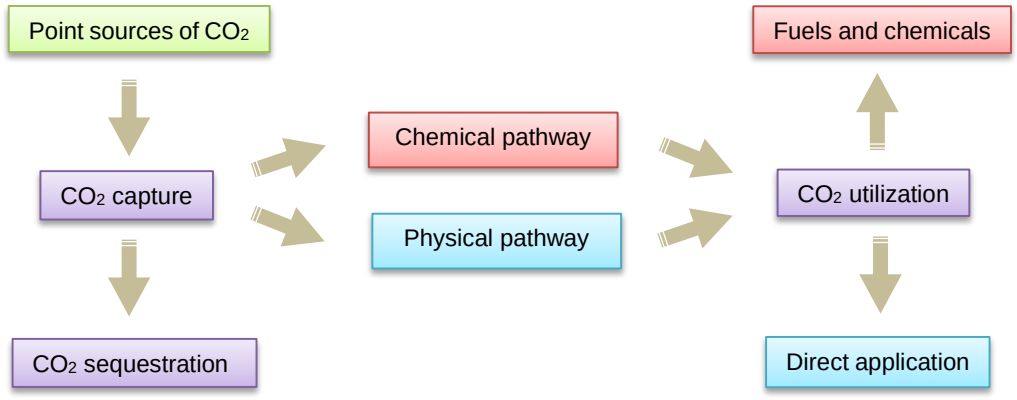

Figure 1: Schematic of CO_2 capture, sequestration and utilization from point sources

2. Methodology and results

This contribution presents simulation of methanol production as a promising option for significant CO_2 emission reduction. Methanol, as one of the most useful products, has multiple industrial applications, such as it could be used for production of formaldehyde, acetic acid, dimethyl ether and other chemicals [Van-Dal and Bouallou, 2013], as a fuel, solvent, energy carrier and in many other applications [Dalena et al., 2018]. Simulation is performed for different point sources of CO_2, from power plants, cement factories and aluminium industry. Influences of impurities and CO_2 concentrations in the flue gas on methanol production are investigated. As the feasibility of the process largely depends on the catalyst, simulation also considers various catalysts and the dynamics of catalyst deactivation. Finally, sensitivity analysis is performed in terms of CO_2 capture cost, prices of CO_2 allowances and methanol prices to obtain simple economic bound [Biegler et al., 1997] of various studied alternatives.

Preliminary results show that by MEA absorption about 50 % CO_2 was captured from flue gas, and methanol conversion from captured CO_2 was around 30 %. Furthermore, the effect of impurities content on the methanol productivity was determined in the packed bed reactor. It was found, that the reaction rate of methanol formation decreased significantly with the addition of higher percentages of impurities. In terms of the stability of catalyst in the parallel packed bed reactor in the aging tests, it was found that aging does not influence CO_2 conversion significantly.

Highlights

- Formaldehyde is sourced from methanol and air and used for melamine non-woven material
- Environmental evaluation of renewable formaldehyde from biomass and waste is performed
- OpenLCA software, ecoinvent 3.1 database and data from Aspen Plus models are used
- Environmental evaluation is compared with non-renewable formaldehyde from natural gas

1. Introduction

Melamine Etherified Resin (MER) non-woven, commercially known as smartMELAMINE, have a great potential for various applications, such as mobility, as a construction material, for thermal protection (fire blocker, thermal protective clothing, thermal insulation), filtrations and other industrial applications. To produce MER non-woven, mainly formaldehyde and ammonia are used as raw materials. Both could be produced from renewable sources and offer great potential for reducing environmental burdens. Formaldehyde is produced from methanol and air, where methanol could be sourced from various waste materials, while ammonia could be produced from nitrogen by using renewable sources (renewable hydrogen and electricity).

2. Scope

In this contribution environmental evaluation of formaldehyde is performed, which is sourced from renewable methanol, to be used to produce melamine non-woven material. Various waste materials for formaldehyde production are considered, such as wet and dry biomass, waste plastics and waste CO_2. Environmental evaluation is performed with OpenLCA software using the ecoinvent 3.1 database and the data from process models developed using Aspen Plus simulator. Environmental burdens are further compared with those using natural gas as a raw material for formaldehyde production.

Highlights

- Extraction, optimal extracting agent – Laboratory & ChemCAD simulations.
- Distillation, energy demands calculations – Laboratory & ChemCAD simulations.
- Pretreatment of waste water – Reaction & Chemical quantity optimization.
- Green chemistry – viewpoints and goals.

1. Introduction

Whether an aromatic chemical is nitrated via mixed acid processes [1] the nitrated products are washed with acidic, neutral and alkaline waters in order to purify them. Almost all water soluble side products will be dissolved from the products and will appear in the water phase in form of its salts [2].

The waste waters will have also products dissolved, which are unfavorable thus extraction is carried out. Product specific extraction is needed thus undesirable chemicals would not be extracted back. Optimization of extraction is a main target of our experiments, so intermediates and starting materials were tested to measure its capacity and selectivity.

2. Methods

First the technology and possibilities was checked. Alternative chemicals were measured, data were put into ChemCAD. After the data refresh, simulations were carried out [Figure 1]. Optimal solutions were tested in laboratory; results were measured by various analytical methods, HPLC, GC, UV-VIS and FTIR [3].

Energy optimizations and toxicity measurements were tested in ChemCAD and laboratory plant seed tests respectively.

3. Results and discussion

More comparison happened with the extracted waste waters, which was focused on alkaline washing water which is the richest in side-products. The main key factors were the distillation possibilities of the extracting agent, and the pre-treatment investigation related with Fenton oxidation.

Green chemistry factors were checked and examined, and we can say, with optimal extraction agent 60 wt% more products can be extracted from the waste water, which would be more pure because of better selectivity. The distillation energy needs is 80% less for the optimal extracting agent [4]. The pre-treatment requires 30 wt% less oxidation agent, and the total nitrate amount

would decrease by 25 wt% in the alkaline waste water [5]. The toxicity of the waste water is reduced by 20% [5].

Fenton oxidation catalyst optimization might cause also reduced amount of waste iron catalyst in the pre-treatment system.

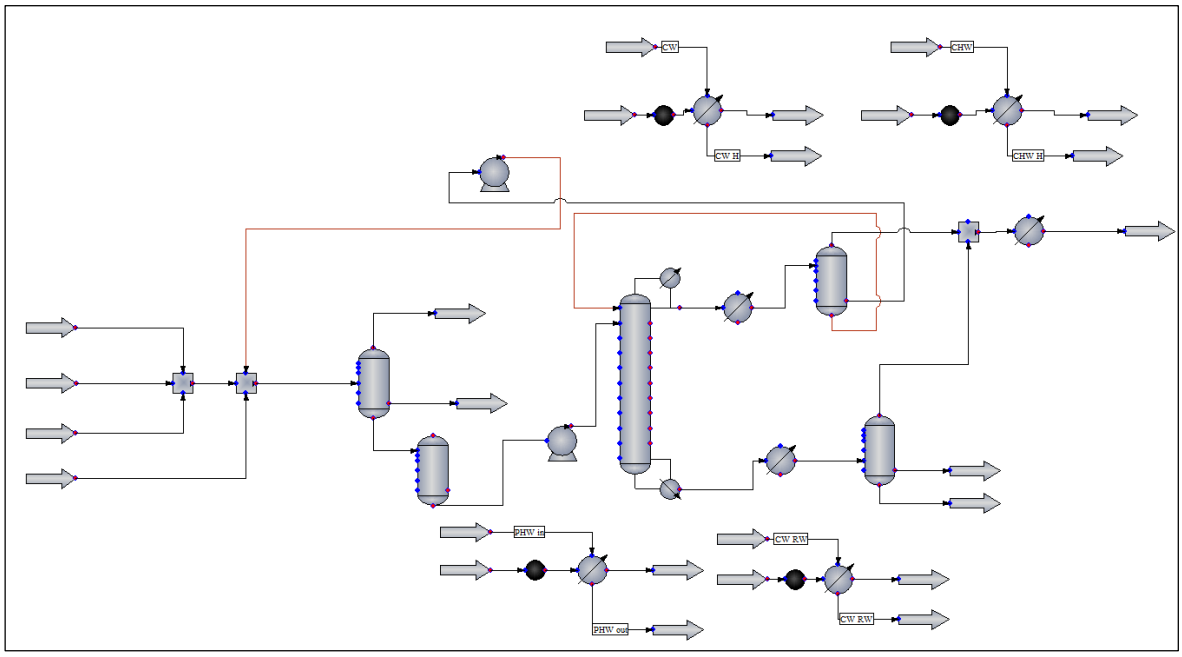

Figure 1. Simulations were set up in ChemCAD environment.

4. Conclusions

When choosing a good extracting agent, it is really important to follow the steams until it is disposed or treated in biological systems. Choosing the best can be difficult, but whether the data are correct that people have, it is recommended to calculate, measure and upscale if possible, before applying one technology. By using computational methods and simulations, cost reduction can appear, it makes easier to find the optimal chemical processes.

First Attempt for Robust Bubble/Dew Problem Solution with Bender EoS

Filippo Bisotti[1], Flavio Manenti[1*]

1 Politecnico di Milano, DMIC Department "Giulio Natta", Piazza Leonardo da Vinci, 32, 20133, Milan, Italy;

Highlights

- Thermodynamic package available only for Air Separation Unite
- Attractive to be used in simulation environment
- Presence of twenty fitting parameters makes Bender EoS very flexible and efficient
- Development of numerical tricks to avoid any trivial and unfeasible solutions

1. Introduction

The Bender Equation of State is a specific thermodynamic package available for Air Separation Unit. Bender EoS is essentially composed by twenty fitting parameters which let very flexible and efficient prediction of thermodynamic of air mixture. The model has been implemented to solve bubble/dew problems. The main difficulty is to avoid the convergence of the system toward trivial solution, which is actually unfeasible. In addition, strong nonlinearities in the formulation of the Equation of State and in the mixing rules make the solution quite stiff (Figure 1), where for very small change of the density value, pressure solution rapidly diverges. Therefore, some tricks have to be applied in order to drive the system toward the right solution

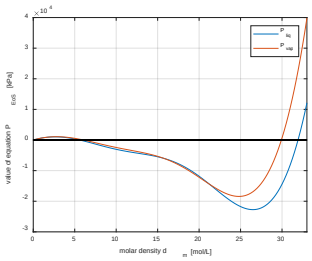

Figure 1 – pressure prediction with Bender EoS for liquid (blue line) and vapor phase (red)

2. Methods

In order to solve a vapor-liquid equilibrium the following nonlinear system has to be solved

$$\begin{cases} f_k^{vap} - f_k^{liq} = 0 & for\ k = 1\ (N_2), 2\ (Ar), 3\ (O_2) \\ P - P_B^{vap} = 0 \\ P - P_B^{liq} = 0 \\ \sum_{k=1}^{3} x_k - 1 = 0\ \vee\ \sum_{k=1}^{3} y_k - 1 = 0 \end{cases}$$

According to the thermodynamic model, pressure is function of temperature, density and composition of the phase (m): temperature and pressure dependence appear in mixing parameter

$$P_m = d_m T \left[R + \left(a_1 - \frac{a_2}{T} - B \right) d_m + C d_m^2 + D d_m^3 + E d_m^4 + F d_m^5 + (G + H d_m^2) d_m^2 \cdot \exp(-a_{20} d_m^2) \right]$$

To prevent any possible divergence of the solution due to nonlinearities, a sensitivity analysis on the several mixing coefficients and, finally, on the global term appearing inside the square brackets has been done. This clearly depicts that exists for both phases a feasibility region owing to that absolute pressure cannot be negative. Obviously, this criterion is adopted to remove any potential unfeasible behavior of the model in any iteration during the nonlinear system solution. The system has been solved in VSC++ 2013 combined with the BzzMath Library numerical tools.

3. Results

Figure 2 compares the solutions of dew problem in pressure for dry air with the results of other EoS directly implemented in Aspen-Hysys: Peng-Robinson, BWR and Bender one. The experimental data are taken from NIST experimental campaigns' results published in literature

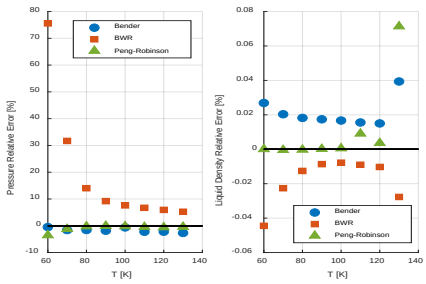

Figure 2 – relative error comparison of pressure and liquid density prediction with three different EoS

4. Conclusion and future developments

Bender model is an effective thermodynamic tool to predict the behavior if air components mixtures and its results are comparable to those obtained from commonly used Equation of State in ASU design. Indeed, it is also accurate near both the triple and the critical points of the mixture. In addition, more reliable results and convergence are ensured by forcing the solver to avoid the unfeasible region. Therefore, considering that Bender EoS's parameters directly derive from a numerical fitting, the partial loss of physical meaning can be overcome by properly selecting and imposing physical constraints on the thermodynamic model itself. In the future, further numerical tricks may be applied not only to increase the predictive capacity and help the convergence but major efforts should be focus on decreasing the computational time without loss in accuracy and precision.

Ionic Liquid Design and Process Simulation for Shale Gas Separation

Xinyan Liu[1], Yuqiu Chen, Xiangping Zhang[2], Suojiang Zhang[2], Xiaodong Liang[1], Rafiqul Gani[3], Georgios M. Kontogeorgis[1*]

1 Department of Chemical & Biochemical Engineering, Technical University of Denmark, DK 2800 Kgs. Lyngby, Denmark;

Highlights

- A three-stage framework for IL-based shale gas separation is proposed.
- Two ILs are selected and designed based on a database and UNIFAC-IL model.
- An IL-based hybrid separation scheme for shale gas model has been designed with a potential energy-saving objective.
- IL-based gas separation has the potential to achieve a low energy consumption and economic cost.

1. Introduction

Shale gas, considered as the clean energy and a substitute for coal, has attracted increasing attention in recent years. It needs to go through a series of processing units to obtain the upgrading commercial gas. Traditional common technologies for shale gas separation include energy intensive distillation and solvent based absorption. Distillation is usually applied for light hydrocarbon gas separation in which the separated gas is recognized as an important raw gas for synthesizing many industrial chemicals. The process includes columns with large numbers of trays to get a high purity product at low temperatures and high pressures resulting in a high energy consumption and negative environmental impact. The solvent-based absorption technology is widely used for separating gases such as CO_2, H_2S which need to be removed in order to satisfy the emission standard of air pollutants. Having some advantages of non-volatility, flexible designing, ionic liquid (IL) has been paid much attention. It is reported that different ILs can be used for different gases absorption[1]. Therefore, a strategy for a five-gas shale gas model separation process synthesis where both traditional distillation and IL-based absorption are employed has been developed. However, the numerous combinations of cation and anion make it a challenging task to search for the optimal one for this shale gas separation. Then selection-screening methods are proposed first. The associated process simulation and evaluation are performed.

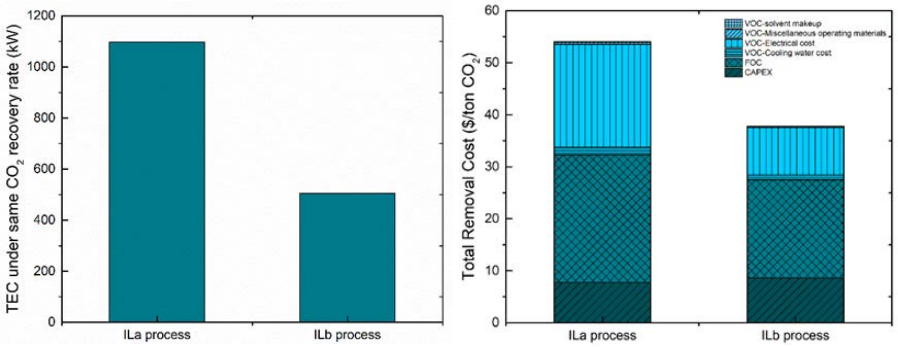
2. Methods

In this work, we first establish an experimental database on gas solubility and Henry's law constant in various ILs. Then database is applied for the predicted model development including corrected COSMO-RS model and UNIFAC-IL model. The activity coefficients of gas in ILs are calculated based on these predicted models so that the gas solubility in new ILs which is not

included in experiments could be predicted [2]. A three-stage methodology proposed for the shale gas separation process design and evaluation will be highlighted. The first stage involves IL screening, where two options are applied. One is only based on the experimental database. The other is a computer-aided method which could be used to automatically obtain the optimal IL on the group contribution basis. The second stage is process design, where the important design issues are determined. Then overall separation scheme is generated. The third stage is process simulation and evaluation. Rigorous process simulation is conducted after the development and verification of related thermodynamic model. Here, a model shale gas containing five gases is assumed as a case study to highlight the application of this methodology.

3. Results and discussion

A five-component shale gas model, which consists of 80% CH_4, 7% CO_2, 7% C_2H_6, 3% C_2H_4, 3% H_2, is assumed in this work. Based on the experimental database, it's found only CO_2 could be absorbed by IL. One optimal IL-a ([thtdp][phos]) has been selected with both high solubility of CO_2 and high selectivity of CO_2/CH_4. Besides, another IL-b ([MMPy][eFAP]) is designed based on a UNIFAC-IL model with a higher selectivity of CO_2/CH_4 than IL-a. Both these two ILs are applied for further simulation to be evaluated. Then a shale gas separation scheme is proposed including two parts: IL-based process for CO_2 removal and traditional distillation columns for other light hydrocarbon gas separation. Evaluated results for total energy consumption and economical cost are shown in Fig.1. IL-b based process gives an improved energy-based technology.



(a) (b)

Figure 1. Process evaluation on a) total energy consumption and b) total CO_2 removal rate

4. Conclusions

This work proposes a hybrid IL-based technology for shale gas separation where the IL is used to remove CO_2 and distillation is applied to obtain the desired final products. A three-stage methodology, in which systematic IL screening, process design and simulation, and process evaluation, is established. Two ILs are selected through two options. IL-b with its good separation results provides a promising recommendation for future solvent development of gas separation process. Future work would focus on further removing the hydrogen for syngas production combining with the removed CO_2 as well as separation and use of C_2H_4 and C_2H_6.

Highlights

- The new role of Process Systems Engineering (PSE) focusing on process synthesis.
- Future research challenges that process synthesis will have to face.

1. Introduction

Process synthesis is a dynamic research domain widely explored by the process systems engineering (PSE) community. This topic was first put forth 60 years ago. Westerberg in his retrospective on design and process synthesis, has defined process synthesis as the part of engineering "where one invents the structure and operating levels for a new chemical manufacturing process"[1]. Process synthesis applies to both the design of a completely new process flowsheet and the retrofit and optimization of an existing process. Furthermore, process synthesis is the assembly and interconnection of unit operations into a process network involving different physical and chemical phenomena to transform a material into desired products for given energy inputs with the goal of optimizing either economic, environmental, and/or social objectives [2]. This dynamics of this research will be further increased due to the future research challenges that process synthesis will face, e.g., biomass transformation, shale production, embedded process, modular plant design, and intermittent production of energy.

2. Methods

A systematic literature review method composed of a search strategy and an analysis of the collected documents are performed. The purpose is to identify the main methods and approaches developed in the literature and to examine them thoroughly. The PSE research groups several topics or subjects: continue or batch, simulation or optimization, Linear Programming or No Linear Programming with or without integer variables, mono or multi- objective….. We identify the most influential research teams and papers that played major roles. In the considered period2011-2016, 1288 articles were published, and 16 research teams wrote 95% of them only. While these teams are all working on process and conceptual design, from figure 1, one can identify a first category of authors who are more focused on optimization methods, i.e., Barton, Biegler, Floudas, and Grossmann. For these groups, process synthesis is one application of the optimization methods that they develop in their research teams because the conversion of process alternatives into mathematical models often results in MINLPs that are difficult to solve. For other authors, mono- or multiobjective optimization is often a tool that is included in their methodology. One major

observation from this figure is that the authors study the process synthesis under the domain of their scientific backgrounds. Indeed, You, Puigjaner, and Srinivasan are more focused on supply chain; Klemes, Kravanja, El Hawagi, and Marechal on heat integration aspects, whereas Maravelias tackles the problem with his vision as a scheduling specialist. A majority of authors are more on the process design area except for two of them who are more focused on conceptual design, i.e., Gani and Engell. Finally, another category of researchers, composed of Marquardt and Ng, try to have a more comprehensive approach that seeks to integrate all previous elements.

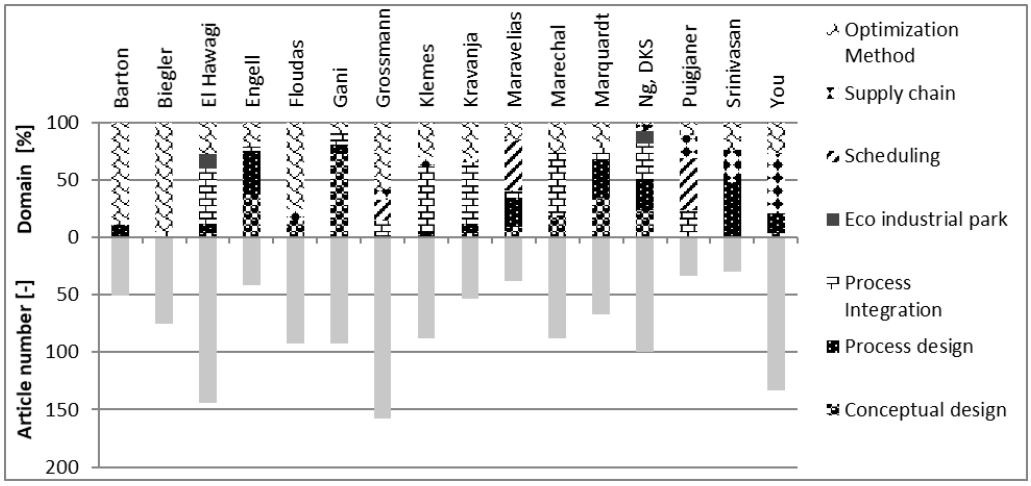

Figure 1. Relationship between domain clusters and research teams

3. Conclusions

In addition to these future challenges, theoretical advances are also required. Obviously, the development of optimization methods and algorithms must continue to provide solutions to the global optimization problem. Either conventional or intensified unit operations require more detailed models to introduce small-scale phenomena, which influence the performance of unit operations. Such an approach leads to the introduction of multiscale information in the design process. The development of methods to handle uncertainties is also a crucial challenge. During the process design stages via optimization approaches, hybrid approaches, or through metamodeling (multiparametric approach, “surrogate model,” etc.), the introduction of inaccuracies and/or uncertainties on data is performed by local sensitivity studies or calculation of flexibility indices. In recent years, new methods of global sensitivity (e.g., Sobol method and chaos polynomials) have emerged, allowing the effective modeling and propagation of uncertainties in numerical simulation. Similarly, machine-learning methods have expanded considerably, for example, in the treatment of partitioning or discrimination problems. Furthermore, the modeling of poorly known data remains a major asset of the fuzzy logic. A possible strategy of renewing the methods for design processes could be the use of these three techniques, separated or combined, in order to reach more robust solutions that can allow inaccuracies/uncertainties inherent to the design stage, but at the same time, deal with hazards during process operation.

Highlights

- An open-source design tool for a fully integrated H_2-CCS chain is developed
- Combining SMR, CCS and salt caverns enables to meet heating and CO_2 emissions regulations in the UK
- Dynamic behavior of a CCS plant shows smooth responses to SMR load fluctuations
- Large flow fluctuations are not desirable for the compressor train operation

1. Introduction

Carbon Capture and Storage (CCS) is currently considered as the "most important technology" to decarbonize the industrial sector by the International Energy Agency (IEA). This technology can in principle be integrated with industrial process plants, separate out the carbon dioxide and transport it to a suitable location for long term underground storage. Similarly, hydrogen (H_2) will play an important role to decrease the carbon emissions from fossil fuel combustion, primarily due to its use as an ultraclean fuel in the heating and transportation sectors, as well as a process feedstock.[1] Contrary to natural gas that produces about 180 gm/kWh CO_2, hydrogen emits no GHGs (at the point of use). However, steam reforming of methane (SMR) and coal gasification, which are currently considered to be the most feasible and economic routes to large-scale H_2 production, also produce significant quantities of CO_2.[2] Therefore, it is crucial to develop strategic H_2-CCS infrastructure to meet the targets in the Paris 2016 Climate Agreement, which have resolved to reduce carbon emissions by over 80% by 2050.[3] The ELEGANCY project enables the evaluation of integrated H_2-CCS chains with respect to technological and economic efficiency, operability and environmental impact. To this end, this contribution is focused on the development of an open-source systems modelling framework with a steady-state design mode and a dynamic operational mode. The methodology developed is applied to five national case studies: Netherlands, Switzerland, United Kingdom, Germany and Norway.

2. Methods

The modelling toolkit developed involves two modes: *(1) Design mode:* Steady state model where the user can explore the time evolution of system design (e.g. choice, scale and location of key technologies and network structure for H_2 and CO_2). For this purpose, we use the Resource-technology network (RTN) methodology, which integrates key elements such as space, time, resources, technologies, infrastructure/Networks to obtain optimal H_2-CCS configurations in terms

of costs (CAPEX and OPEX). The Mixed Integer Linear Programming (MILP) models are developed using Python software. QGIS is used for geographical visualization. (2) *Operational mode:* This enables the user to simulate dynamic behavior of the designed system including intermittent operation. The ranges of key systems variables such as flowrate, temperature, pressure and impurity profiles are quantified. Different technologies for H_2 production are assessed including steam methane reforming and autothermal reforming. The models are developed using OpenModelica software and are compared to relevant ASPEN, gPROMS and Matlab codes.

3. Results and discussion

An open source H_2-CCS steady-state model based on the RTN framework has been successfully developed. The toolkit provides the location, type, number and capacities of process and storage technologies, the distribution infrastructure linking one region to another and the retrieval rates of all resources in the system in every location in the time horizon. Figure 1a shows an example of the implementation of the model to the UK as a case study. It is found that combining SMR with salt cavern technologies enables the production of sufficient amounts of H_2 to meet the heating demands in the UK. The integration of SMRs with CCS technologies is able to reduce the carbon emissions content from 180 gCO_2/kwh in natural gas to approximately 50 gCO_2/kwh from H_2, resulting in a 73% reduction in overall emissions.[4] Regarding the operational mode, a dynamic model for integrated SMR-CCS processes is successfully developed. A scheme of the dynamic model of a CCS plant in OpenModelica is shown in Figure 1b. Some key results indicate that the CCS section has a smooth response to load fluctuations of the SMR plant, and the required stabilization time of the CCS plant is closely related to its liquid residence time. Large flow fluctuations are not desirable for the compressor train operation. Simulations showed that a single compressor train with recycle valve surge control is able to meet the desired performance.[5]

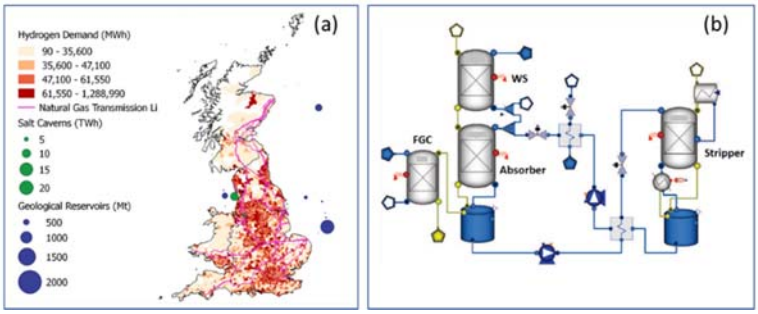

Figure 1. (a) Design mode, H_2-CCS, UK Case study. (b) Operational mode, Dynamic model of CCS plant.

4. Conclusions

In this study, we describe an open-source system modelling framework with a steady-state design and a dynamic operational modes that has been developed in the Elegancy project. The modelling toolkit is applied to five national case studies providing particular strategies to implement efficient H_2-CCS networks. The results obtained for the UK case study are relevant to accelerate implementation of the low-carbon gas network for Leeds.

Highlights

- Nitrogen production
- Membrane separation process
- Membrane material
- Process synthesis

1. Introduction

Membrane processes are one of the key technology for gas separation applications. They combine a series of key advantages that can result in energy efficient, small sized and environmental friendly processes. Among those processes, nitrogen production from air by membrane gas separation processes is a mature technology, which is applied in numerous industrial sectors (chemistry, food, aeronautics, space...). Depending on the nitrogen purity requirements (typically between 90 and 99.9%), single stage or multi-stage membrane process configurations are used. The main challenge is then to be able to build and provide tools to optimally design membrane processes that is mainly the answer of the question: what is the best membrane material and the best process architecture to achieve my separation targets?

A very large number of advanced membrane materials have been recently reported, showing increasing permeability and/or selectivity for air separation applications (i.e. trade-off limits of dense polymeric materials for the O_2/N_2 pair gas [1]) compared to the commercially available membranes. The interest of these new materials in terms of nitrogen production cost and their impact in terms of process configuration have never been reported through a process synthesis study. The results of the optimization (process synthesis) are expected to generate useful guidelines for membrane material development: is it better to push selectivity or permeance in order to decrease NEA production cost? Is it interesting to combine different membranes in a multi-staged unit, in order to achieve lower production costs? This is what this study is aimed to answer.

2. Methods

Based on a tailor made global optimization methodology and program [2], optimal process configurations achieving minimal production cost are first identified for standard and commercial O_2/N_2 separation membranes (PSf [3] and PPO[4]) for four different levels of N_2 purity. (90, 95, 99, 99.9%). The same strategy is then performed with membrane materials considered as a variable of the system, with the possibility to combine different materials in multi-staged systems. The choice of the membrane materials can be freely made in the domain delimited by the trade-off limit. The

impact in terms of nitrogen production cost for the different purities and the corresponding optimal membrane materials and process configurations are discussed.

3. Results and discussion

The acceptable domain for O_2/N_2 separation membranes considered based on [1] (the green region in the Figure 1). Consequently, the optimal process configuration with associated operating conditions and the lowest N_2 production cost is obtained while converging to the optimal membrane performances for different nitrogen purity levels.

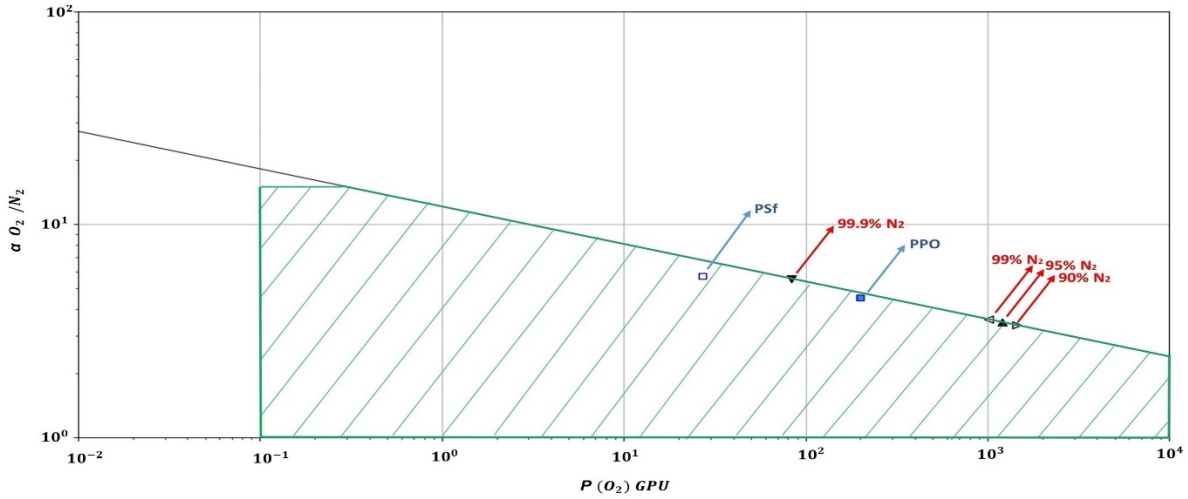

Figure 1. Commercial available membrane materials (blue squares) and the optimal performance membranes for different nitrogen purity levels indicate with triangles.

4. Conclusions

Surprisingly, a medium membrane selectivity combined to a high permeability is shown to systematically offer the best set of performances, for mono or multistage systems. In contrast with current practice, vacuum operation and recycling loops are shown to generate lower N_2 production costs with high performance membranes. For the set of parameters tested in our study, it seems that the use of different membranes in a multistage system does not offers attractive improvement potentialities. It is obvious that this statement does not systematically hold for gas permeation and should be reconsidered from case to case.

Tar Removal by Catalytic Cracking in Biomass and Waste Gasification

Juma HAYDARY*, Jakub HUSAR, Patrik ŠUHAJ

Institute of Chemical and Environmental Engineering, Slovak University of Technology in Bratislava, Radlinského 9, 812 37 Bratislava

* juma.haydary@stuba.sk

Highlights

- Thermal and catalytic cracking of tar from biomass and waste gasification was studied
- Different types of clay based and char based cheap catalysts were characterized and tested
- Both calcined and Ni impregnated clay catalysts reduced the tar content
- Char based catalysts showed large catalytic effect in the reduction of tar

1. Introduction

Gasification of biomass or solid waste produces combustible gases consisting mainly of H_2, CO and CO_2. Air, oxygen, steam or their mixtures can be used as a gasifying agent [1]. Although much attention has been devoted to gasification in recent years, there are still a number of challenges to full commercialization of biomass and solid waste gasification [2].

One of the critical issues in biomass and waste gasification is the quality of produced gas. To be used in internal combustion engines or turbines, the gas should fulfil relatively strict requirements for gas composition, heating value and tar content. Production of fuel quality gas requires the removal of tar from the producer gas. This work deals with secondary catalytic tar cracking in the gasification of biomass and waste, using low cost catalysts. Different types of catalysts based on two different types of materials (red clay (RC), tire pyrolytic char) have been prepared by calcination (carbonization) at different conditions and/or impregnation with Ni. The catalysts were tested by using toluene and p-Xylene as model tar components and also by experiments with gasification of RDF (Refused-Derived Fuel) samples.

2. Methods

The catalysts were characterized by pore structure and specific surface measurement (before and after use), thermogravimetric analysis, elemental analysis and X-ray diffraction analysis. In the first step, the catalyst activity was tested by cracking of a model organic compound at different conditions. In the next step, the catalysts were used for cracking of tars in a two stage laboratory scale gasification unit, where the composition of producer gas and gas tar content were observed for different process conditions and catalyst types. As the raw material in these experiments, RDF, a fraction of municipal solid waste, MSW was used. The gas composition was measured by gas chromatography GC. Tar content of the gas was measured using a standard method based on tar capture in isopropanol and subsequent distillation at specific conditions and gravimetric measurement.

3. Results and discussion

Char based catalysts were thermally stabilized (carbonized) at temperatures from 800 to 1000 °C. Ni impregnated char catalysts were prepared by impregnation of carbonized char catalysts. Specific surface area of char catalysts increased from 28 m^2/g to 105 m^2/g due to carbonization. Char based catalysts showed large catalytic effect also in the reduction of tar in the gas from the RDF gasification. Char catalysts prepared by carbonization at 900 °C reduced the tar content of producer gas by 92.3 % compared to the non-catalytic (thermal) decomposition process.

The red clay containing mainly SiO2 and some amounts of Al_2O_3, Fe_2O_3, $CaCO_3$, $MgCO_3$ and others [3] had the initial specific surface area of around 100 m^2/g; however, its surface area decreased by calcination up to 35 m^2/g. Both calcined and Ni impregnated clays reduced the tar content of the gas up to 80 and 91.8%, respectively. An example of tar yield versus clay catalyst to RDF ratio is shown in Figure 1. Ni impregnation of both clay on char catalysts resulted in higher H_2 content of the produced gas [4].

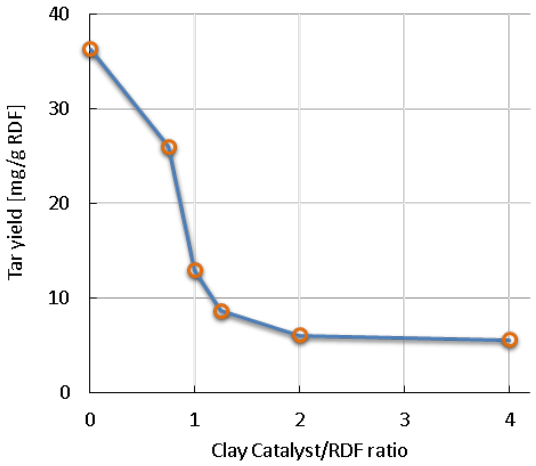

Figure 1. Tar yield versus catalyst/RDF ratio (Temperature: 800°C)

4. Conclusions

Calcined red clay and carbonized pyrolytic char can serve as low cost catalyst in the removal of tar from gas produced by the gasification of solid waste and biomass. Impregnation of these catalysts with Ni leads to better char removal and higher content of H_2 in the gas, however it can also represent additional costs related to catalyst preparation and after use treatment.

A Population Balance Model for the Dynamic Simulation of Enzymatic Hydrolysis of Lignocellulosic Biomass in Batch or Fed-Batch Bioreactors.

Vasileios Margaritopoulos[1], Christos Chatzidoukas[1,*]

[1] *Chemical Engineering Department, Aristotle University of Thessaloniki (AUTH), 54142, Thessaloniki, Greece*

**Corresponding author: chatzido@auth.gr*

Highlights

- Endo- and exoglucanases synergy-the role of cellulose chain length distribution.
- Continuous varying substrate accessibility to the enzymes.
- Hydrolysis yield improvement from batch to fed-batch operation of bioreactors.

1. Introduction

Biomass hydrolysis is a critical step in biochemical processes where cellulose is degraded to glucose for the production of biofuels and useful chemical products. Enzymatic hydrolysis is a promising method for glucose production due to its low energy demand and mild operating conditions [1]. However, the multiple phenomena that occur make the hydrolysis process complex, impeding the comprehension of the exact mechanism. Thus, the commercialization of the process is still considered a challenge. Detailed mathematical models provide the means for further elucidating the dominant mechanisms and process optimization. Various semi-empirical models have been developed, however they usually suffer an over-parameterization or their predicting capability is confined within certain experimental conditions due to a simplified and macro-scale approach of the problem. In this work a mechanistic model is developed deepening further on meso- and micro-scale phenomena involved in the hydrolysis of lignocellulosic biomass, while accounting for critical substrate characteristics such as particle size, cellulose chain length distribution and lignin content. The dynamic evolution of the substrate accessibility to the enzymes is efficiently captured by the model in order to prove the hydrolysis yield reduction [5], experimentally observed in bioreactors of high solids loading compared to those of lower solids loading, demonstrating the model handiness for the operational design of fed-batch bioreactors.

2. Methods

Biomass hydrolysis refers to the degradation of cellulose to its oligomers, meaning glucose and cellobiose. The enzymatic hydrolysis is catalyzed by two types of cellulases named endo- and exo-glucanases. Endoglucanase attacks β-1,4-glycosidic bonds within the cellulose chain with random chain scission, while exoglucanase removes single units of cellobiose with chain end scission [3,4]. A population balance technique is applied [2,3,4] to describe the dynamic evolution of cellulose chain length distribution, from the distinct action of each enzyme as is described below:

$$x_{mer} \xrightarrow{endoglucanase} y_{mer} + (x-y)_{mer} \qquad x_{mer} \xrightarrow{exoglucanase} (x-2)_{mer} + cellobiose$$

The model emphasizes on the fractional accessibility of the substrate to the surrounding enzymes adopting a layer-by-layer exposure of the cellulose chains and a binding mechanism of the enzyme

on these chains. The Langmuir isotherm is employed to describe the adsorption of soluble enzymes on both surficial cellulose and lignin of the insoluble biomass particles to account for the heterogeneity of the hydrolysis mechanism. The entire dynamic model is developed and solved with the gPROMS® simulation platform.

3. Results and discussion

Endoglucanase is responsible for generating quickly cellulose chains of shorter length and providing to exoglucanase additional chain ends. Exoglucanase, hydrolyzes the substrate by generating soluble oligomers. Cellulose hydrolysis would be practically unaccomplished in the case where only endoglucanase was used, however, its role is not negligible since the generation of shorter chains increases the exoglucanase efficiency. The derived model uncovers these phenomena, the synergy between the two types of enzymes and the way endogenous traits of the substrate, such as particle radius, cellulose chain length distribution and lignin content are involved in the hydrolysis reaction rate. Precisely, as the hydrolysis proceeds new substrate layers of non-degraded cellulose chains, tangled with lignin, are exposed. The hydrolysis rate takes its maximum value at the beginning of the process since the quantity of enzymes that can bind effectively on the biomass is the maximum possible. Progressively, the particle radius is reduced and less amount of enzyme is adsorbed on the particle's surface. Moreover, the lignin fraction in the particle increases, leading to the reduction of the effectively bound enzymes and finally the total rate of hydrolysis, without any product inhibition effect being necessary for such a response.

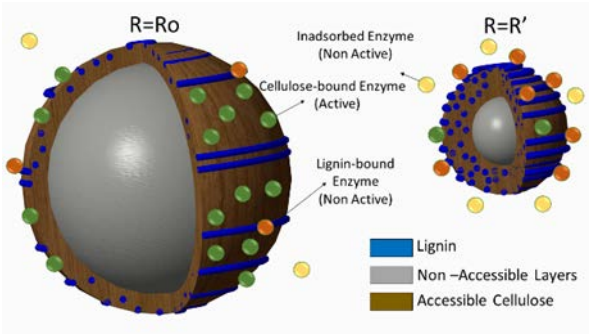

Figure 1: Graphical representation of particle hydrolysis.

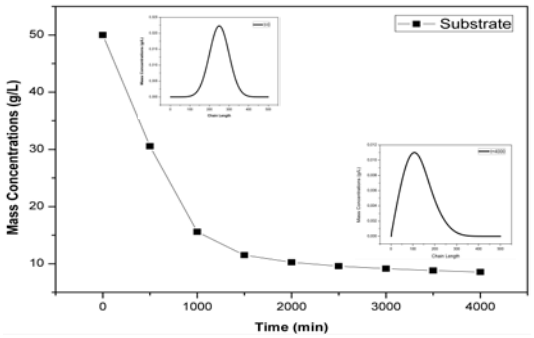

Figure 2: Time profile of cellulose hydrolysis.

4. Conclusions

A generic mechanistic model, which takes into consideration factors like chain length distribution, lignin content, particle size and specific surface area, has been built up. The influence of substrate characteristics on the catalytic efficiency of the enzyme highlights the importance of the pre-treatment the lignocellulosic biomass is subjected to. A model-based investigation of the optimal dynamic operation of fed-batch hydrolysis bioreactors can be essentially supported by the proposed mathematical model.

Enzymatic hydrolysis of Cytisus striatus: acid sulfite pretreatment optimization.

Álvaro Vaz[1*], Tânia Gomes[2], Rogério Simões[1]

1 FibEnTech Research Unit, University of Beira Interior, Rua Marquês D'Ávila e Bolama 6201-001 Covilhã, Portugal; 2 University of Beira Interior, Rua Marquês D'Ávila e Bolama 6201-001 Covilhã, Portugal

**Corresponding author: avaz@ubi.pt*

Highlights

- Pretreatment conditions affect total recovered sugars (6% up to 69%) and generated degradation products.
- For a given sulfite load, more acidic conditions lead to higher sugar release and further material fragmentation, increasing degradation products.
- Moderate loads of sodium bisulfite (1%) and sulfuric acid (2.25%), release practically all hemicelluloses.

1. Introduction

Ethanol production from lignocellulosic material includes three major steps: biomass pretreatment, which fragments the lignocellulosic matrix to facilitate the enzymes access to the substrate; hydrolysis, where the polysaccharides are converted into fermentable sugars (e.g. glucose and xylose) [1]; and finally, fermentation that produces ethanol or other biologically based chemicals (e.g. lactic acid, succinic acid) [2]. The aim was to study the effect of pretreatment operative variables, namely sodium bisulfite and sulfuric acid loadings, temperature and time, on released sugars in Cytisus striatus enzymatic hydrolysis with a Novozymes® cocktail. Pre-treatment intends lignin and hemicelluloses removal, reduced cellulose crystallinity and lignocellulosic network porosity increase in order to facilitate enzyme access.

2. Methods

Cytisus striatus was chipped with a Retsch Mühle knife mill with 10 mm x 10 mm sieve, being fines removed with 18 mesh screens, resulting a material with 1-2 mm width and 10 mm long. Chips were then submitted to different reaction conditions, with a central composite experimental design 2^4+star, exploring the following variables: sulfuric acid charge (0-3%), sodium bisulfite charge (0-4 %), maximum temperature (150-190ºC) and time at maximum temperature (0-30 minutes). For each assay, 30 g (o.d.) broom chips were treated in 200 mL stainless steel reactors with 5/1 (v/w) liquid-to-wood chip ratio. The temperature profile was as follows: after impregnation at 90ºC (60 min.), the temperature was raised to its maximum in 90 minutes, remaining at that temperature for 30 minutes. The reactors were then suddenly cooled down with tap running water, and acid hydrolysates were recovered and the solid residues were mechanically disintegrated and thereafter subjected to enzymatic hydrolysis with an enzymatic cocktail from Novozymes® including 6 different enzyme solutions (cellulase complex: 5%, xylanase: 0.25%, β-glucosidase: 0.6%, enzyme complex: 0.4%, hemicellulose: 2%, glucoamylase: 0.06%) suitable for lignocellulosic materials

hydrolysis purporting bioethanol production. The cellulase loading (NREL procedure) was 6.6 FPU/mL. The never-dried pre-treated solid residues were placed in 50 mL falcon tubes at 1% solid content (0.4 g o.d. solids/tube) and adjusted with citrate 50 mM buffer solution of pH 5.5 up to a total volume of 40 mL per tube, improving agitation with 0.3 mm glass spheres. All tubes were homogenized in a vortex and inserted horizontally into a 50ºC water bath. Solids were subjected to enzymatic hydrolysis for 7, 15, 24, 48 and 96 hours and the enzymatic hydrolysates sugar content was determined by HPLC.

3. Results and discussion

The different factors effect (NaHSO3 load [A], H2SO4 load [B], temperature [C] and time at T_{max} [D]) on different response variables was mathematically established. As examples, the equations corresponding to the XMG (Xylose + Mannose + Galactose) and to the released sugars are shown:

$$XMG = 14{,}0 + 0{,}39A + 3{,}06B + 1{,}54C + 0{,}54D - 0{,}12A^2 - 0{,}96AB - 0{,}65AC - 0{,}08AD - 0{,}04B^2 - 5{,}38BC - 2{,}40BD - 1{,}80C^2 - 2{,}30CD - 0{,}74D^2 \quad \text{(Eq. 1)}$$

$$Sugars = 32{,}5 + 7{,}17A + 13{,}02B + 26{,}54C + 8{,}94D + 4{,}73A^2 + 0{,}66AB + 1{,}96AC + 0{,}78AD + 2{,}54B^2 - 1{,}743BC - 0{,}55BD + 1{,}62C^2 + 1{,}58CD - 0{,}23D^2 \quad \text{(Eq. 2)}$$

Standard effects and yield surface response were also obtained and analysed, as seen in Fig. 1 and Fig. 2:

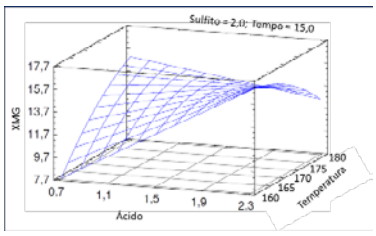

Figure 1. XMG surface response.

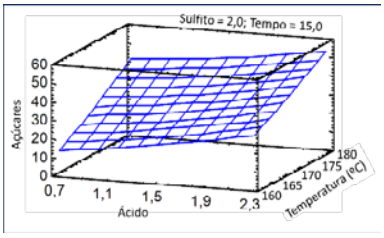

Figure 2. Sugar surface response.

4. Conclusions

Biomass pretreatment with sodium bisulfite in acid environment alters the feedstock structure and composition, making it more suitable for enzymatic treatment. The pretreatment conditions produce an effect on the amount of total recovered sugars and on the generated degradation products. For a given sulfite load, more acidic conditions lead to higher sugar release and further material fragmentation, but also to an increase in degradation products. Moderate loads of sodium bisulfite (1%) and sulfuric acid (2.25%), release practically all hemicelluloses of the raw material. The enzymatic treatment showed to be very sensitive to the pretreatment conditions. The released sugars percentage in the enzymatic hydrolysis ranged from 6.0% to 68.9%. More acidic conditions increase the rate and extent of the enzymatic hydrolysis of the polysaccharides.

Bio-Economy:
Chances, Challenges, and Perspective of the System as a Whole.

Andreas Pfennig

University of Liège, Department of Chemical Engineering - Products, Environment, and Processes (PEPs), Quartier Agora, Allée du six Août, 11, Liège, Belgium,]

andreas.pfennig@uliege.be

Highlights

- Faster growth of world population than expected results in increased challenges for sustainable development.
- Bio-based economy competes with food production for land area, third-generation biomass cannot fulfill the demands.
- Bio-based economy will have sufficient options to be globally realized.
- Bio-energy will strongly compete with food production.

1. Introduction

Humanity is facing grand challenges: we have to reduce the consumption of fossil resources and replace them with sustainable technologies. This implies the use of sustainable raw materials in the chemical industry as well, such as bio-based raw materials or carbon dioxide. Much has been published on the various options for raw materials and technologies to be used. Why one or the other of the many options is more promising than another may not always be obvious.

2. Approach taken

In order to get a realistic insight, balances on available resources are used to gain a holistic picture allowing to answer, how the demands of humanity can be fulfilled. The considerations take into account the general challenges of mankind, namely climate change, energy utilization, and world hunger. The balances build on publicly available data like the FAOSTAT database of the UN. The limits considered are the carbon-dioxide emissions to the atmosphere and the land area required for production of food, bio-energy, and feedstock for the chemical industry. The main raw-material and technology options are discussed and related to these boundary conditions and among each other. For the chemical industry the focus is on mass products such as plastics. Some promising main routes are described, and the practical challenges of their realization are addressed, e.g. supply, conversion and distribution. From these interrelationships the societal responsibilities can directly be deduced.

3. Conclusions

It turns out that the global population growth is significantly faster than usually considered, because major studies don't take the continual slight upward shift in the projection of the UN – which are typically applied – into account. Thus the demand side for resources and the waste produced are underestimated. A high population growth has to be considered at least as one bounding scenario.

Based on different population perspectives, the energy demand is considered and coupled with projections on sustainable energy transition. The results show that the energy transition may be possible but will be significantly more demanding than e.g. projected by the Intergovernmental Panel on Climate Change. The efforts, i.e. the rate at which fossil energy systems are replaced by renewable energy technologies, need to be increased by a factor of five in the EU and a factor of almost 10 worldwide. This means that the time-scale of the change has to be some few decades at most, during which also a bio-economy would need to be established.

Considering land area as scarce resource shows that food supply will be challenging, even, if the agricultural efficiencies are continually increased. Thus, bio-energy should not be fostered to a degree proposed in various scenarios, e.g. also those of the EU.

Finally, these considerations set the scene to discuss the available options for bio-based feedstock for the chemical industry. Different crops are compared and combined with different technological options to analyse, if it will be possible to develop a bio-economy without further increase in world hunger. The results show e.g. that third generation biomass will not be sufficient to supply a majority of the feedstock required. Thus competition with food production for land area is unavoidable. At the same time various options exist which will allow bio-based products with only limited land-area use, see Fig. 1. Of course a suitable mix of the different options wll finally be realized, taking into account climate and soil situation. The options are discussed and related, also considering technological maturity of the resulting processes.

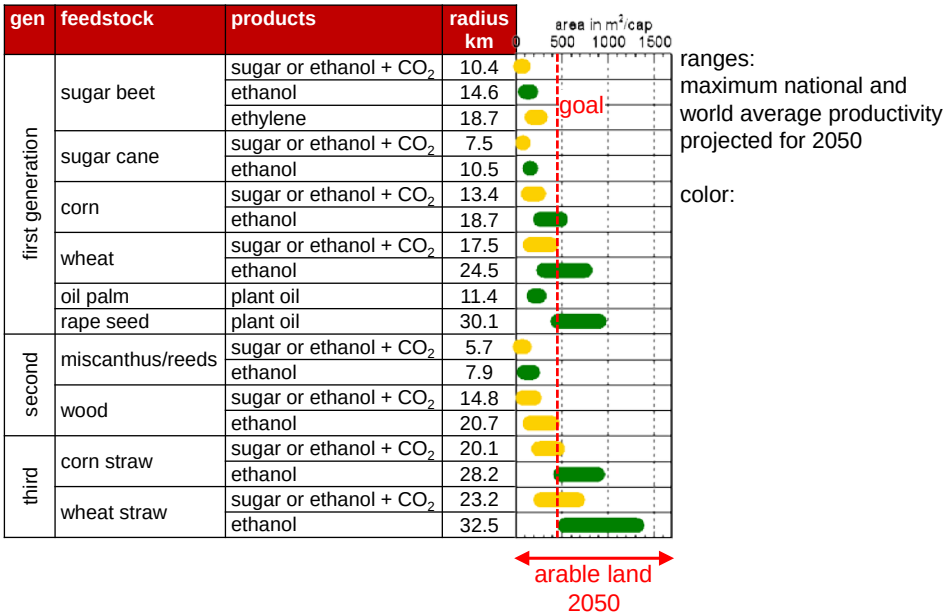

Figure 1. Required land area for a bio-based economy assuming that each path supplies individually the required feedstock.

Along the way, also the utilization of carbon dioxide is evaluated, which can obtained from the atmosphere in a sustainable economy. For the chemical activation of carbon dioxide, energy, presumably in the form of hydrogen is required, which in turn needs a significant additional contribution from renewable energies. This is related to the effects and consequences of bio-economy.

Highlights

- Arthrospira platensis is sustainably grown on food industry wastewaters.
- Microbial electrochemical technologies are introduced through the e-BioPond®.
- Inorganic carbon and dissolved nutrients from the oxidized wastewater are the growth medium.

Abstract

Organic-rich **secondary products** of food industry and **wastewaters** are important sources of nutrients which should be valorised as an important resource rather than being disposed as a waste. We propose a technological application to recover these nutrients for a sustainable Spirulina (*Arthrospira platensis*) cultivation. Spirulina is a microalgae culture whose nutritional value and properties have attracted the attention of both researchers and industrialists. Commonly microalgae cultures are grown is an inorganic medium, which negatively affects the costs of the process. Through the alternative **sustainable microalgae cultivations** using the **e-BioPond**, **microbial electrochemical technologies** are introduced.

In **e-BioPond** (***patent pending Italian deposit 102018000010683 - Nov 29th, 2018***), a separation between the microalgae culture and wastewater is obtained using low-cost composite membranes (***international patent pending n. 102017000110538 - ref E0116619***), with the shape of pipes or panels (**microbial electrochemical pipe/panel, MEP**). The pore dimensions of such materials (<500 nm) is smaller than the microbial cells. This keeps the two environments separated in terms of **microbial contamination**.

Within the inner volume of MEPs, a conductive material acts like a **bioanode**, where wastewater flows and electroactive microorganisms anaerobically oxidize the organic fractions and liberate CO_2/HCO_3- and minerals (NH_4^+, NO_3^-, etc.). On the microalgae-side, another conductive layer acts like a **biocathode**, where electroactive microorganisms reduce the photosynthetic oxygen.

Simultaneously, **inorganic carbon and dissolved nutrients** are allowed to diffuse through the MEP to the cathodic chamber, where they are used as growth medium by microalgae.

In particular, the first lab scale tests enabled to grow around 40 mg_{TSS} $L^{-1}d^{-1}$ of Spirulina when the anodic chamber was fed with 12 gCOD/L. COD removal rate was 0.65 gCOD L^{-1} d^{-1}, dissolved

oxygen in the cathodic chamber ranged between 15 and 18 ppm, and the measured electrical power density was 4 W/m^2.

The final goal of the project would be to test the **quality** of the **Spirulina biomass** that can still be obtained from this sustainable system and, consequently, proceed with the extractions of **proteins** and **pigments** to be used in food, pharmaceutical and feed industries.

Towards Sustainable Marine Biorefineries: Macroalgae Continuous Fractionation with Pulsed Electric Fields and Mechanical Press.

Alexander Golberg, Klimentiy Levkov

Porter School of Environment and Earth Sciences Tel Aviv University, Tel Aviv, Israel.

**Corresponding author: agolberg@tauex.tau.ac.il*

Highlights

- Pulsed electric field generator with gravitation press electrodes was developed
- PEF parameters 4kV, 1kAmp, 1-100µs duration and total power dissipation of 20W
- Macroalgae *Ulva* sp. was electroporated with ~2kV/cm, 12µs duration 200A.

1. Introduction

Of the major technological challenges for bioeconomy is biomass fractionation, or biorefining: similar to oil or gas cracking or refining. An important step in those biomass fractionation processes is the breakdown of cell membranes. This breakdown allows for efficient separation of water from organic material (drying) and also it enables to extract for various uses intercellular components such as proteins, amino acids, lipids, carotenoids and other molecules each of which already has significant market values. One type of these technologies is based on the use of high voltage, short pulsed electric fields (PEF) [1]. However, unique physical characteristics of each species of plant biomass, the dynamics and nature of their changes in the process of electroporation require case by case adaptation of PEF parameters such as applied voltage, number of pulses, pulse duration, frequency and temperature for successful and energy efficiency biomass fractionation. The goal of this work was to develop a laboratory device with adaptive electrical and mechanical components to allow electroporation of the marine macroalgae biomass, an emerging feedstock for biorefinery. Indeed, macroalgae fractionation with pulsed electric fields, once available, could lead to non-thermal, chemical-free extraction of valuable phytochemicals from cells such as proteins, amino acids and carbohydrates [2]. In this work, we report on the development of a laboratory PEF system with asymmetric voltage multiplying and gravitation-press electrode device that enables electroporation of a highly conductive marine macroalgae, a promising but challenging feedstock for the biorefinery.

2. Methods

2.1 Macroalgae *Ulva* sp. Biomass. *Ulva* sp.was grown under controlled conditions in using 40 L macroalgae photobioreactors (MPBR) incorporated in a building's south wall under daylight conditions. Nutrients were supplied by adding ammonium nitrate (NH_4NO_3) and phosphoric acid (H_3PO_4), (Haifa Chemicals Ltd, IS) to maintain 6.4 g m^{-3} of total nitrogen and 0.97 g m^{-3} of total phosphorus in the seawater. The sole CO_2 source was bubbled air.

2.2 *Ulva* sp. biomass electroporation. *Ulva* sp. biomass was harvested and centrifuged in the manual kitchen centrifuge to remove the surface water 3 times for 2 min. The biomass was loaded in the electroporation cell, pressurized with the moving the electrodes and exposed to the external constant electric field from generated by the applied voltage of 600 – 4000 Volt and the 1 – 20 mm

gaps between the electrodes. The voltage drop was measured at the electroporation cell and at the resistor connected in series with a known resistance (5Ohm). Voltages and currents were measured with a PicoScope 4224 Oscilloscope with a Pico Current Clamp (60A AC/DC) and analyzed with Pico Scope 6 software (Pico technologies Inc., UK). Extracted juice was collected at the bottom of the device. The experiment was repeated three times.

3. Results and discussion

The developed system, allows applying for up to 4kV, 1kAmp pulses with 1-100µs and total power dissipation of 20W and up to 10kg of mechanical load. The system has two novel elements: asymmetric voltage charger for energy consumption minimization (**Fig. 1a**) and gravitation-driven press electrode device for continuous fractionation (**Fig. 1b**). The developed device uses a charge source, which consists of a step-up transformer of 220/2000 Volts, a voltage doubler, and an ESC voltage regulating unit. The developed device uses an asymmetric voltage doubling circuit (**Fig. 1a**), which consists of two high-voltage diodes and two capacitors allowing to control the applied voltage at each pulse. This is a new feature, we did not found in the literature. The first is a charging capacitor that, in addition to the voltage doubling function, performs the function of current limitation when the ESC is charged. The second capacitor is the ESC. Images of the voltage and current pulses as recorded applying 2kV (field ~2kV/cm), 12µs duration 200A on 10 g of wet macroalgae are shown in **Fig. 1c.** This is in the range of electric field requirement shown in our previous work to extract proteins from this biomass [3].

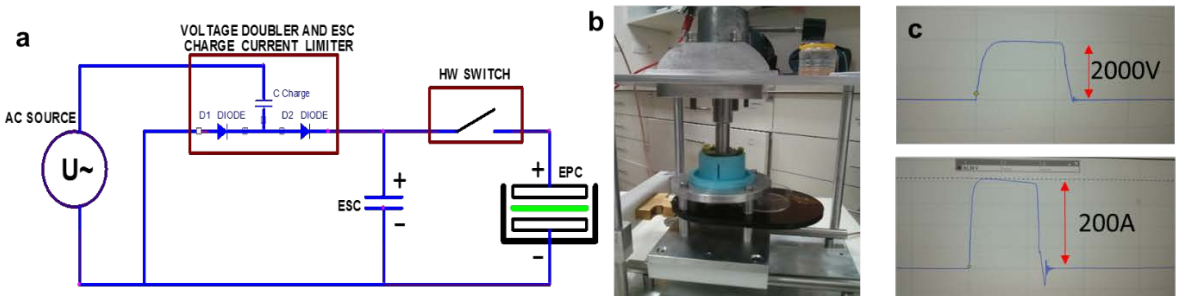

Fig. 1. a. Principle components of the develop laboratory biomass electroporation device. **b.** The gravitational press-electrode device with loaded biomass. **c.** Voltage (top image) and current (bottom image) of Ulva biomass exposed to pulsed electric fields of 2kV

4. Conclusions

Macroalgae biomass is the most challenging feedstock for PEF application in industry because of high salinity which leads to very low resistance of the biomass and very high currents in the system at fields that lead to cell membrane permeabilisation. In this work we developed the device which enables the control over the applied voltage at each pulse, reducing the energy consumption of the electroporation-driven biomass fractionation.

Investigations of molybdenum-promoted manganese-based solid sorbents for H_2S capture

Jianyu Ma[1], Kumar R. Rout[2], Maximilian Sauer[3], Mehdi Mahmoodinia[1], Edd A. Blekkan[1*]

1 Dept. of Chemical Engineering, Norwegian University of Science and Technology (NTNU), NO-7491 Trondheim, Norway

2 SINTEF Industry, NO-7465 Trondheim, Norway

3 Technical University of Munich, Germany

**Corresponding author: edd.a.blekkan@ntnu.no*

Highlights

- Mo-promoted Mn-based solid sorbents for desulphurization were studied
- Real-time residence H_2S concentration was monitored on-line
- Mo addition promoted sorbent capacity and stability significantly

1. Introduction

Biomass gasification and subsequent fuel synthesis is a realistic route to 2nd generation biofuels. However, the produced syngas contains undesired species and contaminants (tar, alkali, sulfur species etc.) that has severe detrimental effects on downstream equipment and catalysts [1]. Therefore, gas cleaning and gas conditioning are important steps. From a process design point of view high-temperature gas cleaning is beneficial in terms of energy efficiency and investment cost. A key contaminant in biomass-based syngas is hydrogen sulfide, and this contaminant must be removed in order to avoid rapid deactivation of catalysts for fuel synthesis, e.g. cobalt-based Fischer-Tropsch catalysts [2]. Several materials have been proposed for high-temperature sulfur removal and manganese is reported to be a promising candidate based on thermodynamics (calculated sorption properties at high temperatures) as well as other chemical features (resistance to reduction, volatilization and carbide formation) [3]. The properties of sorbents can be improved by addition of promoters. Molybdenum oxide is selected in this study as a promoter on account of its ability to provide higher desulphurization capacity and improve stability of catalysts [4].

2. Methods

A series of Mo-promoted manganese sorbents supported on alumina were prepared by incipient wetness impregnation method using Mn-nitrate and ammonium molybdate as precursors. The samples were dried at 90°C and calcined at 700°C to decompose the salt. The nominal Mn loading was 15 wt% and Mo loadings were 2wt%, 5wt% or 8wt%, and 8wt% made using 2-step impregnation. Their H_2S sorption properties were investigated in a laboratory setup, see [5] for further details. The sorption was done on pre-reduced samples at 600°C using a dry gas mixture containing 0,4 vol% H_2S and 40% H_2, the balance being inert gases (Ar, N_2). The regeneration was done at 650°C and ambient pressure, using a gas containing 25 vol% air. The testing was performed as 10 cycles of sorption - regeneration. The residual H_2S level was monitored at different sorption temperatures with a specific sulphur analyzer, Thermo-Fisher 450i.

3. Results and discussion

All the samples initially adsorbed H_2S down to a very low level. After some time the concentration of H_2S in the exit gas started to increase (breakthrough), the sorption was then terminated by flushing the reactor with inert gas. The sorbent capacity before breakthrough were calculated from the amount H_2S adsorbed. Subsequently the sorbent was regenerated by diluted air. The only sulfur species detected in the gas phase during regeneration was SO_2. The initial sorption capacities declined in the following order: 15Mn5Mo-Al_2O_3> 15Mn8Mo-Al_2O_3> 15Mn8Mo-2step-Al_2O_3>15Mn2Mo-Al_2O_3>15Mn-Al_2O_3, indicating that addition of Mo increases sorbent initial capacity. After one cycle, the capacities for sorbent 15Mn8Mo-Al_2O_3 and 15Mn8Mo2step-Al_2O_3 increased obviously and remained stable for subsequent cycles. However, the capacity of 15Mn2Mo-Al_2O_3 suffered large deactivation and turned to be even lower than sorbent without Mo. The sorption capacity after 10 cycles declined in the following order: 15Mn8Mo-2step-Al_2O_3> 15Mn8Mo-Al_2O_3> 15Mn5Mo-Al_2O_3>15Mn-Al_2O_3>15Mn2Mo -Al_2O_3.

The residence H_2S concentration after sulfidation by 15Mn8Mo-Al_2O_3 was as low as around 1.95ppm at a sorption temperature of 400°C. At 600°C, the residual concentration increased to around 2.65ppm. In contrast, the 15Mn-Al_2O_3 showed a similar result at 400°C, 2.4ppm, however, a significantly higher value of 11ppm was recorded at 600°C sorption temperature.

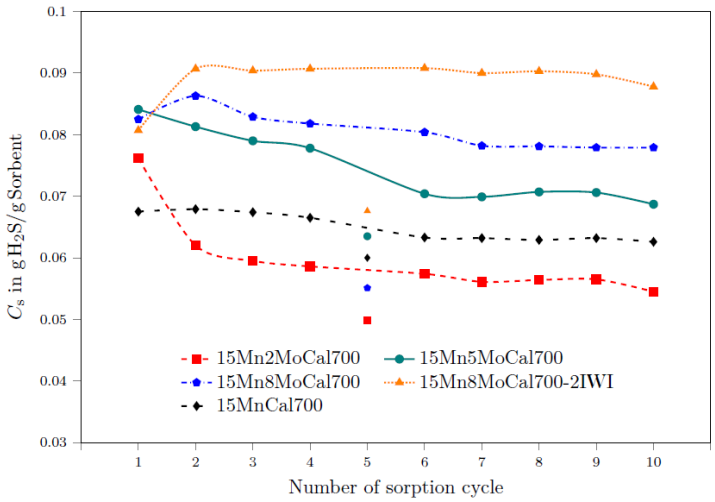

Figure 1. Capacities of Mn-based sorbents promoted with Mo.

4. Conclusions

The addition of Mo is found to be beneficial for Mn-based sorbents, in terms of capacity, stability and residual H_2S concentration in the gas phase after sorption.

Full-field assessment of gaseous flow within open-cell foams: comparison of µCT-based CFD simulations and magnetic resonance velocimetry results

Mehrdad Sadeghi[1], Mojtaba Mirdrikvand[2], Georg Pesch[1], Wolfgang Dreher[2], Jorg Thöming[1]

[1]University of Bremen, Faculty of Production Engineering, Chemical Process Engineering, Bremen, Germany
[2]University of Bremen, Faculty of Chemistry, in-vivo MR group, Bremen, Germany

Highlights

- µCT-based CFD simulations of gaseous flow within open-cell foams were performed.
- CFD simulations are based on real structure of open-cell foams in a foam reactor.
- Magnetic resonance velocimetry (MRV) method was used for flow mapping and verification of CFD results within the open-cell foams.

1. Introduction

Open-cell foams, which are also known as solid sponges, enjoy beneficial morphological properties such as a low pressure drop, a high thermal conductivity and an excellent soli-gas heat and mass transfer which make them a good choice as monolithic catalyst supports. Computational fluid dynamics (CFD) simulations have been employed as a cost-effective and reliable numerical tool for the study of transport phenomena through catalytic sponges; however, their irregular and complex geometries demands high computational effort. Nevertheless, the complexity of the geometry is a major cause for the good performance of the solid sponge. It significantly controls flow pattern and the sponge's heat and mass transfer characteristics. Apart from detailed experimental studies, this fact requires in-depth numerical studies which spatially resolve transport phenomena in the sponge locally [1]. Magnetic resonance velocimetry (MRV) is a non-invasive method which has been applied for measurement of flow within solid sponges. In this study, the obtained flow fields and velocity profiles form CFD simulations were compared with magnetic resonance velocimetry (MRV) measurements.

2. Methods

In this study, we simulated the entire fully-resolved geometry of sponges which were obtained from micro computer tomography (µCT) imaging of real samples. The Procedure is summarized in Figure 3 in the Appendix. Due to highest investigated Reynolds number (based on reactor diameter, 25 mm) for the flow rate of 1.5 Sl min^{-1} (Re= 76.49, u_{in}=0.051 ms^{-1}), laminar flow regime and incompressible condition was considered. To ensure the simulations are grid-independent, a grid analysis was carried out for different meshing densities. To guarantee that the simulated flow results are physically correct, they were validated against pressure loss correlations for foams at flow rates from 0.5 to 20 SL min^{-1}. Subsequently, CFD results containing 41.1 millions of computational cells were validated by experimental velocimetry measurements and literature correlations. We investigated numerically and experimentally the incompressible gas flow within three cylindrical (25 × 68 mm) 20 PPI Al_2O_3 open cell foams in a row (See Table 1 in Appendix for

morphological properties). A gas flow of methane at different flow rates of 0.5, 1 and 1.5 L min^{-1} was examined. In this study, CFD simulations are based on the real, large segments of sponges. This allows us to measure the differences between CFD simulations and full-field MRV measurements. The computational cell size and MRV voxels are 0.1 and 0.8 mm, respectively.

3. Results and discussion

In comparison with homogeneous (porousSimpleFoam solver of OpenFOAM) models, µCT-based CFD results (solved using the simpleFoam solver from OpenFOAM) showed the sensitivity of velocity profiles to the local morphology of open cell foams (Figure 4 in Appendix). The obtained flow fields form CFD simulations and MRV measurements are presented in Figure 1. We compared axial velocity profiles of CFD and MRV results for the middle section of porous structure. The results showed remarkable agreement with an accuracy of ±10% (see Figure 2). Furthermore, the obtained average radial velocity profiles from CFD and MRV data are in good agreement together (see one example in Figure 5 in Appendix). This justifies the use of CFD of large sponge segments as an adequate and reliable tool for the study of gaseous flow within porous structures.

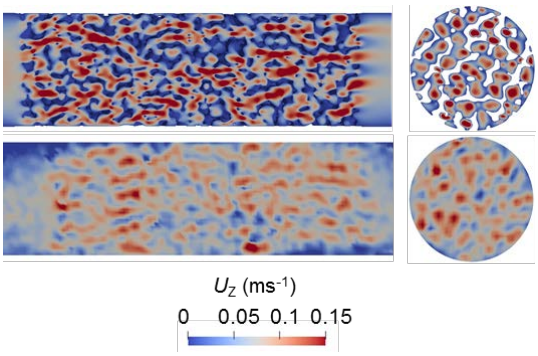

Figure.1. Obtained flow fields form CFD simulations (top) and MRV measurements (bottom)

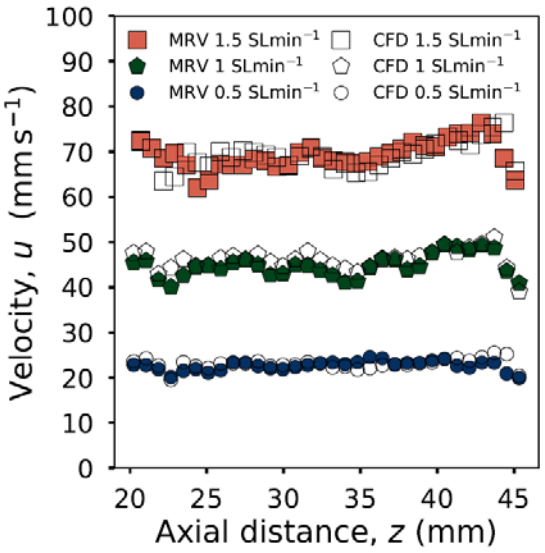

Figure.2. Obtained average axial velocity profiles within the middle Al_2O_3 sponge from CFD simulations and MRV measurements for different flow rates of 0.5, 1 and 1.5 L min^{-1}.

4. Conclusions

The quantitative agreement between CFD and MRV results amplifies the reliability of CFD simulations and underpins the capability of NMR-based measurements for *in-situ* temperature and concentration measurements. Obtaining similar results with both methods improves the reliability of either method. Finally, full-field numerical and NMR-based experimental studies of heat transfer and chemical reactions within catalytic sponges are on the way.

Appendix

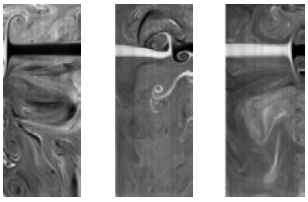
Highlights

- Mixing of dissimilar fluids in CIJs is described for a viscosity ratio range 1:2-1:60
- Mixing of dissimilar fluids is studied at flow rate ratios ranging from 1:1 to 1:4
- New design equation for CIJs mixers is proposed with an extended validity range

1. Introduction

Confined Impinging Jets (CIJs) mixers are one of the most energy efficient devices for mixing flow streams because the full power of the inlet streams is focused on the opposed jet at an impingement point. CIJs in the 10 mm scale range are able to generate mixing scales as small as 10 µm in less than 100 ms [1]. The most efficient operation of CIJs occurs at a specific flow regime, the chaotic flow regime that onsets above a critical jets Reynolds number $Re_c \approx 120$ [1]. The fast decrease of the mixing scales at this regime is associated to the formation of a vortex street in the mixing chamber. Fonte et al. [2] clearly shows that the chaotic flow regime for $Re > Re_c$ was only possible if the jets were balanced at the mixing chamber axis. Figure 1 shows Planar Laser Induced Fluorescence (PLIF) images of the mixing of a dyed and clear fluid in CIJs. The best mixing performance is associated to the chaotic flow regime with the onset of the vortex street (Figure 1b).



(a) **(b)** **(c)**

Figure 1. PLIF images of mixing of equal fluids, with one jet at $Re = 304$ and for three different flow rate ratios [1].

Fonte et al. [2] developed the Elastic Analogue Model (EAM) based on the balance of the jets kinetic energy rate to predict the position where the opposed jets contact in the mixing chamber, i.e., the impingement point position. EAM was validated from Computational Fluid Dynamics (CFD) simulations and experimentally for the mixing of fluids with the same viscosity. EAM enables the description of the jets balancing for jets with different flow rates, for CIJs with different diameter of the opposed injectors, and of fluids with different viscosities. Because of that, this model enables the design of CIJs for many processes, such as, emulsification processes in food (e.g. mayonnaise), pharmaceutical and cosmetic industries.

Recently, the validation of EAM was extended for mixing of fluids having different viscosities [3]. These results showed some divergence from EAM, and so application of this model to design the mixing of dissimilar fluids still needs further studying. In this work, the previous EAM model is further developed from the balance of jets momenta and compared with the numerical and experimental data. The objective is the development of a rigorous tool capable to design CIJs which can be used to mix fluids with different viscosities.

2. Methods

CFD simulations described in this work was studied using ANSYS Fluent and the CIJs model presented by Brito et al. [3]. Thus, mixing was studied with CFD setting the Volume-Of-Fluid (VOF) model which tracks the interface between two immiscible fluids with no surface tension. Only the impact of viscosity on the impingement point position is studied and, because of that, the surface tension between fluids was neglected. The experimental flow visualizations were obtained from PLIF images using the setup described in Brito et al. [3].

3. Results and discussion

Figure 1 shows the plots of the non-dimensional jets' impingement point position, ξ, as function of jets kinetic energy ratio, ϕ_K, for one of the case studies, the mixing of two fluids with viscosity ratio 1:2 at $Re = 50$ and $Re = 100$. The modification of EAM (new model) corrects the deviation between EAM and experimental and CFD results that was reported by Brito et al. [3]. The new model enhances the description of the flow providing a valuable design tool for industrial applications.

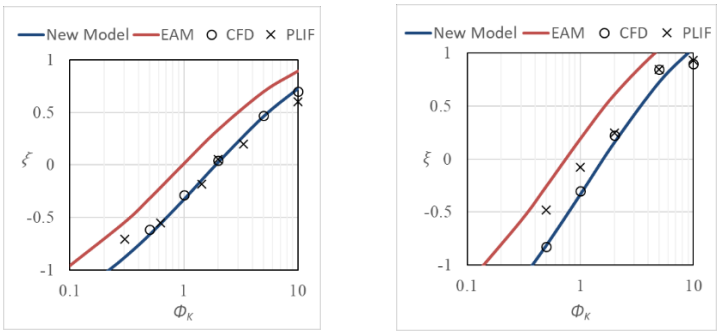


Figure 1. Impingement point position at a) Re=50 and b) Re=100 for mixing of two fluids with viscosity ratio 1:2.

4. Conclusions

A new model is proposed to predict the balancing position of jets impingement point in CIJs. Results show that the new model enhances the CIJs flow prediction for dissimilar fluids. This model enables the optimal design of CIJs, as far as mixing is regarded, changing the flow rate ratios and jets' diameter for industrial applications involving dissimilar fluids, such as, emulsification processes.

Characterizing the dispersion of Cellulose Micro/Nanofibers hydrogels

Jose L. Sanchez-Salvador, M. Concepcion Monte, Ana Balea, Angeles Blanco*, Carlos Negro

*Chemical Engineering and Materials Department, Universidad Complutense de Madrid, Avda. Complutense s/n, 28040 Madrid, Spain. *Corresponding author: ablanco@ucm.es*

Highlights

- Gel point is used to evaluate CMF/CNF dispersion
- Stirring speed modifies CMF/CNF hydrogels network
- CMF/CNF dispersion affect to their application efficiency

1. Introduction

Cellulose micro/nanofibers (CMF/CNF) have gained attention due to their desirable properties as high strength, stiffness, high surface area or low toxicity [1,2]. The methods to disintegrate cellulose fibers into substructures are well-known. However, CNF characterization is an area still under development [3]. The history of CNF before its use has a significant effect on their efficiency. Therefore, the dispersion of CNF hydrogels is an important parameter to understand and optimize their effectiveness in several applications, e.g. strength additive or wastewater treatments. Nowadays, there is not a methodology to quantify how stirring speed influence on the CNF network in suspensions. For this reason, the adaptation of a parameter used to measure NC sedimentation, the gel point (ϕ_g), is proposed [4-6]. ϕ_g, the volume concentration in the boundary between dilute and semi-dilute region, may be considered the lowest volume fraction at which all primary flocs are interconnected throughout the container, and form a self-supporting network [5]. The aim of this work is to show how CNF/CMF hydrogels perform at different stirring speed using the ϕ_g as parameter to quantify the dispersion in hydrogels.

2. Methods

CMF/CNF were obtained from recycled old newspaper. It was disintegrated in a pulp disintegrator at 30,000 revolutions before soaking. CNF were obtained using TEMPO-mediated oxidation with 10 mmol of NaClO/g dry pulp and 4 steps of homogenization at 600 bars in a homogenizer. CMF were obtained by refining the pulp in a PFI mill at 5,000 revolutions and 6 homogenization steps. Both products were characterized [1]. ϕ_g was evaluated with 250 mL of CMF/CNF suspensions at different concentrations (C_o), stirred with a 3-bladed propeller stirrer at several speeds for 10 min. Crystal violet was used as dye to visualize suspensions. Then, they were settled for 2 days (CMF) or 8 days (CNF) to claim fibers deposition. The curve C_o vs. the relation deposit height / initial height (H_s/H_o) was fitted with a quadratic equation for each speed. The linear term gives the ϕ_g [4-6].

3. Results and discussion

Figure 1 shows C_o vs. H_s/H_o for CMF/CNF at different stirring speeds. Gel point values were obtained from the fit of quadratic equations and Figure 2a shows Gel point for each stirring speed.

$ø_g$ decreases slightly in both cases with stirring speed until a minimum value and then, $ø_g$ increases. The suspensions with the stirring speed that produce the lower $ø_g$, have the higher Hs/Ho relation (Figure 2b). The opening of the network increase with stirring speed until the lower $ø_g$ in which the fibers start to break and destroy the structure, decreasing H_s/H_o relation. The results were compared using Electronic Microscopy. An opening network would be the more effective state to applicate CNF/CMF hydrogels in applications as strength additive in cardboard or water-based inks treatment.

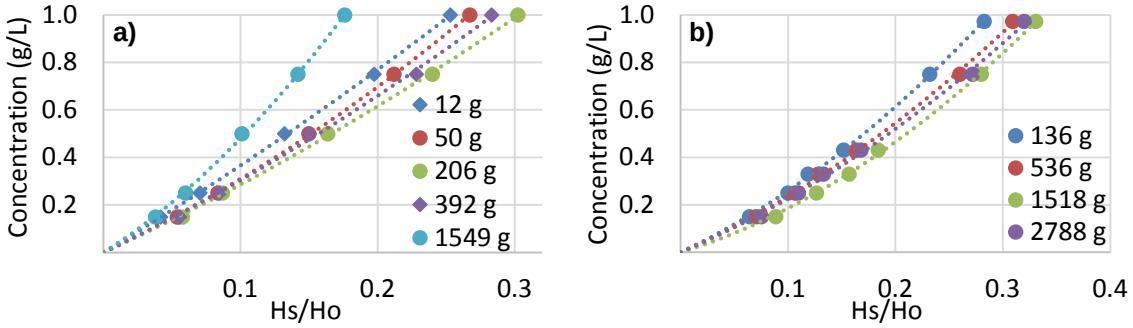

Figure 1. Gel point representation: a) CNF; b) CMF.

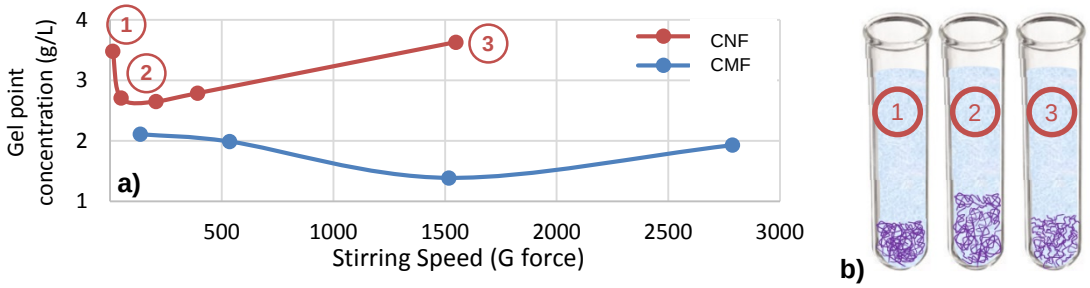

Figure 2. a) Influence of CNF/CMF gel dispersion on Gel point; b) CMF network representation with stirring speed.

4. Conclusions

$ø_g$ of CNF/CMF at different stirring speeds have a minimum for each material with a lower stirring speed in CNF due to the high fibrillation and an easy break. Suspensions stirred when $ø_g$ is minimum have the most opening network and they would be the most effective state to applicate the hydrogel. However, higher stirring speeds break the fibers and destroy the networks. Gel point methodology can be used in other cellulosic materials to obtain the optimal network configuration.

Highlights

- The catalytic oxidation of propylene into acrolein is studied.
- Kinetic parameters are identified by optimization.
- A milli-channels heat exchanger reactor is developed to intensify heat transfer.
- Numerical validations by CFD calculations are performed.

1. Introduction

Acrolein synthesis is a key stage in the multi-step methionine production process, which is an amino acid used as a nutritional additive for animal feed. Acrolein is produced by heterogeneous and exothermic catalytic oxidation of propylene in gaseous phase. Numerous side reactions can occur leading to a moderate acrolein yield. The conventional industrial reactor is a multitubular fixed bed cooled by molten salt. The axial temperature profile in tubes presents a quite large hot spot which is partly responsible for the promotion of side reactions. The use of an intensified milli-channels heat exchanger reactor (HEXR), in which the catalyst is wash-coated on the wall, is then required especially to better control the temperature profile and to avoid the use of hazardous molten salts. Besides, additive manufacturing offers the opportunity to develop new HEXR configurations and to avoid solder joints by manufacturing the device in one unique piece. Then, the HEXR is built by metal 3D printing. This work consists in:

- the determination of a precise kinetic model to enhance catalyst performance prediction,
- the sizing of the new milli-channels HEXR,
- the validation of the device by CFD calculations.

2. Kinetic modelling

The first step of the work is therefore to improve the prediction of the kinetic model with respect to the experimental data. A first reaction scheme was established by Arntz *et al.*[1] from measurements of initial formation rates of products. A more complete kinetic model, containing 10 species and 10 chemical reactions, was also developed by Redlingshöfer *et al.*[2]. A new kinetic model was then established by taking into account information from literature and experimental observations. This kinetic model considers the propylene adsorption and the oxidation ratio of the

catalyst surface. Experimental data were collected on a catalytic screening platform consisting in isothermal fixed bed reactors coupled by on-line gas chromatography. Influences of temperature, gas hourly space velocity and oxygen to propylene molar ratio have been studied. A one-dimensional plug flow pseudo-homogeneous reactor model has been developed in order to interpret the 200 performed experiments. A set of kinetic parameters, minimizing the difference between the experimental results and those obtained by the model, is found by an optimization method.

3. Design and validation of the HEXR

The optimal operating conditions based on this new kinetic model have been determined in order to maximise acrolein yield. The yield is optimal for isothermal conditions, which is confirmed by the literature[3]. This isothermal behaviour can be achieved in an intensified HEXR[4]. The HEXR is designed by taking into account different constraints (process specifications, safety constraints, catalyst wash-coating constraints and maximal dimensions of the 3D printing machine) and then by calculating and studying different items:

- the number of channels required to convert the fixed mass flow rate of reactants,
- the fluid flow configuration (cross flow or co-current),
- the shape of fluid distributors and collectors,
- the temperature profile of the reactive and coolant sides.

Finally, after sizing the HEXR, some validations concerning safety aspects have been performed by CFD calculations. The influence of a potential thermal runaway is simulated in a section of the device to confirm the efficiency of the heat transfer. Besides, to evaluate the mechanical strength of the HEXR, a study is performed by using the temperature profile of the nominal case and by applying it to calculate the mechanical constraints on the structure. The same work is performed by considering a pressure gradient between both fluid sides.

4. Conclusions

An intensified mini-channel HEXR, presenting interesting performances, has been designed and manufactured by metal 3D printing. A complete simulation, coupled with the kinetic model, for a fraction of the device, as well as experiments on the manufactured unit, have yet to be done.

A Power-to-Liquid Process – An alternative Process for the Production of (Poly-)Oxymethylene Dimethyl Ether (OME) based on Methanol.

Lara Theiss[1,2], Mohamed Ouda[1], Franz K. Mantei[1], Achim Schaadt[1], Robert Güttel[2]

Highlights

- Methanol (MeOH) oxy-dehydrogenation to dimethoxymethane (OME_1) and formaldehyde (FA) shows high potential for efficient OME synthesis
- Reasonable MeOH conversions with high OME_1 and FA selectivities
- Successful water separation *via* membranes, as one of the crucial steps in all OME synthesis processes

1. Introduction

Due to their interesting thermo-physical and intrinsic combustion properties, (poly)oxymethylene dimethyl ethers (OMEs) have a high potential as diesel fuel alternative, "green" solvents or as CO_2 absorbent [1, 2]. The greatest challenge for introducing OME into the market is the lack of an energy-efficient, economically feasible and scalable industrial process for the synthesis of OME with a certain chain length. A promising synthesis route includes the formation of formaldehyde (FA) and dimethoxymethane (OME_1) by oxidative dehydrogenation of methanol (MeOH) in a single reactor first, using a porous solid catalyst providing both acidic and redox sites. Subsequently, FA and OME_1 are converted into higher OMEs, e.g. $OME_{3\text{-}5}$. The crucial issue in the first step is the stoichiometric by-product water, which limits the equilibrium yield and has to be removed prior to the second higher OME synthesis step. Thus, the water management plays a major role in the overall process. However, due to several azeotropes in mixtures containing FA, MeOH, water and OME_1, separation by distillation is cumbersome. Therefore, alternative processes like the application of membranes gain a lot of interest [3], which is aimed at in the present contribution.

2. Methods

In order to investigate the oxidative dehydrogenation of MeOH and the water removal by membrane technology systematically, a Design of Experiment (DoE) is applied. This allows quantitively evaluation of the correlation between input parameters, such as temperature, pressure and membrane material, and the most important target parameters, e.g. yield or water separation efficiency. The experiments are performed in two stages: A continuously operated plug flow reactor using a self-made bifunctional catalyst was used for MeOH dehydrogenation at 200-300°C and 1 bar. The obtained product mixture was continuously subjected to two membrane units. Moreover, a short cut model for the reaction and the separation step is applied, in order to simulate the whole process for addressing scale up issues.

3. Results and discussion

First results of the oxidative dehydrogenation of MeOH and the subsequent separation of water by selected hydrophilic membranes show promising results. **Figure 1** shows the molar fractions of the oxidative dehydrogenation reaction product (denoted with "Reaction"), which is subsequently directly introduced into the membrane unit during the test run. The molar fractions of the retentate (denoted with "Retentate") shows that almost a complete separation of water could be achieved at different ratios of sweepgas to reaction product stream (denoted with "R"). Moreover it is found that the amount of the other components does not change significantly in the retentate, which indicates a rather selective water separation. During reaction, MeOH conversion of about 40% and OME_1 and FA selectivities of 20% and 50% could be determined. Molar ratios of OME_1 to FA of 0.4 - 0.8 were obtained, which is a crucial target parameter for the subsequent synthesis for higher OMEs.

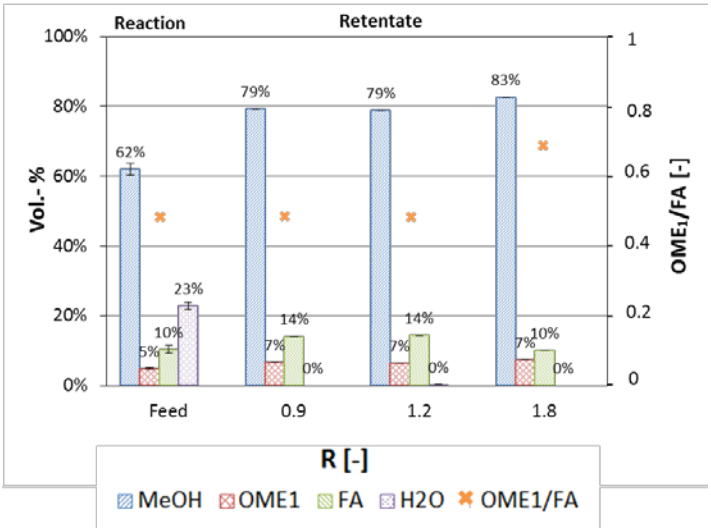

Figure 1. Exemplary combined reaction and separation test run, performed in a plug flow reactor and using a hydrophilic membrane. The initial molar fraction of methanol is 40%. R is the ratio of sweepgas to the membrane feedgas.

4. Conclusions

The oxidative dehydrogenation of MeOH directly into OME_1 and FA shows promising results. By producing OME_1 and FA in one synthesis step, a simple, efficient and scalable synthesis pathway for the production of higher OME can be provided. The separation of water, as one of the biggest challenges in OME synthesis, could be achieved successfully by applying hydrophilic membranes. Maximizing the MeOH conversion, without changing selectivities, as well as the long-term stability of the membrane performance will be investigated successively.

Highlights

- Activity experiments over CO_2 methanation catalysts were performed.
- Ruthenium, nickel and bimetallic catalysts were prepared and tested.
- Nickel-based catalysts presented higher activity, selectivity and stability.

1. Introduction

Power-to-Methane is an attractive solution for the storage of the surplus renewable energy from intermittent and fluctuating natural sources (e.g. sun, wind), by the conversion of the electric energy into a chemical. To this end, the surpluses are firstly transformed into H_2 (via water electrolysis), and afterwards into methane that can be stored and transported through the existing natural gas grid [1]. Methane is produced through the Sabatier reaction (Eq. 1) using the renewable H_2 and captured CO_2, the latter being available from emission sources such as power plants, cements kilns or oil refineries [1-2].

$$CO_2 + 4H_2 \rightleftharpoons CH_4 + 2H_2O \qquad \Delta H_{298K} = -165\ kJ \cdot mol^{-1} \qquad (1)$$

Due to the exothermic nature (and negative change in number of moles), the Sabatier reaction is thermodynamically favored at low temperatures (and high pressures). To overcome kinetic limitations and achieve acceptable rates and selectivity, especially at low temperatures, highly active catalysts are required [2]. In this work, metal-based heterogeneous catalysts for the CO_2 methanation were screened regarding to their activity, CH_4 selectivity and stability.

2. Methods

2.1 Catalyst synthesis

Catalytic tests were performed on 4 materials: in-house synthesized Ru(2%)/SiO_2, Ni(34%)MgAl, Ru(0.5%)/Ni(34%)MgAl and a commercial catalyst supplied by Degussa (Ru(1%)/Al_2O_3).
Ni(34%)MgAl was prepared by the co-precipitation method, while Ru(0.5%)/Ni(34%)MgAl was prepared by wetness impregnation over the nickel-aluminum derived hydrotalcite. Ru(2%)/SiO_2 was obtained by wetness impregnation over a commercial SiO_2 support (Sigma Aldrich).

2.2 Catalyst screening

The experiments were conducted using *ca*. 100 mg of catalyst particles sized between 200-250 µm and diluted in inert beads that were loaded into a tubular fixed-bed reactor (*L*=12 cm; I.D.= 0.72 cm). The reactor was warmed up at a heating rate of 5 $^oC \cdot min^{-1}$ until 300 ^oC or 650 ^oC and held 1 or 2 hours at that temperature, for the Ru or (Ru)Ni catalysts, respectively. Catalyst activation was performed using a stream of 10 vol. % H_2 balanced in N_2. Activity tests were conducted sequentially

at 250, 300 and 350 °C using a reactant stream made of N_2 (30 mL_n/min), H_2 (16 mL_n/min) and CO_2 (4 mL_n/min) that was fed for 75 minutes. Catalyst stability was assessed at 350 °C during 24 hours before decreasing the temperature and submitting the catalyst to new activity measurements at 300 °C and 250 °C. CO_2 conversion (X_{CO2}) and CH_4 selectivity (S_{CH4}) were calculated according to Eq. 2 and Eq. 3, respectively, with F_{CO2}^{in} being the CO_2 inlet molar flow rate, and F_{CO2}^{out}, F_{CH4}^{out} and F_{CO}^{out} the outlet molar flow rates of CO_2, CH_4 and CO, respectively.

$$X_{CO2} = \frac{F_{CO2}^{in} - F_{CO2}^{out}}{F_{CO2}^{in}} \quad (2)$$

$$S_{CH4} = \frac{F_{CH4}^{out}}{F_{CH4}^{out} + F_{CO}^{out}} \quad (3)$$

3. Results and discussion

Nickel-based catalysts Ni(34%)MgAl and Ru(0.5%)/Ni(34%)MgAl were the most promising materials with the highest CO_2 conversion ($X_{CO2,MAX}$ = *ca*. 81-92 % at 300-350 ºC) and CH_4 selectivity (≥ 99 %) (cf. Fig. 1). They also revealed stable performances after 24 hours on stream (cf. Fig. 1a). However, CO_2 conversion is lower for the bimetallic Ni-Ru catalyst compared to the Ni(34%)MgAl sample, particularly at 250 °C (62.5 % vs. 36.6 % - cf. Fig. 1a). The undesired formation of CO was limited with both Ni(34%)MgAl and Ru(0.5%)/Ni(34%)MgAl; the maximum CO fraction obtained was 587 ppm, and was null at 300 °C. Regarding to the other ruthenium catalysts tested, it was found that CH_4 selectivity drops abruptly after 24 hours on stream (cf. Fig. 1b). These catalysts become more active towards carbon monoxide with CO selectivity reaching 34.1 % and 41.3 % at 300 °C for the Ru(1%)/Al_2O_3 (Degussa) and Ru(2%)/SiO_2, respectively (cf. Fig. 1b).

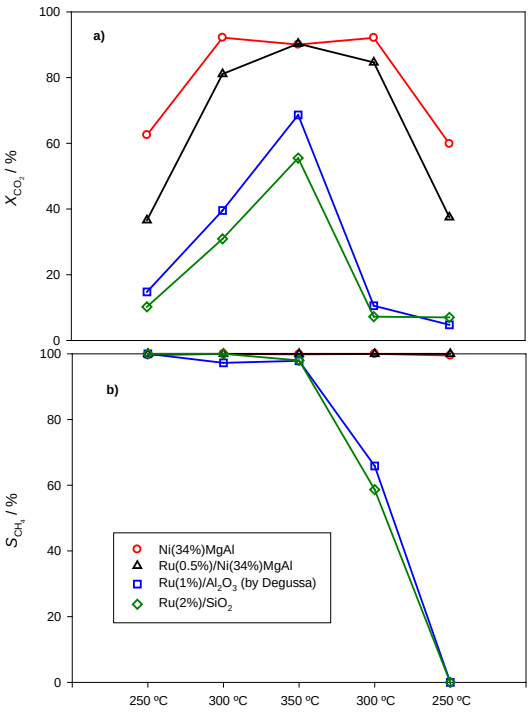

Figure 1 - CO_2 conversion (a) and selectivity to CH_4 (b) attained at the different temperatures.

4. Conclusions

The nickel-based catalysts, Ni(34%)MgAl and Ru(0.5%)/Ni(34%)MgAl, presented higher activity, selectivity and stability, when compared to the commercial Ru(1%)/Al_2O_3 and prepared Ru(2%)/SiO_2 catalysts. Ongoing detailed physical-chemical characterization will help establishing relationships between catalytic performances.

CO_2 methanation activated by Ni/MgO catalysts

Astrid Loder[1]*, Susanne Lux[1], Matthäus Siebenhofer[1]

1 Institute of Chemical Engineering and Environmental Technology, Graz University of Technology, Inffeldgasse 25/C/II, 8010 Graz, Austria

**Corresponding author: astrid.loder@tugraz.at*

Highlights

- Ni/MgO catalysts are active for the CO_2 methanation and 100 % selective to CH_4.
- Higher Ni load leads to higher CO_2 conversion.
- The rate law shows a correlation between frequency factors and Ni load.

1. Introduction

Carbon dioxide hydrogenation utilizes CO_2 to produce hydrocarbons and carbon monoxide. The product selectivity is influenced by the catalyst and the process parameters. If methane is the main product, the process is called CO_2 methanation. [1] CH_4 can be transported in already existing pipelines for natural gas and acts as a chemical hydrogen storage.

$CO_2 + 4\ H_2 \rightarrow CH_4 + 2\ H_2O$

A bifunctional nickel magnesium oxide catalyst was investigated. Nickel provides the adsorbent capacity for hydrogen and is highly selective to CH_4. [2] MgO activates carbon dioxide and suppresses possible catalyst deactivations. [3] MgO reduces the negative impact of water on the catalyst. The Ni/MgO catalyst is a cheap, highly active, easy to synthesize and robust catalyst. [4] The reaction kinetics for the CO_2 methanation and the catalysts activity were investigated to describe the reaction for a future industrial application.

2. Methods

The Ni/MgO catalysts were prepared via wet impregnation. Calcined magnesium oxide was mixed with a solution of nickel nitrate hexahydrate ($Ni(NO_3)_2*6H_2O$) and water. The catalysts were dried, calcined and reduced in hydrogen atmosphere. Four Ni/MgO catalysts were prepared with 11, 17, 21 and 27 w% nickel load.

The CO_2 methanation experiments were performed in a bench scale fixed bed tubular reactor. The product gas was continuously analyzed by a Caldos27 thermal conductivity analyzer for H_2 and Uras26 infrared photometer for CO_2, CO and CH_4. The H_2:CO_2:N_2 ratio of the feed gas flow was 56:14:30 and ambient pressure was applied. Steady state experiments were performed between 533 to 648 K and 1.2 $m^3\ kg^{-1}\ h^{-1}$ to 14.9 $m^3\ kg^{-1}\ h^{-1}$.

3. Results and discussion

A high nickel load leads to a higher CO_2 conversion. The highest CO_2 conversion was achieved at 598 K with a 27 w% Ni/MgO catalyst. At higher temperature the CO_2 conversion drops caused by

the lower equilibrium conversion. Nickel loads over 30 w% are only beneficial for temperatures lower than 600 K. The methane selectivity was 100 % for every Ni/MgO catalyst.

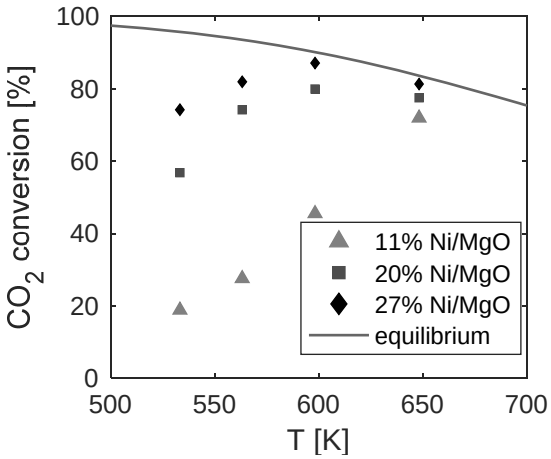

Figure 1. CO_2 conversion for the carbon dioxide methanation with catalysts of varied Ni load at 3.7 $m^3\ kg^{-1}\ h^{-1}$ and the equilibrium CO_2 conversion.

The rate law of the CO_2 methanation consists of a forward reaction, a backward reaction and an adsorption term. The temperature dependence was modelled by an Arrhenius approach. The frequency factors show a correlation to the Ni load of the catalyst.

4. Conclusions

The CO_2 methanation is an opportunity to reduce CO_2 emissions. A bifunctional Ni/MgO catalyst is active for the CO_2 methanation and 100 % selective to CH_4. Higher nickel loads result in higher CO_2 conversions up to 30 w% nickel load and 600 K.

Highlights

- Transient operation of the Sabatier reaction on Ni catalysts
- Dynamic simulation the methanation in a Berty reactor
- Storage effects on the catalyst are visible during concentration forcing
- Steady-state kinetics fail to describe the transient behavior

1. Introduction

Heterogeneously catalyzed processes are usually operated in steady state. The coupling of these processes to renewable energy sources, such as the methanation of CO_2 in the Power-to-Gas process, may require a dynamic operation of the reactor. Reaction kinetics resulting from steady-state measurements, mostly in the form of Langmuir-Hinshelwood-Hougen-Watson approaches, are typically used for the reactor design or the investigation of suitable operating conditions. The simulation of the periodic operation of a methanation reactor based on steady-state kinetics predicted dramatic effects of the inlet composition on temperature profile and outlet composition [1]. However, the underlying description of the reaction rate is a strong simplification of the actual processes on the catalyst surface. A detailed description of the transient and steady-state operation can be achieved by microkinetic models [2]. But microkinetics are rarely applicable for simulation and design on the reactor scale. Therefore, the aim of this study is dedicated to the detailed experimental investigation of the dynamic methanation on Ni catalysts in order to verify whether steady-state kinetics can describe the observed transient phenomena.

2. Methods

In order to develop a proper kinetic approach, measurements with a Ni catalyst in a Berty reactor are carried out. At temperatures of 200 - 400°C and pressures up to 30 bar, this reactor can be regarded as an ideally mixed continuous stirred tank reactor (CSTR). Through online analysis of the gas composition with a mass spectrometer, both stationary and dynamic measurements can be performed with high temporal resolution. For the investigation of the dynamic behavior of the methanation reaction, concentration pulses and steps are applied to the system. The high frequency of the step changes also allows for a periodic modulation of the system. During the dynamic catalyst operation, storage effects of adsorbed educts and intermediate products become visible. Additionally, the storage capacity is studied via the adsorption of CO_2 and H_2 at reaction temperatures by volumetric and dynamic adsorption methods, which allows the determination of adsorption isotherms and adsorption kinetics. Based on the experiments, approaches for the reaction kinetics (steady-state, dynamic) are developed. These are used in a model of the Berty

reactor to explore the limits of steady-state kinetics and the applicability of simplified dynamic kinetics. The Berty reactor is modelled as a CSTR taking the catalyst as a separate solid phase into account.

3. Results and discussion

The bang-bang operation of a Ni/Al_2O_3 catalyst, where the reactor inlet composition is alternated between pure H_2 and CO_2, can be described with a relatively good accuracy by using a published steady-state reaction kinetics [3]. Figure 1 shows the transient operation of the same catalyst with a flush of He between the step changes in order to remove the remaining CO_2 from the gas phase. Switching to H_2 then leads to desorption of adsorbed CO_2 and methane formation sets in. This simple experiment nicely illustrates the failure of the steady-state reaction kinetics. Since H_2 and CO_2 do not simultaneously occur in the reactor, the calculated reaction rate is always zero. The observed methane formation reveals that significant quantities of CO_2 and/or carbon containing intermediates are adsorbed on the catalyst surface, which is also evidenced by the adsorption measurements.

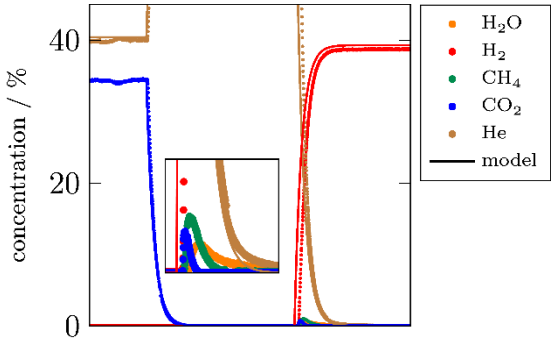

Figure 1. Experimental (dots) and simulation (solid) results when the Berty-reactor is flushed with He for 10 min between a change from CO_2 to H_2. The zoom is located at the step change of H_2. Conditions: 20 wt.-% Ni/Al_2O_3, 0.5 g, 250 °C, 2 bar, 200 mL_N/min.

4. Conclusions

The comparison of the reactor simulation and kinetic experiments shows, that steady-state kinetics are able to predict transient phenomena of the Berty reactor when both reactants are present in the gas phase. If, however, a component is missing, as shown in the experiment, the steady-state kinetics cannot correctly reproduce the behavior of the reactor. In order to be able to reproduce the transient results, it is necessary to develop dynamic kinetic approaches which can also be used on the reactor scale.

Direct epoxidation of linseed oil by hydrogen peroxide: thermal risk assessment

Wander Y. Pérez-Sena[1,2], Pasi Tolvanen[2], Lionel Estel[1], Tapio Salmi[2], Sébastien Leveneur[1,2]

1.Normandie Univ, INSA Rouen, UNIROUEN, LSPC, EA4704, 76000 Rouen, France

Highlights

- Adiabatic experiments for the epoxidation.
- Thermal risk assessment for different epoxidation routes.
- Kinetic model for the direct epoxidation.

1. Introduction

The use of vegetable oil as industrial feedstock could be a promising substitute to petroleum-derived sources. For instance, production of biodiesel from transesterification of vegetable oils is a well-developed process at the industrial level. Vegetable oils are used in industry because they are renewable, biodegradable, non-toxic and abundant.

One of the first step is the epoxidation of vegetable oils. Epoxidized vegetable oils can be seen as platform molecules because they can be transformed into different chemicals [1] such as polyols, carbonated vegetable oils [2] and polyurethanes [3-4].

Conventionally, production of epoxidized vegetable oils is done by the Prileschajew method. It is a liquid-liquid reaction system, with several consecutive and parallel exothermic reactions [5]. The first step is the production of percarboxylic acid in the aqueous phase. Then, the percarboxylic acid diffuses into the organic phase to epoxidize the unsaturated groups. Due to the presence of several exothermic reactions, the risk of thermal runaway exists [6-7].

The issues of the Prileschajew method are:

-production of organic waste during the process;

-acidity of the reaction mixture favors the side reaction of ring-opening;

-separation step and waste treatment are more demanding;

-formic and acetic acids are the most used and can cause some corrosion.

Hence, direct epoxidation of vegetable oil by oxygen and hydrogen peroxide is seen as the best option concerning thermal safety, waste treatment and selectivity. The objective of this study is to compare the thermal risk for the epoxidation of linseed oil by three chemical systems: Prileschajew oxidation by using peracetic acid, Prileschajew by using performic acid and by the direction epoxidation of hydrogen peroxide on alumina. For the evaluation of the thermal risk on the epoxidation of linseed oil, the TMR_{ad} (Time to Maximum Rate under adiabatic conditions) was

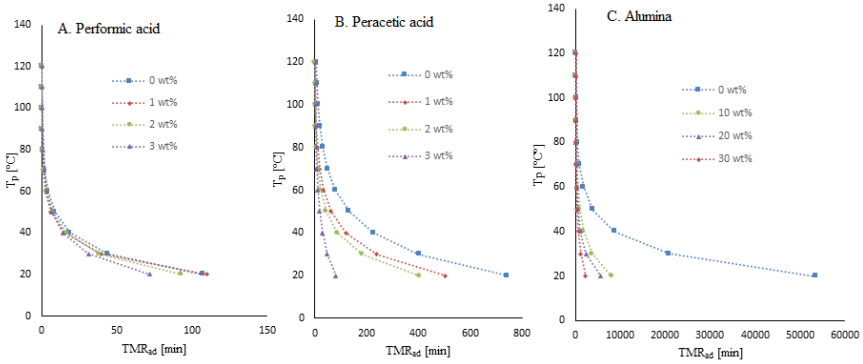
chosen as a reliable safety parameter to identify the probability of hazardous scenarios. The adiabatic calorimeter ARSST standing for Advanced Reactive System Screening Tool was used [8] to determine TMR_{ad}. We have decided to use the most conservative assumption implying to determine the TMR_{ad}(Tp) at the initial temperature Tp by using the zero- order approximation.

2. Methods

Experiments were performed in a pseudo-adiabatic calorimeter: ARSST (Advanced Reactive System Screening Tool) following the heat loss compensation principle by using and electrical heating supply [8]. To decrease the evaporation, experiments were performed under high pressure of nitrogen.

3. Results and discussion

We have tested the influence of different parameters on the thermal risk parameter TMR_{ad} such as concentrations of reactants or catalyst. Figure 1 shows the evolution of TMR_{ad} at different catalyst concentrations for the Prileschajew by formic acid catalyzed by sulfuric acid, Prileschajew by acetic acid catalyzed by sulfuric acid and epoxidation by Al_2O_3.



Figures 1. Process temperature Tp versus TMRad for the epoxidation by performic acid (A); by peracetic acid (B) and direct epoxidation by hydrogen peroxide over alumina (C) with different weight percentage of catalyst.

4. Conclusions

Figure 1 shows that direct epoxidation by alumina is thermally safer than the Prileschajew ones. The continuation of this work is the kinetic modeling of these reactions to know which process is more efficient from a kinetic viewpoint.

Determination of the Factors Responsible for Stabilization in Hydrotreating.

Ngoc Yen Phuong Cao[1], Benoit Celse[1*], Denis Guillaume[1], Isabelle Guibard[1], Joris W. Thybaut[2]

1 IFP Energies nouvelles, Rond-point de l'échangeur de Solaize, BP 3, 69360 Solaize, France; 2 Ghent University, Laboratory for Chemical Technology, Technologiepark 914, Ghent, B-9052, Belgium

**Corresponding author: benoit.celse@ifp.fr*

Highlights

- Stabilization is due to chemical phenomena and depends on feed and operating conditions
- Stabilization follows a first-order transfer function
- A characteristic time parameter is defined for stabilization

1. Introduction

Hydrotreating is a catalytic conversion process in petroleum refineries, among others for removing organic nitrogen, sulfur and oxygen from hydrocarbon streams. A kinetic model is mandatory for the design and simulation of this process. It is usually developed based on data acquired at steady state conditions. A significant challenge in this respect is that establishing the steady state requires several days, leading to long duration to acquire sufficient experimental data for kinetic model construction. However, during the transient state, effluent analyses are carried out at regular time intervals to determine whether the steady state has been reached. The aim of this work is to have a better understanding of the stabilization behavior by estimating the influential factors, such that the data acquired in this period can also be employed for kinetic modelling.

2. Methods

The experimental data are obtained using the hydrodenitrogenation pilot plant operating in a continuous manner in IFP Energies Nouvelles. The total catalyst volume in the reactor is 50 cm^3. Operating conditions are switched after having reached the steady state corresponding with the previous operating conditions. Data cover 11 Vacuum Gas Oil (VGO) feeds over two catalysts. Liquid Hourly Space Velocities (LHSV) vary between 0.5 and 4 h^{-1}, the total pressure between 50 and 140 bar and the temperature between 350 and 410 °C. The data are measured as the *'liquid product nitrogen content'* with time on stream, including 920 measurements, see Figure 1. One *'episode'* is defined as a series of points corresponding to one experimental run.

A hydrodynamics study on the pilot plant has been done using a tracer technique. Stabilization evolution is assessed via exploratory data analysis [1]. It resulted in a first-order transfer function as shown in Equation (1). The characteristic time τ of each episode presented in the equation is estimated via nonlinear least-squares problem (solid line in Figure 1). A multiple linear regression

with interaction technique is then used for τ prediction to evaluate the phenomena underlying the transient data. The most influential input variables are estimated via variable selection technique *'leaps'* [2].

$$N = N_{init} + (N_{final} - N_{init})\left(1 - e^{\left(\frac{-(TOS - TOS_{init})}{\tau}\right)}\right) \quad (1)$$

Where:

- N : product nitrogen at a specific TOS (ppm)
- N_{init} : first point of episode (ppm)
- N_{final} : last point of episode (ppm)
- TOS : time on stream (h)
- TOS_{init} : TOS corresponding to N_{init} (h)
- τ : characteristic time (h)

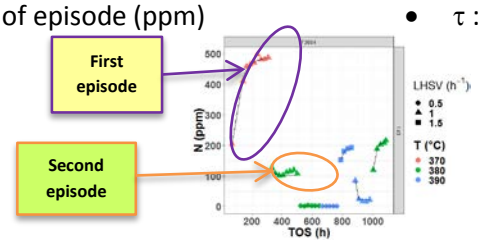

Figure 1. Data representation (Feed F3884, P = 140 bar, point : experimental data, solid line : model fitting Equation (1))

3. Results and discussion

The stabilization evolution of the tracer component is significantly faster than the stabilization of hydrodenitrogenation. Chemical phenomena are therefore involved in the stabilization. τ reflects the time required to reach the steady state. First episodes take more time to stabilize than other episodes. Two linear models for τ were built: one for first episodes (model M1) and another for other episodes (model M2). Model M1 was achieved with a R^2 of 0.83, see Figure 2. It contains three variables (LHSV, feed resin, pressure) and one interaction term LHSV*resin. An inverse relationship between LHSV and τ was found. The interaction term shows that the impact of LHSV on τ depends on the value of feed resin which is the polar components with high molecular weight. A direct relationship between pressure and τ was observed. Temperature is not an influential parameter for stabilization. However, stabilization of other episodes seems more complex. Model M2 relies by not only on the operating conditions and feed properties but also on the operating conditions of the previous episode.

Figure 2. Parity plot with 95% confidence interval for model M1 *(left, R^2 = 0.83)* and model M2 *(right, R^2 = 0.66)*

4. Conclusions

Stabilization behavior is a critical point for hydroprocessing experiments. Two models (one for the first episode, another for the others) were built to predict the stabilization time and assess the most influential parameters (LHSV, resin, pressure). The models will be tested against new data.

Supercritical Water: a Roadmap to Biorefineries Through Innovation.

María José Cocero, Tijana Adamovid, Luís Vaquerizo, Celia Martínez.

Bioecouva Research Institute, High Pressure Processes group. Valladolid University

**Corresponding author: mjcocero@iq.uva.es*

Highlights

- Ultrafast supercritical water (SCW) hydrolysis to avoid hydrolysis products degradation.
- Ultrafast preheating to avoid hydrolysis products during the heating step.
- From the conventional hydrothermal ionic reaction media to the non-ionic SCW media.
- Efficient lignocellulosic biomass fractionation in sugars and lignin.

1. Introduction

The selective fractionation of the lignocellulosic biomass in its main components (hemicellulose, cellulose and lignin) is a challenge of the sustainable biorefineries development that has not been solved yet. The complexity of the biomass and its structure limit the process by mass transfer. In addition, the crystallinity of cellulose complicates its dissolution in conventional solvents. Water at temperature and pressure above the critical point (374ºC and 22MPa) has physical properties that allow dissolving the cellulose. The water ionic product changes from 10-12 at 300ºC to 10-19 to 374ºC, so at subcritical water conditions the ionic reactions mechanisms are favoured and at SCW conditions the radical mechanism predominates. The decrease of the ionic mechanism reaction avoids the loss of selectivity that occurs in the conventional hydrothermal processes. Additionally, SCW has low viscosity and high diffusivity that facilitate the penetration of water into the complex structure of the lignocellulosic matrix, whilst its low dielectric constant, similar to non-polar organic solvents, enhances solubility of organic compounds. Under these conditions, the hydrolysis of biomass fractions is extremely rapid and presents a means to achieve a significantly more process intensive fractionation of biomass.

Reaction speed – while being an advantage to process intensification – is also a significant disadvantage to selectivity at longer reaction times, leading to degradation of hydrolysis products and resulting in complex reaction mixtures. To take advantage of the properties of the SCW and avoid the degradation of hydrolysed products, we have introduced the ultrafast process by operation at residence times below 1 second. This process allows the hydrolysis of the cellulose, but avoids the hydrolysis of the sugars. The control of the residence time is possible by our innovative reactor design: the sudden expansion micro reactor that preheats the biomass in residence times below 10ms, by direct mixture of the SCW and the biomass suspension, and cools the reaction effluent by the Joule Thomson effect that takes place during the depressurization.

This process allows fractionating lignocellulosic biomass in the next stages: i) separation of extractives as polyphenols, antioxidants, starch, proteins or oils; ii) hydrolysis of hemicellulose to

produce hemicelluloses oligomers and C5 sugars; iii) hydrolysis of the cellulose fraction to produce a liquid effluent, mainly C6 sugars, and a solid effluent, mainly lignin (1).

2. Methods

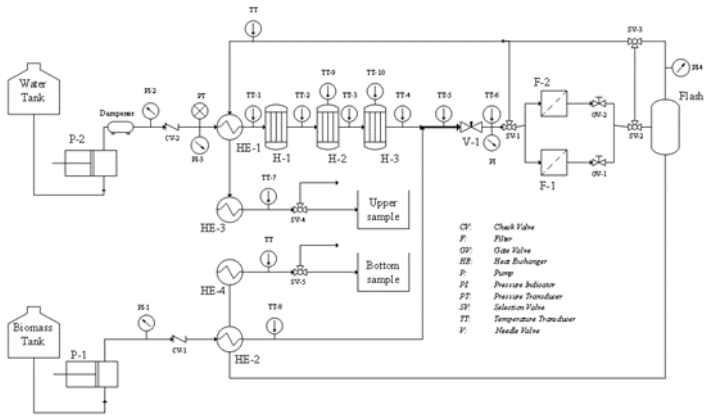

Figure 1 presents a pilot plant flow diagram for lignocellulosic biomass fractionation. The pilot plant operates at temperatures of 400ºC, pressures of 25 MPa and biomass suspension flow of 10 kg/h. The pilot plant has four units: 1) biomass pumping, 2) SCW production, 3) reaction and 4) heat integration and energy recovery (2)

3. Results and discussion

The fractionation of pulp sugar beet is presented as an example of lignocellulosic biomass fractionation. The effect of the residence time on the composition of the liquid effluent sugars is presented in Figure 2. Sugar beet pulp has a concentration of pectin of 27%; although the pretreatment extracts the pectins, the remaining pectins hinder the flow of SCW into the complex biomass matrix, requiring longer residence times. These residence times increase degradation, but even at residence times of 230ms, the C6 yield is higher than 80%, significantly higher than the conventional processes (3).

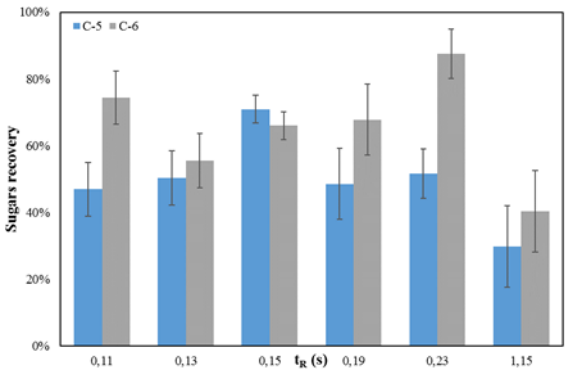

Figure 2. Beet pulp SCW hydrolysis at 390°C and 25 MPa. C-6 and C-5 liquid concentration at different reaction times.

4. Conclusions

The SCW ultrafast hydrolysis is a selective process for the fractionation of lignocellulosic biomass in a liquid effluent of C5 and C6 sugars than can be used for fermentation, and a solid effluent that is mainly a lignin composite. Any HMF is produced.

Highlights

- It is the first time that $NaHCO_3$ hydrothermal reduction is performed using non-edible biomass.
- A higher extent of liquefaction of biomass was achieved by adding $NaHCO_3$.
- Biomass with high-content in holocelluloses (sugar bagasse) achieved higher yields.

1. Introduction

Production of fuels and chemicals from renewable sources is extensively investigated due to the low level of fossil fuels reserves and their impact on environment. Among the different technologies hydrothermal valorization of lignocellulosic biomass has been intensely investigated. High temperature water (HTW) exhibits outstanding properties c, playing different roles in the reaction, such as reactant, solvent and catalyst.

Increasing carbon dioxide (CO_2) levels are having harmful consequences for the environment. Different processes have been envisioned as effective methods for CO_2 conversion into useful chemicals and fuels, being hydrothermal processing one of the most innovative. CO_2 hydrothermal reduction has already been studied using metals and organic model compounds[1,2]. Combining both processes of hydrothermal biomass valorization and hydrothermal CO_2 reduction to produce useful chemicals would lead to an optimized and greener process.

In this research, CO_2 conversion to formic acid in hydrothermal media was carried out using non-edible lignocellulosic biomass (pine needles and sugarcane bagasse), demonstrating the possibility for the first time the use biomass residues as a reductant for CO_2 reduction in a one-pot reaction.

2. Methods

Reactions were performed in a 100 mL batch reactor with a magnetically driven impeller. Biomass (pine needles, PN, or sugarcane bagasse, SB) were presoaked overnight in 25mL of distilled water, and placed afterwards in the reactor, adding extra 25 mL of water and sodium bicarbonate ($NaHCO_3$) as a CO_2 source. After sealing and purging the reactor, the reactor was placed in a heating jacket, previously preheated, and setting this point as t=0'. After the desired reaction time, the reactor was cooled and liquid and solid samples were collected. Liquid samples were analyzed using HPLC and TOC techniques, while solid samples were analyzed through FTIR and SEM.

3. Results and discussion

To study whether biomass residues can convert $NaHCO_3$ into formic acid in one-pot reaction, both PN and SB were treated with and without $NaHCO_3$ for 30 min at 250ºC (0.50M $NaHCO_3$ and 1.0g of biomass). Results showed that not only a higher production of formic acid when $NaHCO_3$ was added in both cases, but also to a higher content of dissolved organic carbon in liquid samples, achieving a higher extent of biomass liquefaction. Comparing both biomass types, SB achieved a better yield to formic acid (referenced to the initial amount of biomass) than PN. This may be caused by a higher amount of holocelluloses (sugar-based biopolymers) in SB than in PN.

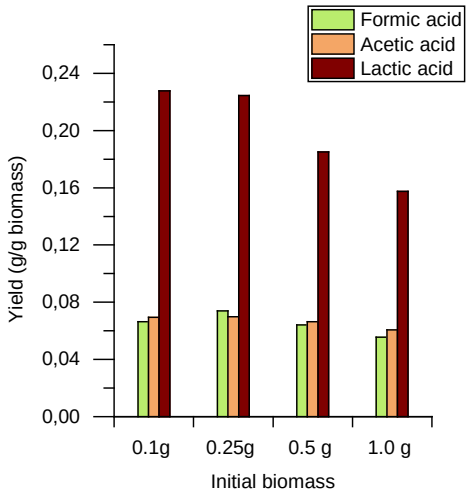

Figure 1. Influence of the amount of initial SB at 250ºC for 30 min.

Thus, selecting SB as reductant, different reaction parameters were optimized, such as initial amount of biomass (0.10g, 0.25g, 0.50g and 1.00 g, results shown in Figure 1), temperature (225ºC, 250ºC and 275ºC) and time (15 min, 30 min, 60 min, 90 min and 180 min). The best yield to formic acid was achieved using 0.25 g of SB in a 50 mL solution of 0.50M $NaHCO_3$ at 250ºC for 180 min (0.10g of formic acid per gram of initial sugar bagasse). Among the different by-products resulting from the biomass liquefaction and hydrolysis, acetic acid, lactic acid, glycolaldehyde and glyceraldehyde were detected in the highest concentrations.

4. Conclusions

For the first time, the possibility of converting $NaHCO_3$ as CO_2 in hydrothermal media was accomplished using biomass residues. Despite future work should study in the mechanism of the reaction and the implementation of the processes in a continuous pilot plant, this work is a promising starting point for a novel method of CO_2 and biomass valorization.

The Kinetics of Ethylene Oxide and Its Substituents in the Autocatalytic Reaction with Fatty Amines.

Pia Müller[1*], Wyatt Winkenwerder[2], John van der Schaaf[1]

1 Department of Chemical Engineering and Chemistry, Eindhoven University of Technology, P.O. Box 513, 5600MB, the Netherlands; 2 Nouryon, Brewster, New York 10509, United States

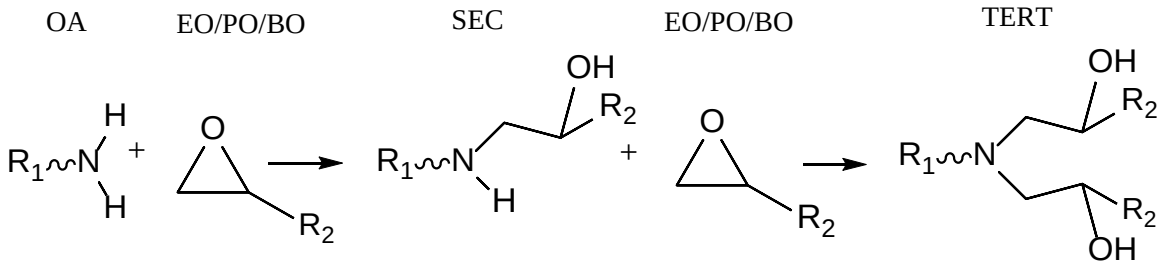
**Corresponding author: p.muller@tue.nl*

Highlights

- Ethylene-, propylene- and butylene oxide follow one reaction mechanism
- Lower or no substitution of the epoxide ring increases the reaction rate

1. Introduction

The reaction of fatty amines with two equivalents of epoxide is an industrial process producing surface-active compounds used in several applications, such as paints, corrosion inhibitors, and textiles. The reaction follows an S_N2 mechanism, which is auto-catalyzed by the formed intermediate (SEC) and the end product (TERT) shown in Figure 1.



R_1=C_8 alkyl chain
R_2= H (EO), CH_3 (PO), CH_2-CH_3 (BO)

Figure 1. Reaction scheme.

As described by Smith [1], the reaction is catalyzed by alcohol groups, such as the formed products. Sundaram and co-worker found that butylene- (BO), propylene- (PO), and ethylene oxide (EO) react with organic amines in an aqueous phase following the same mechanism [2]. Furthermore, the reaction rates decrease for increasingly substituted epoxides. In this work we aim to proof this correlation for the reaction with fatty amines without the influence of external catalysts or solvents.

2. Methods

Butylene- (BO) and propylene oxide (PO) reacted with octylamine (OA) as model substrate in a microchannel (10 ml). The reaction was carried out at 130 - 160 °C and pressurized to 10 bar. The data was collected by the switch flow method. For EO the system was, due to safety reasons, built inside a glovebox with a set pressure of 60 bar. The products were analyzed by GC, NMR and FTIR.

3. Results and discussion

For the reaction of PO with OA experimental data were collected in flow (Figure 2). Based on preliminarily experimental data a kinetic model was fitted. The overall reaction for PO was 1.5 times as fast as for BO. It is expected for EO an increase in rate by at least a factor 2 compared to PO. The reaction proceeds slowly until significant amounts of SEC are formed. This could be avoided by using a CSTR or recycle system to further increase the process efficiency. Compared to the industrial process the continuous set-up is superior due to the higher saturation of the amine with epoxides.

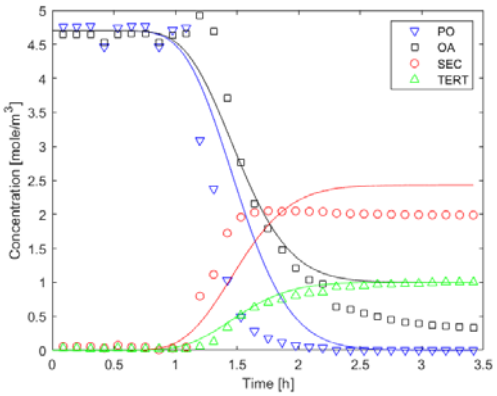


Figure 2. Exemplary reaction of PO with OA in a 1/1 ratio at 140 °C and 10 bar.

4. Conclusions

A kinetic model fitting the experimental data for the reaction of BO, PO, and EO with amines was found and shows a rate dependency towards the substitution degree. The kinetic data collected are of high importance for the intensification of the industrial process. Using a continuous flow system, the intrinsic safety risks associated to the process could be overcome and different options for advanced process engineering can easily be tested and predicted.

**Corresponding author: maria.gonzalez-martinez@cea.fr*

Highlights

- 14 woody and agricultural biomasses were deeply characterized in torrefaction.
- Extracted cellulose, hemicelluloses and lignin from five biomasses were also torrefied.
- Biomass characterization and family type strongly impacted its behavior in torrefaction.
- Biomass behavior in torrefaction was better represented by the extracted components.

1. Introduction

Due to its diversity and dispersion, biomass waste is currently underexploited. To face this issue, the European project MOBILE FLIP proposes to develop mobile conversion processes, among which torrefaction. This mild thermal treatment (200-300°C, 10min to 1h, default-oxygen atmosphere) gives rise to a solid with optimized processing properties and condensable coproducts with high-added value as “green” chemicals.

Biomass is a highly diverse resource, whose properties are very different from a coniferous to a deciduous wood, or from an agricultural by-product to an herbaceous crop. This diversity may impact biomass thermochemical conversion, together with biomass macromolecular composition in cellulose, hemicelluloses and lignin [1]. The upscaling of biomass torrefaction to industrial units requires therefore the modelling of both solid conversion and gases released versus feedstock type and its macromolecular composition. Up to now, only few studies, typically based on a reduced number of biomasses, have characterized and modelled both solid and condensable species during torrefaction versus biomass type. Furthermore, torrefaction tests on macromolecular components are scarce and based on commercial constituents [1,2].

The objective of this study is to develop a torrefaction model able to predict both solid and volatile species yields versus operating conditions and biomass type. Experimental data is obtained from extracted macromolecular components from 5 woody and agricultural biomasses.

2. Methods

14 biomasses were selected as representative of the European diversity and of the main biomass families: pine, pine forest residues, Scot pine bark (coniferous wood); ash wood, beech, poplar, willow (deciduous wood); miscanthus, reed canary grass (herbaceous crops); corn cob, grape seed cake, sunflower seed shells and 2 wheat straws (agricultural by-products) [3]. From them, five were identified as reference biomasses for analyzing the impact of biomass characteristics in torrefaction and further modelling: ash-wood, beech, miscanthus, pine and one wheat straw. An optimized extraction procedure was proposed to recover cellulose-, hemicellulose- and lignin-

based fractions from the five reference biomasses. The extracted fractions and the raw biomasses were characterized in terms of sugar composition (except lignin) and torrefaction behaviour.

Experiments were performed on a thermogravimetric analyzer coupled to a gas chromatography mass spectrometer device through a heated storage loop system (TGA-GC/MS). Solid degradation and volatile species release were studied in torrefaction experiments in chemical regime [4].

3. Results and discussion

The results obtained with the raw biomasses confirmed that their macromolecular composition strongly influences their behaviour in torrefaction. The heterogeneity of the resource, particularly in the case of agricultural biomasses, highlights this result [3].

A very different behaviour was observed for the extracted components compared to commercial compounds, particularly in the case of cellulose. This suggests that a limitation could be induced by the common use in literature of commercial compounds for torrefaction modelling. Macromolecular component properties were shown to strongly impact their behaviour in torrefaction, particularly hemicellulose sugar composition and cellulose crystallinity.

Furthermore, differences in release kinetics of volatile species during torrefaction were observed, even for volatiles belonging to the same chemical family (acids, furans, ketones).

Derived from these results, a torrefaction model based on the additive contribution of extracted cellulose, hemicelluloses and lignin to biomass behaviour in torrefaction was proposed, and this for the 5 representative biomasses. Two levels of detail were proposed (mod 1 and mod 2), in function of the extracted fractions considered (Figure 1, models for pine and wheat straw).

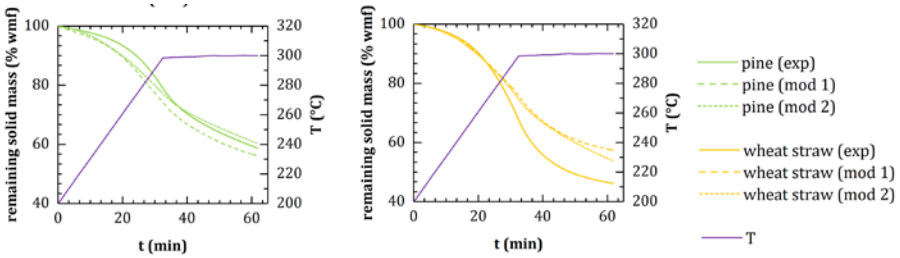

Figure 1. Remaining solid mass loss versus temperature and time in torrefaction for pine and wheat straw in TGA-GC/MS (exp) and modelled through the first-level model (mod 1 curves) and the second-level model (mod 2)

An improved representation of the behavior of biomass in torrefaction in terms of solid mass loss kinetics was achieved with the proposed model. This improvement was especially remarkable for deciduous and coniferous wood, while the representation was less accurate for agricultural biomasses. This torrefaction model was extrapolated to the 14 raw biomasses initially selected.

4. Conclusions

Biomass family and macromolecular composition were shown as key factors determining biomass behavior in torrefaction. Compared to previous models based on commercial compounds, the use of macromolecular components directly extracted from different biomasses through an optimized procedure allowed improving the representation of raw biomass behaviour in torrefaction.

Modelling and simulation of a sorptive reactor unit for Power-to-Gas applications featuring CO_2 capture and utilization (CCU)

Carlos V. Miguel[1], Jonathan C. Gonçalves[2], Alírio E. Rodrigues[2], Luís M. Madeira[1]

[1]*LEPABE - Laboratory for Process Engineering, Environment, Biotechnology and Energy, Faculty of Engineering, University of Porto, Portugal;* [2] *Laboratory of Separation and Reaction Engineering - Laboratory of Catalysis and Materials (LSRE-LCM), Faculty of Engineering of University of Porto, Portugal*

**Corresponding author: mmadeira@fe.up.pt*

Highlights

- The proof-of-concept of a sorptive reactor for CCU was performed.
- Process intensification improves CO_2 desorption capacity and kinetics.
- A model for reactor simulation and optimization was proposed.

1. Introduction

Power-to-Gas concept (PtG) relies in the chemical storage of electrical energy surpluses in the form of a gas, with hydrogen and/or methane commonly considered the most suited options [1]. The electricity generated powers H_2O electrolysis to produce H_2 (and O_2) which, in turn, can be further converted to CH_4 through the CO_2 methanation reaction (Eq. 1).

$$CO_2 + 4H_2 \rightleftharpoons CH_4 + 2H_2O \qquad \Delta H_{298K} = -165\ kJ{\cdot}mol^{-1} \tag{1}$$

A sorptive reactor for PtG applications able to capture and convert CO_2 to methane in the same unit is presented and modeled to describe its operation.

2. Methods

2.1. Experimental

The sorptive reactor consists in a tube with *L*=15 cm and ID=2.07 cm, packed with alternating layers of a K-promoted hydrotalcite and a Ni-based catalyst with a sorbent/catalyst ratio of 3.15. A synthetic flue gas stream (15 mol % of CO_2 in N_2) was fed to the bed and CO_2 retained by the sorbent. The sorption step ended when the feed was switched to pure H_2 for the reactive regeneration step, where CO_2 desorbs and is converted to CH_4 (and H_2O) at the catalyst layers (cf. Eq. 1). Experiments were performed at low pressure (≤2.5 bar) in a range of *T*=300-350 ˚C.

2.2. Reactor model assumptions

Reactor model assumptions are: 1) ideal gas behavior, 2) axially dispersed plug flow, 3) absence of radial profiles, 4) presence of heat and mass resistances between gas and solid phases and the reactor wall, 5) CO_2 sorption occurs only at the hydrotalcite material, 6) CO_2 sorption equilibrium is described by the dual-site Langmuir model [2], 7) CO_2 sorption kinetics described by the linear driving force model [2], 8) CO_2 methanation kinetics described by the rate equation given in [3], 9) mass transfer in the radial direction of catalyst spheres is described by pore diffusion, 10) pressure drop follows Ergun equation, 11) constant porosity assumed within each layer. Model validation against experimental is ongoing and the gProms software used to solve model equations.

3. Results and discussion

Fig. 1a shows the CO_2 desorption curves during cycle 5 and 6, where N_2 or H_2 were used as purge gas, respectively. Fig. 1a highlights that the desorption kinetics was faster when H_2 was used (i.e. cycle 6) because the reaction of desorbed CO_2 with H_2 at the catalyst layers produces H_2O (cf. Eq. 1), that is known for its ability to regenerate hydrotalcites [2]. Besides faster desorption kinetics, the *in situ* H_2O formation leads also to the complete reestablishment of the initial CO_2 sorption capacity (i.e. cycle 0 vs. cycle 7 in Fig. 1b).

The proof-of-concept of the sorptive reactor concept was successfully performed; the sorbent retained 0.30 moles of CO_2 per each kg (with T=350 ˚C and p_{CO2}=0.20 bar), and the catalyst was able to convert 99 % of captured CO_2, mostly into CH_4 (n_{CH4}/n_{CO}≈25,000).

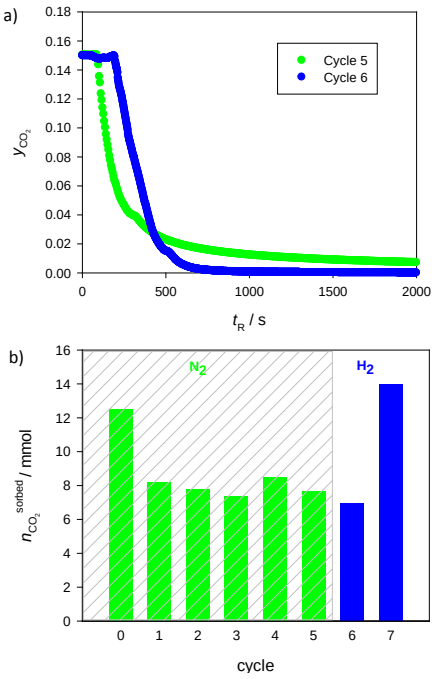

Figure 1. a) CO_2 desorption curves during regeneration in cycles 5 (with N_2) and 6 (with H_2) and b) CO_2 sorption capacity with cycling. T=350 ˚C and P=1.34 bar.

4. Conclusions

The performance of a sorptive reactor for PtG applications was presented. The experimental data highlights that the CO_2 capture step benefits from process intensification. Ongoing modelling and simulation work will provide the key to optimize and boost the reactor performance, while reducing the experimental effort, particularly to find the best operation conditions and bed configurations to enhance the CH_4 purity at the reactor outlet and comply with the natural gas grid specifications (data not shown).

Plastic Waste Catalytic Pyrolysis in a Reactive Semi-Batch Distillation

Everton Santos[1], Bruna Rijo[1], Maria Amélia Lemos[1*], Francisco Lemos[1]

1 CERENA, Dep. Eng. Química, Instituto Superior Técnico, Universidade de Lisboa, 1049-001, Lisbon, Portugal

**E-mail: mandal@tecnico.ulisboa.pt*

Highlights

- The use of the ZSM-5 catalyst caused a significant increase in the gas and liquid fractions of products.
- Increasing the temperature, the gas and liquid formation increased, and solid yield decreased.
- The composition of liquid formation, in catalytic pyrolysis, was mostly in the range of gasoline.

1. Introduction

The generation of plastic waste is constantly increasing. In the context of processing waste from electric and electronic equipment (WEEE), recycling plastics from electric cable waste has attracted increasing attention in recent years. Although the priority is generally given to the recycling of the conducting metal, due to its higher value, large amounts of plastic from electric cable waste are released into the environment without an effective disposal [1]. This incorrect disposal causes great problems to the environment, since, plastics (part of electric cable) are not easily degraded and remain in the environment for a long time if disposed in a landfill [2]. A large part of this waste may also be incinerated [3]. New processes are needed to increase the percentage that is recycled. The use of feedstock recycling, for example by resorting to pyrolysis may be an attractive alternative. It allows us to obtain a broad distribution of products, including char, oil/wax and combustible gases from plastic wastes [4]. In this work, the influence of temperature on the catalytic pyrolysis of the electrical cables waste (ECW) will be analysed.

2. Methods

The ECW were provided by Pyroplas. The samples were washed and crushed into coarse grains. The catalytic pyrolysis experiments were carried out using an unstirred glass distillation reactor in semi-batch operation at atmospheric pressure. The catalyst used was a ZSM-5 and ratio catalyst/plastic was 1%. The reactor was initially flushed with N_2, then about 10 g of the plastic waste material were placed in the reactor which was heated at 10 °C min^{-1} to a final temperature ranging from 450 to 500°C. The final temperature was maintained for 90 min. On top of the reactor there is liquid collection vessel below the condenser where the coolant water was fed at 20 °C to control the product that escaped into the gaseous phase. The gases that escaped the condenser were collected in a gas-burette.

3. Results and discussion

The mass yield of the products obtained for catalytic pyrolysis are described in Figure 1, for the three temperatures studied the reaction time was 90 min after reaching the final temperature.

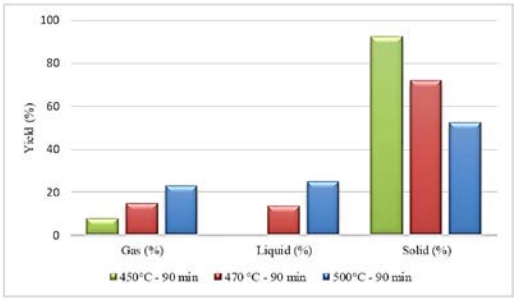

Figure 1: Variation of the yield of products for catalytic pyrolysis of ECW at different temperatures.

It is observed from the results of Figure 1 that the largest amount of products formed is in the solid phase (wax), results which are in accordance with Chaala [5]. For the lowest temperature (450 °C) it was not possible to collect any liquid phase products. It is important to note that the increase of 50 °C in the system did not cause any significant changes in the yield of the products in the liquid and gaseous phase.

The distributions of the products collected in the gas and liquid phase for the catalytic pyrolysis are shown below in Figures 2a and 2b respectively. The wax products obtained were also characterized by TG/DSC.

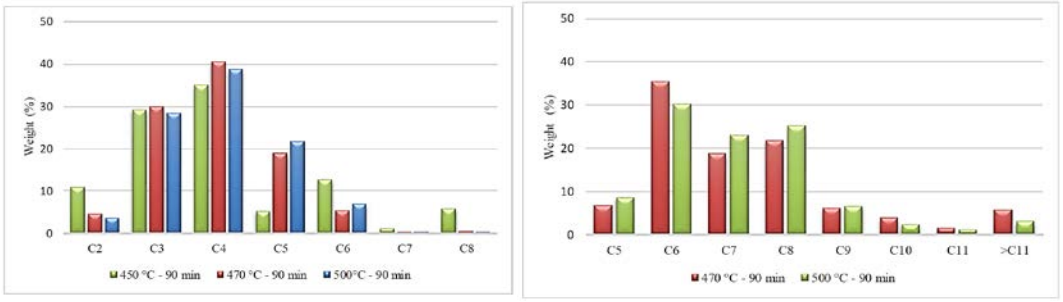

Figure 2: Product distribution (a) Gas phase and (b) Liquid phase.

4. Conclusions

The reactive distillation system was able to reach around 50 % conversion into liquids and gases. Increasing the temperature, the gas and liquid formation increased, and solid yield decreased. The gas phase has a composition in the range from C2 to C8. It is possible to observe that the increasing the temperature there was an increase of C4 and C5 formation and decrease C2 and C6 formation. Heavier fractions of the gas products (C6-C8) were converted into the light products with the increase in temperature of 50 °C in the set-point temperature, which evidences the increase in the C5 for this variation. In liquid phase, the increase of temperature, caused a decrease of the heavier compounds formation (> C11) and increase production of the components of C5, C7, and C8.

The Role of Eucalyptus Pre-treatment on Co-Pyrolysis with PE Wastes

Filomena Pinto*[1], Luís C. Duarte[1], Filipe Paradela[1], Joana Marques[1], Paula Marques[1], Paula Costa[1], Rui. André[1], Florbela Carvalheiro[1] Diogo Costa[1]

Highlights

- Co-Pyrolysis of pre-treated eucalyptus blended with PE Wastes.
- Comparison of different eucalyptus pre-treatments on its pyrolysis.
- In general acid hydrolysis was the most effective pre-treatment.

1. Introduction

Eucalyptus globulus waste was selected for this study, because this species has been largely used in pulp and paper industry in Iberian Peninsula, which has generated high amounts of wastes. Pyrolysis has been widely applied to biomass for the production of bio-oils. Though, bio-oils yields up to 60-75% have been reported [1], the produced bio-oils have some adverse characteristics, like: high contents of solids, ash, oxygen-containing compounds and water and chemical instability, which prevents them from being directly used in fuel conventional engines. Though the quality of the bio-oils may be improved after upgrading catalytic processes, the overall costs are economically prohibitive. In contrast, polyethylene (PE) wastes pyrolysis produce liquids contents up to 85%, containing mainly hydrocarbons suitable to be used in conventional engines after minor upgrading [2]. Thus, co-pyrolysis of biomass and plastics may help to solve the problems associated to bio-oils disadvantages. As a different approach, eucalyptus waste was pre-treated before pyrolysis by auto-hydrolysis and acid hydrolysis to start molecular gradation and easing pyrolysis chemical bonds break-down. These pre-treatments removed hemicellulose and produced added-value products, like: oligosaccharides with applications in the food and pharma industries. Pre-treatments remaining solids were blended with different contents of PE wastes and co-pyrolysed to be converted into pyrolysis liquids to be used as biofuels or as raw materials.

2. Methods

Eucalyptus was pre-treated by different processes: acid hydrolysis and auto-hydrolysis. In acid hydrolysis, eucalyptus wastes were pre-treated at 130°C with an aqueous solution of 1.5 % H_2SO_4, using a liquid/solid ratio of 7 (w/w) at 130°C. While, in auto-hydrolysis only water was used, the same liquid/solid ratio was tested, but at temperatures of 190° and 210°C. The liquid fraction and the solid residue (cellulolignin), obtained after these pre-treatments, were separated at room temperature using a hydraulic filter press (up to 200 bar). The solid was washed with water, pressed again and dried at 45°C. Untreated eucalyptus and pre-treated by all these processes were blended with of PE wastes and co-pyrolysed. Eucalyptus content changed from 0 to 100 wt%. Co-pyrolysis experimental work was carried out in an autoclave at the following conditions: 400ºC, 30 minutes and nitrogen initial pressure of 0.6 MPa. Gases, liquids and solids were analysed according to previous work [3].

3. Results and discussion

There was a significant decrease in hemicellulose content after all treatments, thus yielding cellulose enrichment. As expected auto-hydrolysis pre-treatment at 210°C was more effective than that done at 190°C. Specifically, hemicellulose was completely removed for auto-hydrolysis at 210°C, thus lignin content increased around 30%, together with an increase in the cellulose content, in relation to pre-treated material. Regarding the acid hydrolysis, extractives and soluble ash were removed from the solid phase, together with hemicellulose (near to 85% removal). Thus, there was an increase in the lignin and glucan fractions, that accounted for more than 40 %, each, of the recovered solid material (dry basis). Acid hydrolysis and auto-hydrolysis at 210°C led to the recovery of hemicellulose as soluble saccharides (mainly monomeric pentoses) that can be upgraded by fermentation. While, auto-hydrolysis at 190°C led mainly to soluble oligosaccharides that are directly marketable added-value products. As such, a more integrated upgrade approach can be obtained to yield synergies between the thermochemical and biochemical routes. Though no great changes were observed in Figure 1, in general, acid hydrolysis was the most effective pre-treatment, as it led to the highest contents of liquids, to the highest conversions and to the lowest solids contents. Both auto-hydrolysis led to similar liquids yields, while the lowest liquids contents were obtained for untreated eucalyptus. However, with the rise of PE content, the effect of eucalyptus pre-treatment decreased, because PE is easier to pyrolyse than biomass.

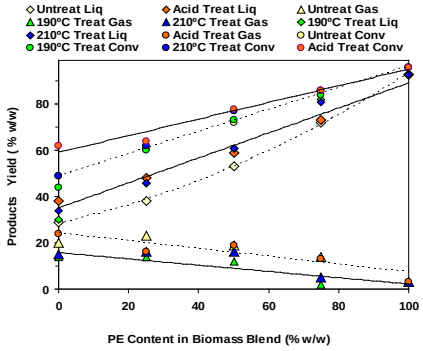

Figure 1. Effect of eucalyptus content and type of pre-treatment on products yields obtained by co-pyrolysis at 400ºC, and 30 min. Solid lines refer to pre-treated eucalyptus and dashed lines to untreated eucalyptus.

4. Conclusions

Eucalyptus pre-treatments weakened initial macromolecular structure and eased pyrolysis. Acid hydrolysis was the most effective pre-treatment, leading to the recovery of hemicellulose as soluble saccharides and to the highest pyrolysis liquids. As PE was easier to pyrolyse, the effect of pre-treatment on co-pyrolysis was more important with lower contents of PE wastes.

Highlights

- Different lignocellulosic biomass from agricultural processes are pyrolyzed to obtain bio oil.
- Fast Pyrolysis technology in a free fall tubular reactor.

1. Introduction

During the last years, biomass has drawn attention as a promising feedstock for its conversion into renewable fuels. The thermochemical process of pyrolysis under which biomass is converted into gas, bio-oil and char has drawn also attention for the different compounds found in bio-oil. Ecuador due to its biodiversity and different climate has different crops with a wide range of compositions, which have shown a great potential for pyrolysis feedstock. Bio-oils obtained from biomass appear to be an attractive option to obtain chemical precursors that have been synthetized from fossil fuels. In this study, we explore the advantages not only about the recovery of chemical precursors from the biomass pyrolysis products, but also the environmental impact of biomass residual waste used as feedstock.

2. Methods

A free fall fast pyrolysis equipment has been designed and constructed to study fast pyrolysis. The equipment consist on a quartz reactor with an oven, which can rapidly heat the sample (40 – 1200C). The outlet streams passes through a cyclone to remove the solid char. The gaseous stream passes through two traps the first trap at -20°C collects the volatiles liquid and the second trap at -10 collects the C2 fractions. The rest of the gasses are directly injected into the GC coupled with two detectors (FID and TCD) for its characterization and quantification. The piping used in the equipment is stainless steel 1/4" for the feed system and the purge separation line. For the online analysis stream after the purge, a 1/8" stainless steel pipeline is used which reaches direct to the GC (Thermo Fisher Scientific, TRACE 1310).

The feedstock used are four different types of Ecuadorian residual biomasses, which were characterized to find the cellulose, lignin, protein, fat and ash content. These biomasses were palm fiber, coffee husks, rice husks and palm rachis. Cellulose content was determined using the protocol

described by Dominguez [1]. Lignin content was determined using the official method AOAC 973.18 [2]. The Kjeldahl method was used to quantify the amount of protein in the samples using a digester DK6 VLEP Scientifica and a semiautomatic distillation unit UDK 139 based on the official method AOAC 960.52 [2]. A modified version of the official method AOAC 2003.05 and 2003.06 [2], which uses a solvent extractor equipment VELP Scientifica SER 148, was followed to determine the fat content in the samples. Finally, ash content was determined using the official method AOAC 942.05 [2]. A Leica DM500 microscope was used to analyze the size and geometry of the fiber of samples. Pictures were taken using the Leica ICC50 HD camera and the fibers were measured with the software Leica Application Suite EZ.

The setup has a solids feeding system that consists of a glass tube with three Teflon ball valves. Valve 1 is used to purge the feed system, valve 2 is used to insert the carrier gas and purge the system, and valve 3 is used to insert the solid sample, with the carrier gas, inside the reactor. For this investigation, the biomass samples were pyrolyzed in a ceramic tubular vertical free-fall reactor using helium as carrier gas. The reaction temperatures used were 500, 550 and 600.

3. Results and discussion

Biomass characterization

The characterization of four types of Ecuadorian residual biomasses were performed to find the cellulose, lignin, protein, fat and ash content. The characterization shows that the samples have a significant amount of cellulose in a range between 15-33 wt% of dry biomass. The biomasses were observed in the microscope to have a reference of their shape and size. Palm rachis morphology showed a cylindrical uniform shape, rice husk a powder heterogeneous distribution and coffee husks and pal fiver showed spherical uniform distributions.

Composition of liquid products of pyrolysis

The liquid products are retained in the liquid trap at −10°C, collected and analyzed using GC-MS/FID/TCD. Preliminary characterization of the products show the presence of C2 gases, acetic acid, hydroxytaldehyde, levoglucosan, levogluconsanone, phenol and various poly phenols. Depending on the pyrolysis temperature the amount of the products varies.

Analysis of the solid products of pyrolysis

The solid products were characterized using a Leica DM500 optical microscope. The observations done after selecting random fibers for each biomass shown a shrinkage of 30% in length and of 1% to 17% in diameter for all temperatures.

4. Conclusions

The wide range of the composition of liquid bio-oils products obtained from Ecuadorian fast pyrolysis show a great potential to obtain chemical precursors for further upgrading processes.

Biomass hydrothermal liquefaction: use of metal catalysts, Zn and Ni, to enhance bio-oil yield and quality.

Benedetta de Caprariis[1], Paolo De Filippis, Lingyu Tai, Paola Bracciale

1 Department of Chemical Engineering, Sapienza University of Rome

**benedetta.decaprariis@uniroma1.it*

Highlights

- The use of Zn and Ni in HTL of oak wood improves oil yields of about 20 %.
- Zn is completely oxidized during the reaction and the obtained bio-oil is richer in H.
- Ni is not oxidized and the resulting oil has higher amount of C (15 % more)

1. Introduction

Hydrothermal liquefaction (HTL) is one of the most promising technologies for the production of bio-oils from biomass. HTL process works at medium temperature (250-400 °C) and high pressure (10-25 MPa) in presence of water which at the used operative conditions acts as a reagent in the biomass decomposition reactions. With respect to the traditional thermochemical processes such as pyrolysis HTL does not need expensive biomass drying pre-treatments and furthermore, the obtained bio-oil has lower oxygen content and thus higher calorific value [1]. HTL has been extensively studied in literature in batch mode and in the last years the first continuous plants have been developed [2,3]. The use of catalysts in order to increase the yields and quality of the bio-oil is of fundamental importance. Alkaline catalysts such as Na2CO3, NaOH, K2CO3, KOH and Ca(OH)2 have been widely employed to enhance bio-oil yields but they do not have any effect on its composition [4]. The use of metal catalyst, in particular Fe, have demonstrated to lead to bio-oil quality improvement by the production of hydrogen in the reaction mass which is used for in situ hydrogenation reactions of bio-oil fragments [5,6].

In this work for the first time the use of Ni and Zn as catalysts for HTL of oak wood was investigated in a range of temperature of 260-340 °C. The effect of the addition of catalysts on the bio-oil yield and quality was attributed to the oxidation of the metal in the reaction condition and thus in the formation of hydrogen.

2. Methods

The tests were conducted in small autoclave having a volume of 10 mL; the reactors were heated in a sand bath with a heating rate of 60 °C/min. The biomass was loaded into the reactor with water in a ratio of 1:5. The amount of catalyst was fixed to 10 % with respect to the biomass weight. The reaction time was set to 15 min. At the end of the reaction time the reactors were quenched, the four products, gas, water insoluble organic phase (bio-oil), water phase containing the soluble organics and solid residue (catalyst+char), were separated as described in [ref]. The bio-oils were characterized with GC-MS and elemental analyses. The state of the metal after the reaction was

evaluated by X-ray diffraction. The organic content of the water phase was measured with TOC analysis.

3. Results and discussion

The results reported in Fig 1a show that the use of catalysts lead to higher bio-oil yields. The highest production of oil is reached with Ni at 330 °C (36 % with respect to the biomass weight). The use of Zn leads to lower increase of the oily phase but promotes the formation of organic compounds soluble in water, in fact the TOC of the water phase obtained using Zn at 330 °C is 21100 ppm compared with 17000 ppm and 15000 ppm obtained using Ni and without catalyst, respectively. The elemental analyses of the oils reported in Fig 1b point out a slight enhancement of the bio-oil quality in terms of decrease of oxygen content. It has to be noted that in the case of the use of Ni this decrease is due to a higher carbon amount in the oil while for the oil produced using Zn the oxygen decrease is related to an increase of the hydrogen amount. This result is consistent with the XRD analyses which report that Zn is completely oxidized to ZnO, demonstrating the H2 production, while Ni is still in its metallic form.

a) b)

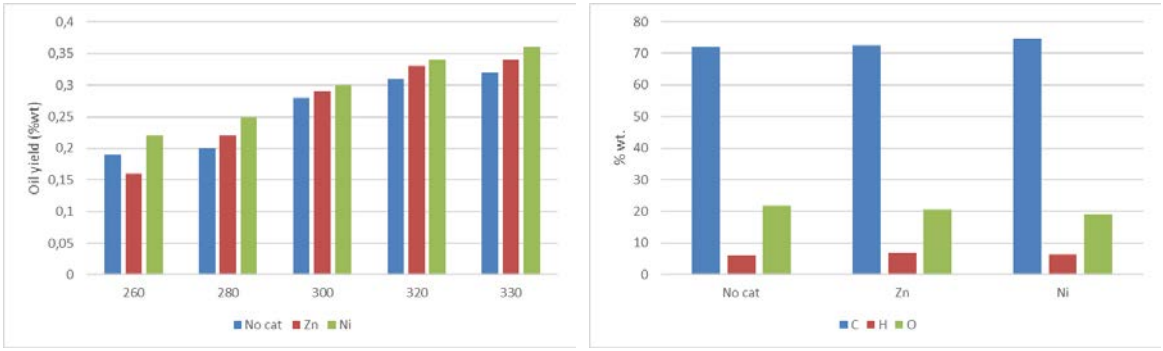

Figure 1. a) Oil yields as a function of catalysts and temperature b) Elemental oil composition.

4. Conclusions

Metal catalysts promotes the formation of the oily phase in the HTL of oak wood; with Ni the enhancement is about 25 % while with Zn 15 %. The quality of the oil is improved, the oxygen amount decrease leading to an increased calorific value which is 28.1 MJ/kg and 30.4 MJ/kg for the oils obtained without catalyst and Ni, respectively.

Steam and Hydro-Thermal Gasification of Canola Hull and Canola Meal Fuel Pellets.

Ramin Azargohar[1], Sonil Nanda[2], Ajay Dalai[1,*], Janusz Kozinski[3]

1 University of Saskatchewan, Saskatoon, SK, Canada; 2 Western University, London, ON, Canada; 3 New Model in Technology & Engineering, Hereford, United Kingdom

**Corresponding author: ajay.dalai@usask.ca*

Highlights

- Canola hull and meal were pelletized using bio-additives with optimized concentrations.
- Steam gasification showed suitable range (1.2-1.6) of H_2/CO ratio for untreated syngas.
- Hydro-thermal gasification of pellets is suitable technique for hydrogen production.
- Steam-gasified biochars showed compact aromatic structure and high surface area.

1. Introduction

Conversion of agricultural wastes to value-added products such as fuel pellets has economic and environmental advantages. Use of abundant agricultural residues such as canola hull and canola meal can benefit both agriculture and industry sections. In this research work, bio-additives including lignin, glycerol, and L-proline were used for production of hydrophobic fuel pellets with high mechanical strength. The concentration of bio-additives in the pellet formulation was optimized based on the relaxed density and mechanical strength of pellets. Then, gasification was used for production of synthesis gas (syngas) and hydrogen from these fuel pellets. For steam gasification, effects of gasification temperature and equivalence ratio (ER) were investigated on the gasification products. For hydro-thermal gasification, the effects of gasification temperature, feed concentration (biomass/water mass ratio), and residence time were studied.

2. Methods

Canola hull and canola meal were provided by the Milligan Biofuels Inc. (SK, Canada). For pelletization, biomass particle size in the range of 100-1,750 µm was preferred. Alkali lignin (as binder), pure and crude glycerol (as lubricant), and L-proline (as plasticizer) were used as bio-additives. Samples were densified in a lab scale single-pelleting unit. Two-stage fixed-bed gasifier and batch reactor were used for steam and hydro-thermal gasification, respectively. A wide range of characterization techniques were used to probe properties of feedstocks, pellets, gas product, and biochars. Central composite design (CCD) was used to design the experiments.

3. Results and discussion

Optimization study for canola hull showed that durability (measured by drop test) and relaxed density of pellets, respectively, were in the ranges of 51-99% and 647-1,110 kg/m^3. This study showed that pellet made of 6, 4, 6, 17 wt/wt % of lignin, glycerol, L-proline, and water, respectively, had the largest relaxed density (1,110 kg/m^3) and durability (99%). An increase in water content up to 17 wt% resulted in better performance for alkali lignin as a binder in

densification process. The pellets' relaxed density and mechanical durability increased with an increase in the moisture content, for the entire range of lignin concentration. Glycerol showed lubricating effects in the form of 10-20 % decrease in pelletization's compression energy. L-proline worked as a plasticizer to increase the mechanical strength of pellet. For canola meal, the optimum formulation identified included 8 wt% alkali lignin, 8 wt% glycerol, 2 wt% L-proline, and 4 wt% water. It had relaxed density of 1,050 kg/m^3 and durability of 99%. As shown in Fig. 1, synchrotron 3-D imaging technique was used to visualize the internal void structure (blue color area) of pellets which is an influential parameter on the relaxed density and mechanical strength of pellets. Fig. 1 shows effects of alkali lignin, glycerol, and water on the internal porosity of canola meal pellets.

For steam gasification with an increase in temperature, concentration of hydrogen (H_2) and carbon monoxide (CO), in the gas product, increased for all ERs. Effect of ER on the gas component concentrations was more intense at the highest temperature (850 ^{o}C), especially in case of increase in hydrogen concentration. In hydro-thermal gasification, with the rise in temperature from 350 to 650°C, H_2 and CO_2 yields increased , due to the enhancement of water-gas shift reaction at higher temperatures in hydro-thermal conditions. The same effect was observed with an increase in residence time (from 15 min to 60 min). However, these yields decreased with an increase in feed concentration. Hydro-thermally produced biochars showed characteristics of amorphous char at high gasification temperatures (≥550 °C). For steam-gasified biochars, higher BET surface area indicated the development of composite char at all gasification temperatures.

4. Conclusions

Use of bio-additives resulted in the production of mechanically durable and hydrophobic fuel pellets. Due to the increasing amount of lignin, glycerol and amino acids obtained, respectively from the pulp and paper industries, biodiesel refineries, and corn wet milling industries, they are promising bio-additives for production of fuel pellets. Steam gasification produced syngas with the suitable range of H_2/CO molar ratio. In addition, it produced biochars with developed porous characteristics which can be used as adsorbent or catalyst. Hydro-thermal gasification produced larger H_2/CO ratio and is more useful for hydrogen production.

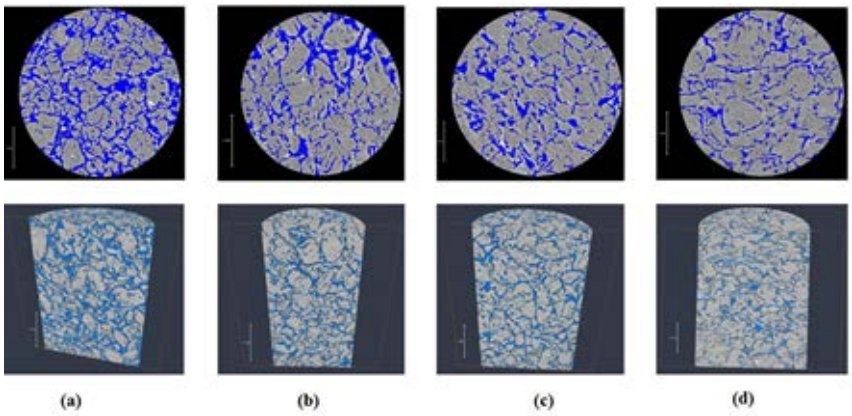

Figure 1. Effects of lignin, glycerol, and water on pellet porosity in the cross section and longitudinal section for the canola meal pellets produced using the optimum formulation as follows: (a) without water, (b) without lignin, (c) without glycerol, and (d) including all ingredients.

On the modeling of the kinetics of high-functionality biopolymers. Application to the polycondensation of sugars

Dimitrios Meimaroglou[1], Sandrine Hoppe[1], Baptiste Boit[2]

1 Laboratoire Réactions et Génie des Procédés,Université de Lorraine,CNRS,

LRGP, F-54000 Nancy, France; 2 Roquette Frères, Lestrem, FR

**Corresponding author: dimitrios.meimaroglou@univ-lorraine.fr*

Highlights

- Industrial polycondensation process of sugar syrups of various compositions.
- Kinetic/topological Monte Carlo modeling framework.
- Dynamic evolution of the exact position and type of each bond of all species.
- Generalized framework, not limited to low-degree oligosaccharides.

1. Introduction

Polycondensation reactions of oligosaccharides are important in several application fields, such as fuel synthesis or food processing. They are generally carried out in the presence of acid catalysts, in temperatures varying roughly within the range of 100 ^{o}C – 200 ^{o}C. Nevertheless, despite their industrial importance, only few kinetic modeling studies are found in the literature [1]. In fact, the primary monomer unit of these reactions is glucose, dominantly found in the form of glucopyranose, which is a cyclic molecule containing five –OH groups, all susceptible to react. Hence, the –OH group in the position 1 of the molecule (i.e., with respect to the anomeric carbon atom) is prone to receive a proton from the –OH group of another glucose molecule, thus eventually forming a glucosidic bond with the parallel release of a water molecule. Such bonds can be formed between the C1 atom of the first glucose and any other C atom of the second glucose, found in positions 1, 2, 3, 4 or 6. In addition, the stereochemistry of the formed bond can be either in α- or β- position, resulting in two kinds of stereoisomer products from each type of bond. This means that nothing but the simple reaction between two single glucopyranose units may result in as much as 11 different disaccharides. At the same time, a series of internal ring-closure reactions of the glucose units that result in structurally different, inert anhydrosugars, further complicate the landscape of this reaction system, before even attempting to extend the study to the reactions of disaccharides, trisaccharides, etc. In the present work, a novel modeling framework is proposed for the simulation of the polycondensation reactive systems of sugars, capable of taking into account the above-described complexity.

2. Methods

The complexity of the system relies primarily on the fact that the each type of glucosidic bond that is formed during the reaction (i.e., α-1-1, β-1-1, α-1-2, etc.), is dictated by a different formation and hydrolysis rate (i.e., mainly due to steric factors). In this respect, in order to be able

to accurately follow the dynamic kinetic developments in the reactor, with respect to the operating conditions and the initial syrup composition, it is crucial to follow all the relevant information concerning the different species concentrations as well as their specific structural characteristics. The first of the above is relatively trivial to achieve via the implementation of any modeling framework that defines the problem through a population-balance perspective. On the contrary, the tracking of the structural information requires an approach capable of treating, in addition to the species concentrations, the associated multi-dimensionality (i.e., expressed in terms of the different bonding positions and stereochemistry of the glucose units). Such a modeling approach has been previously developed and applied on the industrial polymerization paradigm of low-density polyethylene (LDPE) [2]. The developed kinetic/topology Monte Carlo (MC) algorithm, which was implemented in this case to follow the branching architectural developments of LDPE, is adapted in this work to the specificities of the sugars polymerization system.

3. Results and discussion

The modeling predictions were compared against a series of experimental data produced in an industrial pilot-scale reactor, under varying conditions. Some preliminary results on the evolution of the average molecular weight and the molecular weight distribution are given in Figure 1.

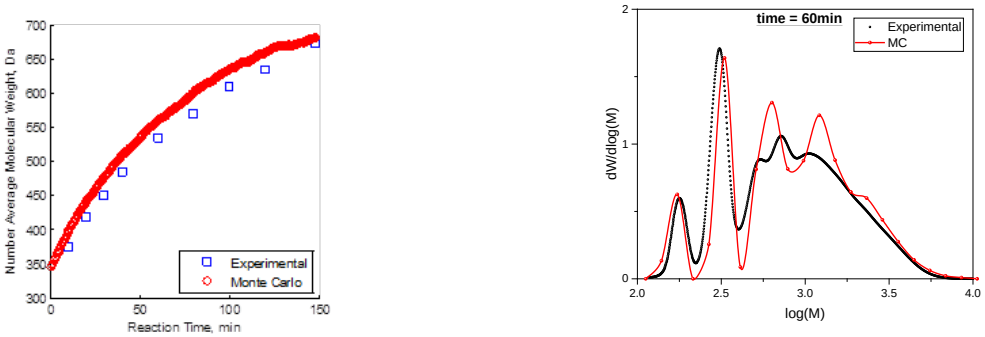

Figure 1. Evolution of the a) number-average molecular weight and a) molecular weight distributions of the formed oligosaccharides. Comparison between experimental data and MC simulations.

4. Conclusions

In the present work, a novel modeling framework is proposed for the kinetic developments of the polycondensation of sugars. This modeling framework relies on the implementation of a powerful kinetic/topological Monte Carlo technique, previously applied for the description of the molecular architecture of industrially-produced highly-branched LDPE. The preliminary results of the study show that, for the first time, an accurate description of the system can be achieved and the compositional and molecular weight evolution can be accurately tracked even for oligosaccharides of relatively high degree of polymerization.

Kinetics of acid-catalyzed hydrolysis of oat β-glucan to produce short chain polysaccharides with controlled degree of polymerization

Tuomo Sainio[1*], Hoang Nguyen[1], Markku Laatikainen[1], Jari Heinonen[1]

1 LUT University, Department of Separation and Purification Technology, Yliopistonkatu 34, FI–53850 Lappeenranta, Finland

Highlights

- Mechanistic model developed for acid hydrolysis of beta-glucan from oat
- The non-random structure of the polysaccharide is included in the model
- Evolution of the molecular weight distribution during hydrolysis is explained

1. Introduction

Natural beta-glucan is a linear, nondigestible polysaccharide composed of D-glucose monomers linked by β-glycosidic bonds. Beta-glucan from cereals (oat and barley) consists of mixed-linkage β-(1,3) and β-(1,4)-D-glucose monomers, whereas β-glucan from yeasts or mushrooms is composed of mixed-linkage β-(1,3) and β-(1,6)-D-glucose units [1, 2]. Enzymatic or acid hydrolysis of β -glucan produces oligosaccharides and short chain polysaccharides that can be used as prebiotic food ingredients.

It is desirable to produce short chain polysaccharides (e.g. DP = 30…50) rather than oligosaccharides from large plant polysaccharides. To achieve this, the reaction conditions and operation of the reactor should be optimized such that degradation to oligosaccharides is minimized. In this work, an accurate kinetic model for acid hydrolysis is developed and validated using experimental data.

2. Methods

Homogeneous acid-catalyzed hydrolysis of oat β-glucan was studied at 323 K and 353 K using HCl and H_2SO_4. The kinetic experiments were carried out in a jacketed glass reactor (Orb system, Syrris Ltd., United Kingdom). The molecular weight distribution (MWD) of β-glucan was measured using SEC–MALLS on HPLC system (Agilent 1200 Infinity series) with an RI detector and a multi-angle laser light scattering detector. To deal with low intensity of small molecules in the samples, a two-step method was used. In this method, the samples withdrawn from the reactor were first fractionated in preparative scale SEC column and the MWD of each fraction was determined using the HPLC SEC-MALLS.

β-(1,4) and β-(1,3) glycosidic bonds are known to have different reactivity in acid hydrolysis [3]. A structured kinetic model was developed that takes into account the difference in the reactivity of

β-(1,4) and β-(1,3) glycosidic bonds as well as their positions in the polysaccharide chain. Numerical solution of the large ODE system was accelerated by using an adaptive Jacobian matrix approach.

3. Results and discussion

The number average molecular weight of oat beta-glucan changes during acid hydrolysis in a manner consistent with assumption of first order kinetics. However, a random scission model does not explain the formation rates of oligosaccharides. The structured model presented here can explain the observations within good accuracy.

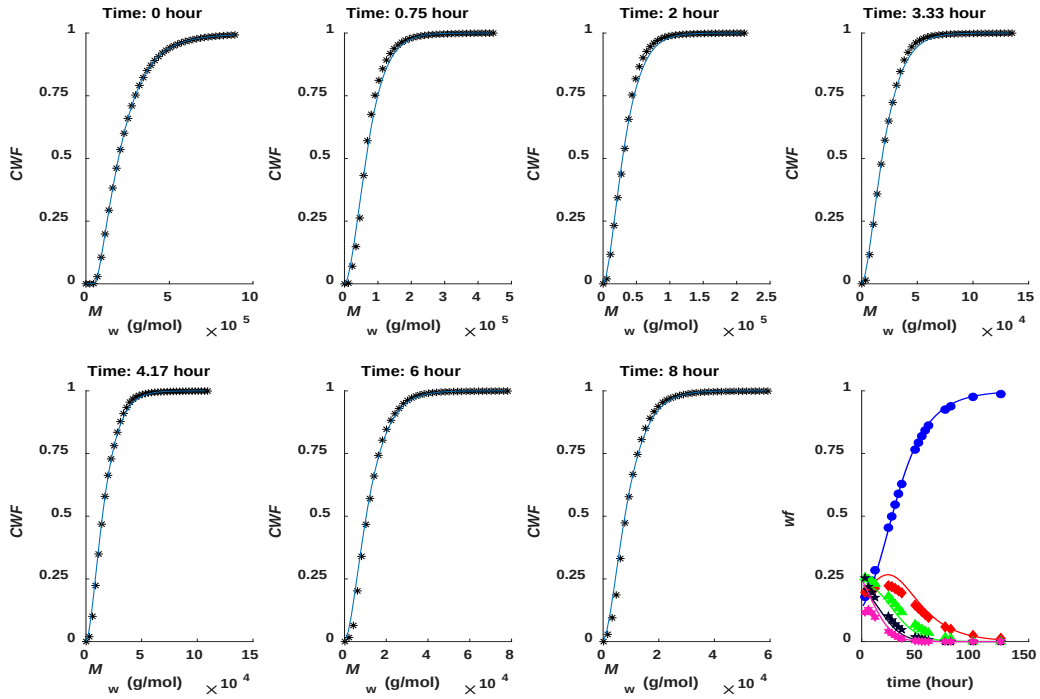

Figure 1. Evolution of the molecular weight distribution of β-glucan with HCl 0.05 M with HCl 0.25 M at 353 K. Oligosaccharides are shown in bottom left: blue = DP 1, red = DP 2, green = DP 3, black = DP 4, magenta = DP 5.

4. Conclusions

The simulation of β-glucan hydrolysis with the new model was in good agreement with the experimental data and shows improvement over existing non-structured models for hydrolysis of plant polysaccharides.

Acceleration of a kinetic Monte Carlo Master Equation Solver for Gas Phase Chemical Kinetics

Andrea Landella[1*], Carlo Cavallotti[2]

1 Via Cividale 23, 20017 Rho, Milano; 2 Politecnico di Milano, Via Luigi Mancinelli 7, 20131, Milano

**Corresponding author: andreagiuseppe.landella@mail.polimi.it*

Highlights

- The MCRRKM stochastic master equation solver is adaptively accelerated.
- Speedup factors reach 1E+25 for low temperature simulations (300 K).
- Rate constant computation is now feasible in the full temperature range.
- Calculated k(T,P) with acceleration are accurate within a factor of 1.2.

1. Introduction

The calculation of pressure and temperature dependent rate constants of gas phase reactions requires the solution of a Master Equation, which describes the energy transfer dynamics between molecules as a continuous time Markov Process[1]. The stochastic approach, or kinetic Monte Carlo (kMC) integration[2], allows to directly extract rate coefficients, but suffers from intrinsic time scale separation between reaction events and internal energy relaxation by strong collisions. The Markov process converges on rare event dynamics[3] and molecules reach thermodynamic equilibrium. In these cases, especially at low temperatures, the stochastic simulation explores energies well below the reaction thresholds, requiring approximately 10^{20} iterations before reaching a reactive event. It is therefore necessary to search and implement solutions that will allow a speedup, or acceleration, of the stochastic simulation algorithm while maintaining high accuracy for the extracted rate coefficients. As such, a validation must be performed with existing solvers, possibly with method-independent (deterministic) ones, to eliminate sources of statistical error.
This problem also arises for deterministic solvers, e.g. MESS[4], that numerically solves the Master Equation as a linear matrix ODE problem, exploiting the physics of the reactive system. Different approaches have been proposed to speed up master equation solvers; the most commonly used one is the Reservoir State Approximation[5], as it defines a fictitious set of energy states, called reservoir, which is treated as a single macrostate. The reactant energy distribution within that state is assumed at thermal equilibrium, thus described with the Boltzmann distribution.
The reservoir dimensions, or the number of lumped energy states under a threshold, are usually taken as an input data and are inherently system dependent. They are directly linked to the reaction barrier energies, thus the chemical mechanism or energy profile. It should be preferable to skip the setting of the reservoir threshold by an adaptive calculation, employed within the code.

2. Methods

The present work examines an existing RRKM Master Equation solver, called MCRRKM[6], which adopts the stochastic solution method. MCRRKM is a research code, developed by prof. Cavallotti at the Applied Physical Chemistry Lab. An acceleration protocol was developed that allows speeding up the kMC integration by introducing an analytical correction for the time the random walkers spend in the Boltzmann equilibrated portion of the energy distribution function.

3. Results and discussion

The acceleration protocol was implemented within MCRRKM with an adaptive calculated threshold, the Thermal Energy Limit, below which energy levels are treated as populated according to the Boltzmann distribution and binned as a single macrostate. The Speedup was found to be dependent only on thermodynamic quantities: the partition function ratio of the unperturbed and perturbed energy states. Below are two main results of the acceleration protocol on two test reactions:

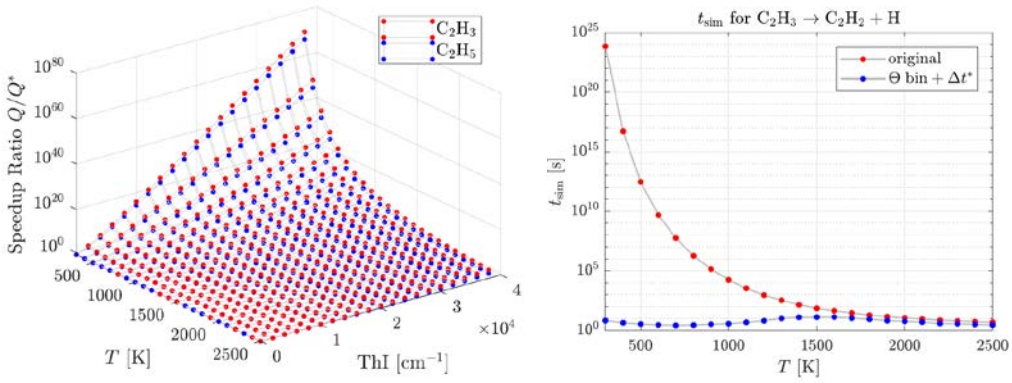

Figure 1. (left) Speedup factor as a function of simulation temperature and thermal energy limit (in 1/cm) for two reactions [C2H3 = $C_2H_3 \rightarrow C_2H_2 + H$, and C2H5 = $C_2H_5 \rightarrow C_2H_4 + H$]. The speedup is super-exponential with temperature, thus at low temperatures the rare-event dynamics problem is solved. The acceleration protocol is effective at low T. (right) estimated simulation time [red] and actual simulation time [blue] for the reaction $C_2H_3 \rightarrow C_2H_2 + H$ at 0.1 bar.

4. Conclusions

This work led to the development of a new acceleration protocol for the Monte Carlo integration of the master equation for reactive systems that drastically reduces computational times, from approximately 10^{20} to 10^{2} iterations to reach a reactive event, making the stochastic solution of the Master Equation feasible at all temperatures. The protocol was validated with respect to MESS, a solver developed by Georgievskii and Klippenstein[4], employing the deterministic approach over two reactions of combustion interest: hydrogen dissociation from vinyl (C_2H_3) and ethyl (C_2H_5) radicals. With temperature and pressure ranges of 300-2500 K and 0.001-1000 bar, rate constants differ by a maximum 1.2 factor (0-20% relative error) from MESS results in all cases.

Implementation of catalytic descriptors within kinetic models. How to predict the nC7 aromatisation selectivity obtained with a new catalyst?

Olivier Said-Aizpuru[1], Florent Allain[1], Aurélie Dandeu[1], Fabrice Diehl[1], David Farrusseng[2] and Jean-François Joly[1]

Highlights

- Integration of catalyst active phase descriptors into kinetic models
- High Throughput catalytic testing for intrinsic kinetics studies
- Bi-functional n-heptane aromatisation catalysis

1. General context and motivations

Several refining or petrochemical catalytic processes show a strong dependence of overall performances upon catalytic active phase composition and structure. Their development requires the identification of the relevant dimensioning parameters of the catalyst that are referred to as "descriptors". Kinetic models provide an indispensable tool for an accurate design of catalytic processes. Extensive descriptions of the active phase behaviour within kinetic models were investigated over the past decades, usually through sophisticated models based on theoretical calculations or more often on advanced characterisations. Yet, the simplicity and a limited amount of parameters of a kinetic model are necessary in order to handle frequent changes in catalytic formulation. There is therefore a deep interest in identifying global catalytic activity descriptors that could be easily measured and controlled by a dedicated catalyst synthesis. We and others have shown that fitting the kinetic parameters of a well-known (*i.e.* model) reaction is an efficient approach to probe and quantify the overall activity of a catalyst. This work addresses the possibility to perform catalytic tests on a model reaction in order to identify relevant and independent descriptors.

2. Objectives and strategy

The frame of this study is to set up a methodology in order to implement active phase descriptors within a lumped kinetic model for the n-heptane reforming reaction (see Figure 1). Aromatisation of n-heptane requires a bi-functional catalysis enabling proton and hydrogen transfer. Thus, a typical naphtha reforming catalyst comprises a metallic phase (sub-nanometric Pt or Pt alloys particles) supported on a mild-acidic support (chlorinated γ-Al_2O_3). A collection of twenty-one active phase formulations specifically prepared in order to exhibit various inter-sites (acid-acid or metal-acid) distances as well as different site ratios is first gathered. Both Pt only and Pt-Sn catalysts are tested and different ranges of Pt (0.3-1%$_{wt}$) and Cl (0.1-1.4%$_{wt}$) are considered. Three objectives are then successively targeted: i) Probing the intrinsic surface reactivity over a variety

of reforming catalysts ii) Determining the effect of a systematic formulation change over the kinetic parameters for different reforming reaction families iii) Finding statistical correlations between kinetic parameters and physico-chemical properties.

A standard catalytic test protocol was designed to investigate intrinsic n-heptane transformation at the surface of the catalyst. Tests were carried out on a high-throughput Flowrence™ (Avantium) device allowing the use of small sample amounts (see Figure 2). The geometry of the reactors allows for a well-defined hydrodynamics and the unit is used close to isothermal mode.

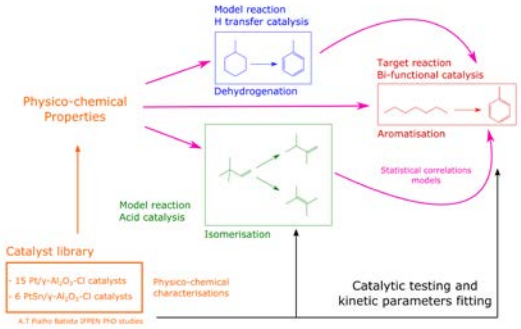

Figure 1. General experimental strategy followed for the identification of catalytic activity and selectivity descriptors.

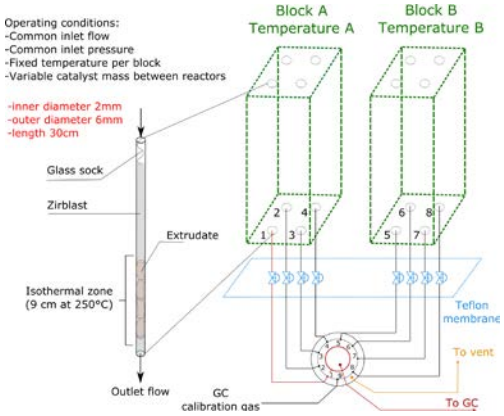

Figure 2. Simplified scheme of the reactive section of the High Throughput Experimental device used for catalytic tests.

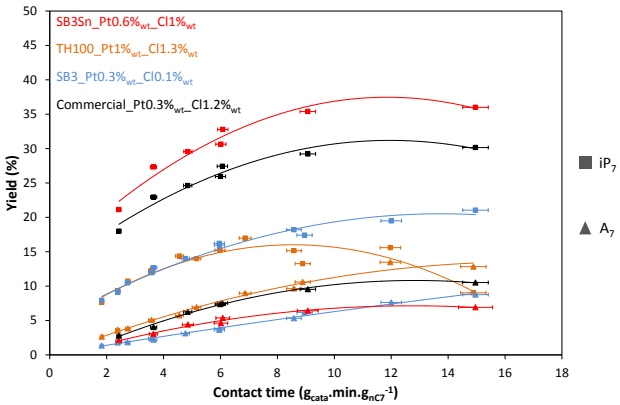

Figure 3. Yield structures obtained at 430°C, 10 barg and H2/HC molar ratio equal to 3. A_7 stands for toluene and iC_7 for paraffinic isomers. SB3 and TH100 are commercial γ-Al_2O_3.

3. First results and outlooks

As shown on Figure 3, there is a strong dependence of the reaction scheme selectivity over the amount of chlorine, the amount of platinum and the presence of a second metal (Sn). Competition between sites could be responsible for aromatisation interception by other reactions such as isomerisation or cracking. Then, the challenge in identifying reforming selectivity descriptors lies in understanding which catalytic parameters rule the interactions between sites.

Once the explicit description of the active phase is included in the kinetic model, it will be validated by comparison with results from catalysts with new active phase formulations, demonstrating the possibility of pre-screening catalysts with the model before moving on to traditional experimental screening.

Reaction and kinetic studies of homogeneously catalyzed benzyl alcohol oxidation in a gas-liquid slug flow microreactor

Jun Yue*, Arne Hommes, Bas Disselhorst

Department of Chemical Engineering, Engineering and Technology Institute Groningen, University of Groningen, Nijenborgh 4, 9747 AG Groningen, The Netherlands

**Corresponding author: Yue.Jun@rug.nl*

Highlights

- Aerobic oxidation of benzyl alcohol was studied over a homogeneous Co/Mn/Br catalyst.
- Wetted and dewetted gas-liquid slug flows were identified in the microreactor.
- A kinetic expression of benzyl alcohol oxidation to benzaldehyde was established.
- A reactor model was developed under mass transfer limited conditions.

1. Introduction

Slug flow processing in microreactors brings significant transport intensification (e.g., enhanced heat and mass transfer rates) and precise process control (e.g., regular flow pattern, narrowed residence time and uniform reaction temperature) that benefit chemical synthesis in multiphase systems. Thus, it represents an attractive means for the intensification of a variety of gas-liquid reactions (including typically selective oxidation and hydrogenation reactions), as well as kinetic investigations thereof [1-3]. In this work, a model reaction, the aerobic oxidation of benzyl alcohol to benzaldehyde in the presence of a homogeneous Co/Mn/Br catalyst, has been studied in a microreactor in the gas-liquid slug flow regime. The microreactor performance has been experimentally characterized under various slug flow conditions, which was interpreted based on the developed kinetic expression and reactor model.

2. Methods

The reaction was performed in a capillary microreactor made of polytetrafluoroethylene, using benzyl alcohol (dissolved in acetic acid) as the substrate, oxygen or air as the oxidant, a mixture of $Co(OAc)_2$, $Mn(OAc)_2$ and NaBr as the homogeneous catalyst. The reaction temperature was up to 150 ^oC and pressure up to 5 bar. The pictures of slug flow were recorded with a digital camera. The collected liquid samples from the microreactor outlet were analyzed by gas chromatography.

3. Results and discussion

Under the investigated conditions, the reaction was found highly selective towards benzaldehyde. Two different types of gas-liquid slug flow were identified: wetted flow (characterized by a complete liquid film surrounding the bubble) and dewetted flow (characterized by a partially wetting liquid film surrounding the bubble); the latter flow suffered from a limited interfacial area available for mass transfer. The transition from wetted to dewetted slug flow depended on the flow velocity and gas-liquid flow ratio (i.e. the bubble length). By a fine tuning of the reaction

temperature and mass transfer (i.e., via the presence of wetted or dewetted flow), the reaction behaviour fell in either kinetic or mass transfer limited conditions. The experimental results at lower reaction temperatures were used to develop a simplified kinetic expression. The experimental results at higher reaction temperatures were well described by the developed microreactor model. The model considers a fast reaction regime, where mass transfer details (under wetted and dewetted slug flows) are based on the literature correlations and the reaction kinetics is based on the current work.

4. Conclusions

Aerobic oxidation of benzyl alcohol to benzaldehyde was studied over a homogeneous Co/Mn/Br catalyst in the microreactor operated under wetted and dewetted gas-liquid slug flows. The reaction was found under either kinetic or mass transfer limited conditions, depending on the reaction temperature. The experimental results at lower temperatures allowed to establish a simplified kinetic expression. This expression, with a further consideration of mass transfer details in slug flow, enabled the formulation of a microreactor model describing the experimental results at higher temperatures.

Highlights

- Epoxidized vegetable oils are environmentally friendly chemical intermediates
- An extensive study of the epoxidation kinetics of vegetable oils was conducted in a loop reactor
- Microwave irradiation and heterogeneous catalysts enhanced the process considerably
- A detailed mathematical model for the multiphase system was developed

1. Introduction

Epoxidized vegetable oils are chemical intermediates to valuable products, such as lubricants, plasticizers or non-isocyanate polyurethanes [1]. Tall oil obtained from forest biomass is a good source for vegetable oils, because it does not compete with the food chain. Epoxidation by the Prileschajew method implies the substitution of a double bond by an oxirane ring caused by a percarboxylic acid that is formed *in situ* from a carboxylic acid and hydrogen peroxide. Two liquid phases are present (oil and aqueous phases) and four reactions proceed simultaneously: formation of percarboxylic acid (perhydrolysis in aqueous phase), decomposition of the percarboxylic acid (aqueous phase), epoxidation of fatty acid (oil phase) and opening of the oxirane ring (oil phase) [2]. The principal method for vegetable oil epoxidation is well known but most of the studies published hitherto are qualitative in their character. Only few modelling studies have been published e.g. [3-4]. For process design, a detailed mathematical model for the complex multiphase system is necessary. The principles of the model and the essential modelling results are reported here.

2. Methods

A tailored recycle reactor system consisting of a vigorously stirred tank reactor, a circulation loop and a microwave source was constructed (Figure 1). The glass reactor was connected to a loop including a microwave cavity (Sairem) and a heat exchanger. Experiments were carried out both in the absence and presence of heterogeneous catalysts to reveal the potential intensifying effect of the catalysts. The cation exchanger Amberlite IR-120 was used as the main heterogeneous

catalyst. The reaction temperatures were 40–70°C and the oil-H_2O_2- acetic acid ratio was varied in the experiments. The organic phase content was 32–45 %v/v.

3. Results and discussion

The main observations from the experiments were: epoxidation of vegetable oils (e.g. model component oleic acid) occurs spontaneously in the absence of the catalyst, but the reaction rate can be considerably enhanced by exposing the system to microwave irradiation and incorporating a catalyst. The benefit of the use of a heterogeneous catalyst (ion-exchange resin) is obvious compared to a homogeneous catalyst (e.g. mineral acid), because the catalyst separation problem is completely avoided when the heterogeneous catalyst is used. An example of an epoxidation experiment is given in Figure 1. A detailed mathematical model was developed for the system, consisting of mass balances of all the reacting components in both aqueous and oil phases. The set of differential equations in the model was solved numerically during parameter estimation. The accuracy of the parameters was checked by standard mathematical analysis and a Markov Chain Monte Carlo (MCMC) method. An example of experimental data and model fit is provided in Figure 2. In general, the model fit was good and the estimated parameters had a good accuracy. The model can be used for prediction of the progress of epoxidation in the absence and presence of microwave irradiation and catalysts.

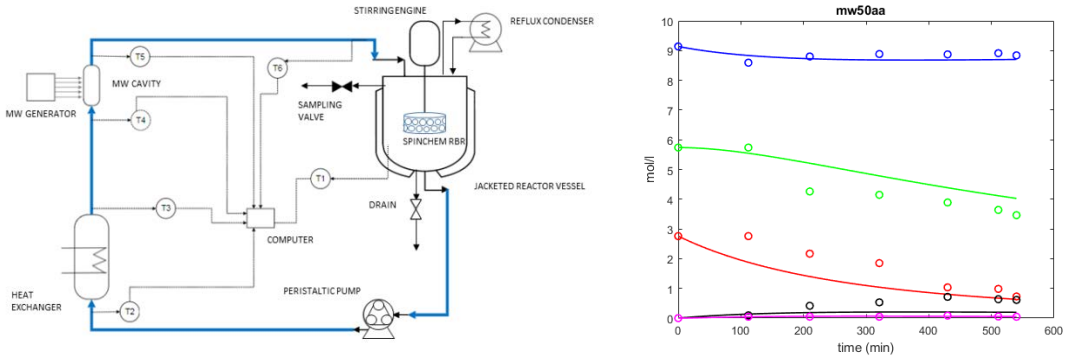

Figure 1. Tailored loop reactor system (left), model fit to experimental data (right); microwaves, 50ºC. In **black**: epoxidized oleic acid, pink: peracetic acid, red: oleic acid, green: hydrogen peroxide and blue: acetic acid.

4. Conclusions

An extensive set of kinetic experiments were carried out for the epoxidation of vegetable oils in a tailored reactor system. Microwaves and heterogeneous catalysts were successfully used to enhance the epoxidation process of a model compound, oleic acid and real tall oil mixtures. A multiphase reactor model was developed and applied to the experimental data. The model gave a good description of the experimental data and thus provides a perspective for process scale-up.

Micromixing efficiency in a rotor-stator Spinning Disc Reactor for liquids with different viscosities

Arturo Neissen Manzano Martinez[1], Melissa Assirelli[2], John van der Schaaf*[1]

1 Laboratory of Chemical Reactor Engineering, Department of Chemical Engineering and Chemistry, Eindhoven University of Technology, P.O. Box 513, 5600 MB Eindhoven, The Netherlands
2 Nouryon Specialty Chemicals, Deventer, The Netherlands

* j.vanderschaaf@tue.nl

Highlights

- Micromixing efficiency of three liquids with different viscosities is presented
- Segregation index decreases with increasing rotational speeds in all situations
- Compared to a stirred vessel, rs-SDR enhances mixing for liquids with different viscosities

1. Introduction

In the last years, Process Intensification (PI) and the development of novel equipment have become key approaches for engineers and scientist to address the challenges of the modern era, e.g reducing waste generation, emissions, energy consumption, etc. However, for a full implementation of new technology in the chemical industry, sufficient knowledge is needed in order to make it attractive and to guarantee functionality in real situations.

One way of reducing the energy-intensive separation steps in a process is by improving selectivity towards desired products, which may be difficult for fast reactions competing for a limiting reagent. In these cases, micromixing – the homogenization of the system at the smallest scale – plays a crucial role. [1]

Previous results proved that the rotor-stator Spinning Disc Reactor (rs-SDR) can enhance selectivity for fast reactions, with estimated micromixing times ranging between 1×10^{-4} to 1×10^{-2} seconds. [2] However, since industrial processes often involve reagents of different properties, the characterization of micromixing efficiency of liquids with different viscosities needs to be investigated.

2. Methods

The "Villermaux-Dushman protocol for experimental characterization of micromixers" [3] was performed with two modifications. Instead of Sulfuric Acid, Perchloric acid was chosen for being a strong, monoprotic acid [4]. Since the kinetics of the system have been a great deal of controversy, the iodide-iodate reaction was studied resulting in an empirical equation for the reaction rate [5] that is in agreement with a previous kinetic study [6].

The experimental setup for the rs-SDR was reported previously [2]. In order to compare with traditional equipment, the protocol was performed under the same conditions (temperature, concentrations, etc) in a 5 L tank, stirred with a propeller stirrer set at 900 and 1200 RPM.

To achieve a comparison on micromixing efficiency between an aqueous system and a viscous/non-viscous system, only the viscosity of the acid solution was increased using 10-20%vol of glycerol.

3. Results and discussion

The preliminary results are summarized in Figure 1. As expected, segregation Index decreases with an increase in rotational speeds. Furthermore, an increase in viscosity reduces the micromixing efficiency as expected. Surprisingly, at low rotational speeds the effects of an increment in viscosity seem to be less than at high rotational speeds. Further investigation is ongoing to explain these results. When comparing the estimated micromixing times in the rs-SDR with the ones obtained in a stirred vessel for the range of local energy dissipation rates used, the rs-SDR exhibits a better performance, due to the high energy input that can be transferred into a very small volume.

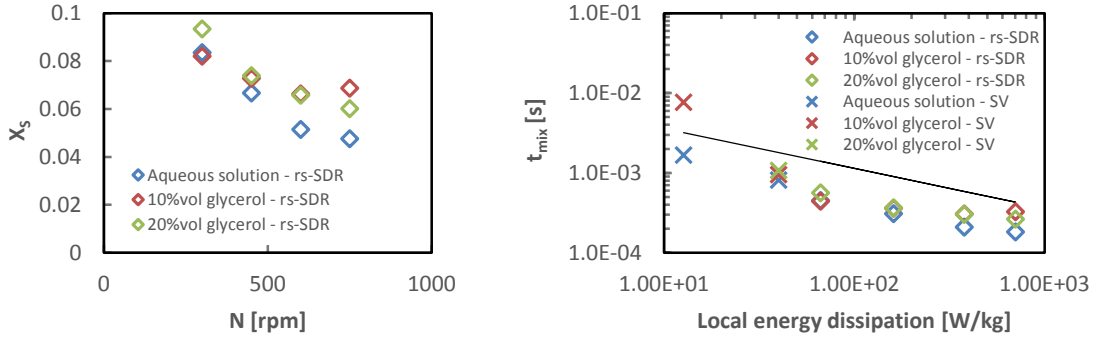

Figure 1. (a) The effect of segregation index with varying rotational speeds for two different viscosities of the injected acid in two different reactors and (b) the estimated micromixing times as a function of energy dissipation rate.

4. Conclusions

The rs-SDR not only shows better micromixing efficiency when compared to a stirred vessel, but it is also less affected by the addition of a liquid of higher viscosity.

Process intensification in direct amide synthesis with catalytic packed-bed milli-reactors operated under induction heating

Evgeny Rebrov[1], Nikolay Cherkasov[1], Pengzhao Gao[2]

1 University of Warwick, Coventry, CV4 7AL, UK; 2 Hunan University, Changsha, 410082, China

**Corresponding author: e.rebrov@warwick.ac.uk*

Highlights

- Induction heating improved catalytic activity by 1.5 times in a direct amide synthesis reaction.
- The initial reaction rate over core-shell catalysts was further increased by 1.7 times r as compared to a mechanical mixture.
- Thermal gradients in a packed bed milli-reactor under RF heating have been analyzed.
- Design criteria for a near-isothermal milli-reactor have been suggested.

1. Introduction

The fact that small-scale and distributed chemical manufacturing systems are proved to offer advantages such as lower capital expenses, compactness of equipment, relatively small energy consumption, and reduced by-product formation has led to the growing interest in newer process intensification methods using reactors with channel diameter in the millimeter range (milli-reactors). These reactors can be heated by induction heating of magnetic microparticles placed inside the reactor to generate heat rapidly and uniformly within the bed, while eliminating hot spots and large radial temperature gradients. Induction heating utilizes easier scalable hardware such as magnetic materials and induction coils connected to an RF generator.

Under RF heating, the composite magnetic catalyst should provide both high heating and reaction rates. A core-shell structure is often used because the shell layer often acts as a catalyst and protects the magnetic core from chemical erosion and aggregation. Over the last few years, we developed a series of core-shell composites for direct amide synthesis, which is one of the most important reactions in pharmaceutical industry [1-3]. The catalytic activity was determined in a reaction between aniline and phenylbutyric acid in a fixed bed flow reactor under induction heating.

2. Methods

The catalytic activity was compared in the reaction between 4-phenylbutyric acid and aniline. A glass reactor (Omnifit HiT, i.d 6.6 mm, 250 cm long) was used. Two HPLC pumps were used to feed the solutions of 4-phenylbutyric acid and aniline in p-xylene to the reactor. The flow reactor was packed with the catalyst pellets (fraction size: 125–250 μm) and it was placed in the center of an 8-turn RF coil operated at 300 kHz. A 5-mm preheating zone was packed with Fe_3O_4 pellets of the same size. A fiber optic temperature sensor was attached to the outer surface of catalytic zone to control the temperature using a PID controller.

3. Results and discussion

Under near-isothermal conditions, no products other than the amide were identified [3]. The reaction kinetics is the first order in respect to both amine and acid and it is controlled by strong product inhibition at conversion levels above 50%. However, even a small deviation of the catalyst temperature from an isothermal operation results in a substantial decrease of selectivity. Because of their small dimensions, larger contributions of axial conduction and heat losses to the environment were observed in the millireactor and, accordingly, the temperature profiles deviate from those observed in large-scale reactors that follow adiabatic operation. Therefore we developed quantitative criteria for the absence of axial temperature gradients in the reactor [4].

The method was applied to control the temperature in the reactor. It was necessary to split up the catalytic bed in several heating sections with additional sections of nonmagnetic catalyst in order to obtain near-isothermal conditions. One nonmagnetic catalytic zone and one heating zone with composite magnetic catalyst forms a single periodic unit that is repeated in the axial direction. Further adjustments were made by varying the position and the length of the individual heating zones. The approach allows to obtain a temperature non uniformity inside the catalyst bed within 2K.

Under isothermal operation, the induction heating resulted in a higher reaction rate as compared to conventional heating. Furthermore, the initial reaction rate was 1.7 times higher over the composite catalyst as compared to the mechanical mixture of the same composition without major changes in the deactivation kinetics. This indicates the importance of the close contact between the magnetic core and the catalytic shell in the composite catalysts. The initial reaction rate decreased by 36% after a period of 55 h on stream. The catalyst activity was restored after a treatment with a H_2O_2 solution.

4. Conclusions

Determination of the temperature profile in an RF-heated catalytic packed-bed milli-reactor is essential for interpretation of kinetic data in these systems. The short distance between the heating source and the catalyst provides an excellent temperature uniformity, and decreases heat losses which are the main problems in conventional heating. This, together with the possibility of fast plant startup, holds promise for these reactors to replace classical batch reactors as well as to be used as remote chemicals plants in a future economy driven by electricity obtained from sustainable energy sources.

Chaotic Mixing in the NETmix Reactor

Joana Matos[1], Ricardo Santos[1], Madalena M. Dias[1], José Carlos B. Lopes[1*]

Highlights

- NETmix is an industrial reactor constituted by chambers and channels.
- The ratio between chamber diameter and channel width is crucial on mixing.
- Different structures of strange attractors can be related with mixing in chambers.

1. Introduction

NETmix is a novel static mixer reactor composed by a meso or micro sized network of mixing chambers interconnected by channels (Figure 1a) [1]. The NETmix network can be obtained by the repetition of the NETmix Unit Block (NUB) (Figure 1b). NETmix is used in industry for continuous production of nanoparticles [2] and other applications are being developed, namely: continuous production of CO2 hydrates [3] and photo-oxidation processes in water treatment [4]. Mixing in NETmix depends on the reactor geometry which influences the flow dynamics. Mixing will be evaluated using particles injections: the best mixture occurs when the particles out fraction is 0.5. The ratio between chambers diameter and channels width, *D*/*d*, (Figure 1b) is studied along with the vorticity history dynamics from phase diagrams that show different structures of strange attractors which are related to the degree of mixing in NETmix.

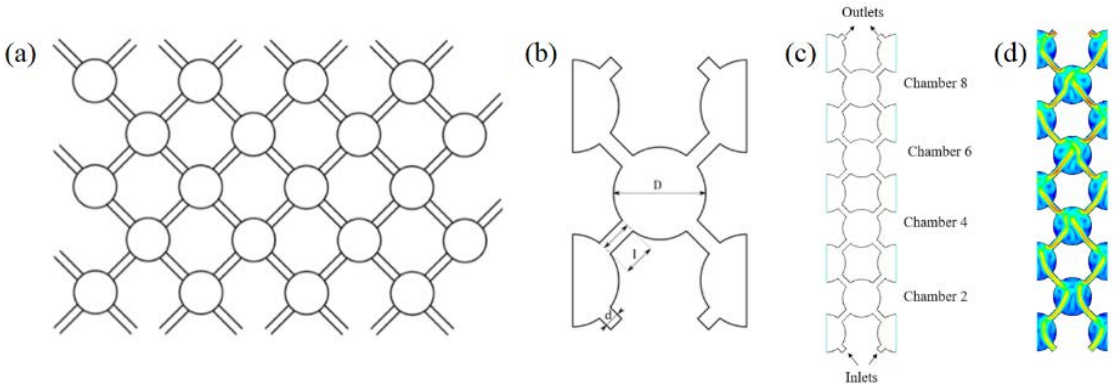

Figure 1. (a) NETmix network, (b) NUB, (c) ExtendedNUB, (d) velocity magnitude contour.

2. Methods

2D CFD simulations (time step, Δt = 1.14× 10^{-4} m/s) with water were performed for Re = 300, using the ExtendedNUB geometry in Figure 1c. The channel width is *d* = 1.00 mm and the chamber diameter varied from *D* = 5.75 to 7.25 mm. The simulated velocity flow-fields (e.g. for *D*/*d* = 6.55 in Figure 1d) were used for particle tracking with Lagrangian Mixing Simulation (LMS). LMS is an algorithm developed by Matos et al. [5] where the mixing interface between two fluids is tracked. Blue particles were positioned at left inlet and red particles at right over the initial velocity field of chamber 6. Along with the flow-time, the particles change their position: Figure 2a for 8.00× 10^{-4} s and Figure 2b for 3.50× 10^{-3} s. Note that in LMS, the number of particles in each series (blue and red) increases to represent accurately the mixing dynamics.

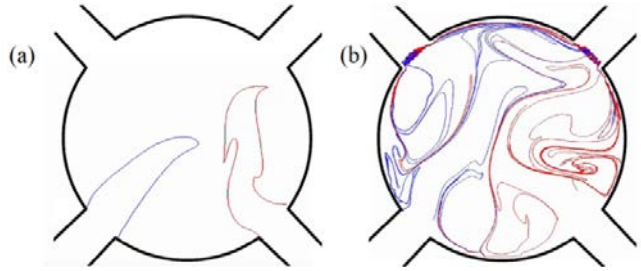

Figure 2. Particles injection in chamber 6 with LMS at different flow-times: (a) 8.00× 10^{-4} s and (b) 3.50× 10^{-3} s.

To study the mixing inside the chamber, the fraction of blue and red particles that leave chamber 6 through right or left channel was recorded using batch particles injections, i.e., maintaining the initial number of particles.

3. Results and discussion

For *D/d* = 5.75 to 5.95, the fraction of particles that go out through the same side from where they were injected is 0.9. This shows that only 10% of the particles are advected to the opposite side of the chamber. When *D/d* is between 6.55 and 6.95, the particles outlet distribution is 0.5 which represents complete mixture between the inlet streams. For larger *D/d* the particles out fraction grows apart from 0.5 again, e.g., at *D/d* = 7.25 the fraction is 0.8, i.e. only 20% of the particles are advected to the opposite side. Phase diagrams show different structures of strange attractors which can be related to the mixture inside the chamber. Figure 3 shows that a good mixture is associated to a strange attractor while a poor mixture is represented by a disorganized structure. The structures clearly show the transition between turbulent (*D/d* = 5.75 and 7.25) and chaotic (*D/d* = 6.55 and 6.78) laminar flows and the best mixing in NETmix (50/50 outlet distribution) is obtained with chaotic flows.

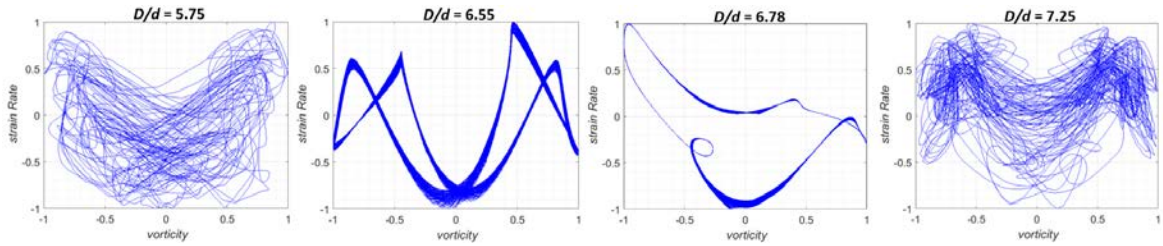

Figure 3. Normalized *Strain Rate* vs *Vorticity* for *D/d* = 5.75, 6.55, 6.78 and 7.25 in the centre of chamber 6.

4. Conclusions

The ratio *D/d* has an optimal range from 6.55 to 6.95 for mixing in NETmix. The optimal degree of mixing is represented by strange attractors.

Highlights

- A new double-basket reactor for hybrid catalysis has been designed.
- A $k_L.a$ of 0.035 s^{-1} is achieved for O_2 gas-liquid transfer.
- Simulated flow field are compared with PIV derived experimental values.
- A.ΔT of up to 15 K in the reactor is achieved through use of wall and coil T control.

1. Introduction

The use of enzymes in fine chemistry has been the subject of much research in the last decades. Among these works the concept of **hybrid catalysis** has recently emerged : the coupling of conventional chemical catalysis with enzymatic catalysis [1,2]. The aim of the GLYCYBRIDE project, on which this study is based, is to develop a synergy between enzymatic and heterogeneous catalysis in a one-pot reactor with the end-application of transforming glycerol into value-added chemicals.

The feasibility of a model one-pot reaction in three-phase hybrid catalysis, one step being an oxidation has been shown [3]. The model reaction proposed is a two-step reaction : an enzymatic catalyzed isomerization of fructose to glucose followed by a heterogeneously catalyzed oxidation of glucose to gluconic acid.

The aim of the present work is to study the design of a double-basket reactor allowing the implementation of the tri-phasic hybrid system. The main challenge lies in the optimal reaction conditions (temperature, hydrodynamics, substrate concentration) that differ between the different catalysis. The design of the reactor (Fig. 1) must thus allow the maintenance of some heterogeneity between the different reactive zones, while ensuring sufficient matter transfer between them.

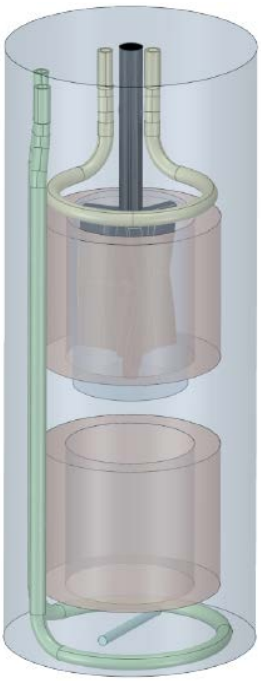

Figure 1: Scheme of the double-basket reactor

2. Methods

The hydrodynamics of the reactor has been characterized by physical methods such as : kLa of O_2 measurement (dynamic method with O_2 probe), mixing time measurement and RTD (NaCl used as a tracer). PIV velocity measurements have also been performed to determine the velocity of the flow field in the different areas of the reactor.

A CFD modeling of the hydrodynamics and thermal behavior of the reactor has been carried out with the Fluent© software (Ansys) using the realizable k − ε turbulence model associated to Multiple Reference Frame model to deal with rotating parts [4].

3. Results and discussion

Values of kLa between 0.02 s^{-1} and 0.035 s^{-1} are measured, consistent with values of single basket reactor reported in the literature. Mixing times of 15 to 20 s are observed for stirring rates above 500 rpm, in good agreement with the one calculated by CFD simulation. RTD measurement showed a behavior very close to the one expected for an ideal CSTR.

The CFD simulation provided the values of velocities in the different parts of the reactor, with velocities reduced in the basket holding the catalysts as expected (Fig. 2). These values are discussed in relation with the experimental one derived from PIV measurements.

The simulation of the thermal behavior of the reactor showed that: (1) Influence of the coils is largely inferior compared to the reactor walls, (2) Magnetic bar stirring rate has a negative but very weak influence, (3) Impeller stirring rate has a negative influence, (4) A large temperature gap between cooling and warming temperatures is necessary (80-100 K) to obtain a gap of 10-15 K in the reactor.

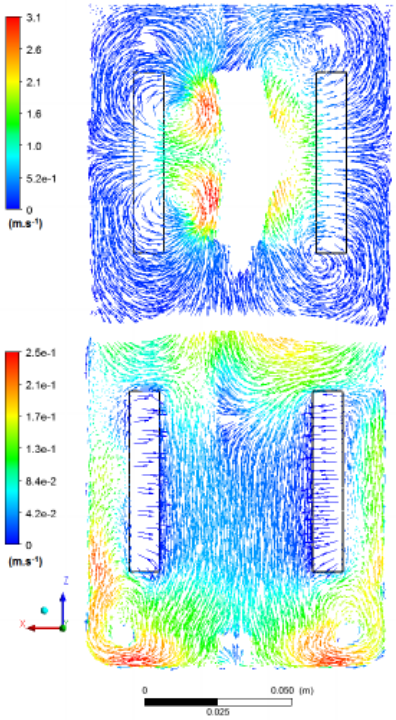

Figure 2: Flow fields on a vertical plane at y = 0 cm. Vector length is normalized. Stirring rates at 1100 rpm for the impeller, 300 rpm for the magnetic bar.

4. Conclusions

A novel double-basket reactor designed for hybrid catalysis has been first characterized for its physical transfer properties such as k_L.a, mixing time and RTD and simulated using CFD. Values of k_L.a measured are consistent with values of single basket reactor reported in the literature. The CFD simulation provided the values of velocities in the different parts of the reactor which have been compared with PIV measurements. The mixing time obtained by simulation are similar to the experimental ones. The simulation of the thermal behavior of the reactor showed that it is possible to obtain two zones in the rector, a "cold" one and a "hot" one with a ΔT of up to15 K while keeping an efficient stirring allowing for good mass transfer.

3D printed continuous reactors for exothermic and corrosive reactions.

Terje Didriksen and Carlos A. Grande

SINTEF. Forskningsveien 1. 0373 Oslo, Norway

**Corresponding author: carlos.grande@sintef.no*

Highlights

- A novel 3D printed reactor was designed for flow chemistry applications.
- Sulfonation of anisole and dilution of sulfuric acid were tested as model reactions.
- Batch and commercial 3D printed reactor used as benchmark.
- Computational fluid dynamics was used to assist in reactor design.

1. Introduction

Exothermic and corrosive reactions are normally carried out in batch units manufactured with expensive steel alloy materials and sometimes with high dilution. Additive manufacturing can be used for continuous reactor design with tailored properties for matching mass and heat transfer rates. Additionally, the possibility of printing in titanium can lead not only to smaller volumes and thus increased safety, but also to higher rates of heat transfer.

Design of tailored reactors is a new area of flow chemistry that can allow higher interplay between design and possibilities to tailor mass, heat and momentum transfer (mixing). This can result in reactors having the properties of micro-reactors but with the advantage of being millimeter size.

Exothermic reactions are present in almost all fields of chemistry. Unfortunately, often the increase of temperature resulting from the reaction not only accelerates the reaction that was targeted, but also triggers other reactions resulting in a net loss of selectivity and reducing conversion towards desired products.

In last years, additive manufacturing has proven that it allows great flexibility in the design of customized pieces. The customization of shapes that is possible to achieve with some 3D printing techniques, can lead to advanced reactors where traditional constrains and trade-offs are displaced to other more profitable design and modes of operation.

2. Methods

We have made batch reactions of sulfuric acid dilution and sulfonation of anisole. We have also used a continuous process in a commercial 3D printed reactor (Innosyn) as a reference.

To manufacture our customized reactor, we have used a genetic algorithm to design optimized shapes for Hartridge-Roughton mixers which are good for mixing at intermediate Reynolds. We have designed a reactor with enhanced heat-transfer properties that was 3D printed using commercial titanium alloy.

3. Results and discussion

Using a genetic algorithm we have designed a Hartridge-Roughton mixer with optimized surface area per unit volume of reactor. Although multi-parametric 3D optimization is required, the computational time required for this task is still larger than finding semi-optimal solutions and test the flow quality experimentally. Once a satisfactory design was achieved, we have made CFD simulations of a single reactor as shown in Figure 1.

Based on the simulation results and on the need of extending the production of products, we have designed a reactor that has 4 parallel reactors and that has enhanced heat exchanger properties. A cut-off of the reactor is shown in Figure 2.

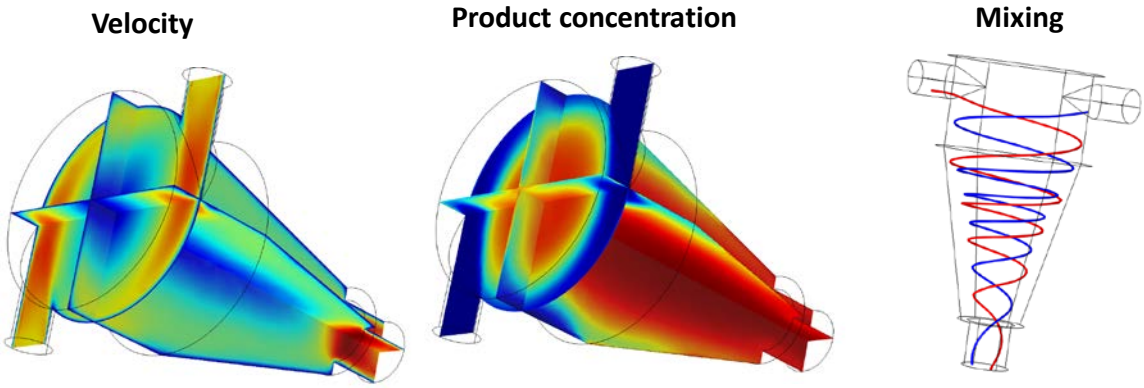

Figure 1. Detailed 3D simulations in the designed mixers.

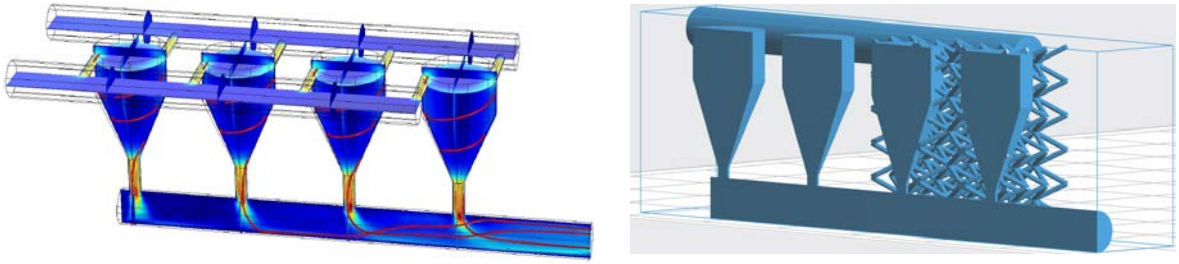

Figure 2. 3D simulations and cut-off of the 3D printed reactor for sulfonation reactions.

4. Conclusions

3D printing allows us to produce tailored reactors that can equilibrate rates of reaction and heat transfer in order to pursue continuous operation even in very exothermic conditions. It is very difficult to make multi-parametric 3D optimization for determining optimal shapes, but some simplifications can be made to reach suitable reactor designs.

Experimental Study of Inductive Heating-Assisted Catalytic Hydrocracking of Naphthalene and Tetralin as Model Compounds of Heavy Oil.

Abarasi Hart [1*], Mohamed Adam [2], John P. Robinson [2], Sean P. Rigby [2] and Joseph Wood [1]

[1] *School of Chemical Engineering, University of Birmingham, Edgbaston, Birmingham B15 2TT, UK*
[2] *Faculty of Engineering, University of Nottingham, Nottingham NG7 2RD, UK*
** Corresponding author:a.hart@bham.ac.uk*

Highlights

- Hydrogenation upgrades poly-aromatics into light hydrocarbon components.
- Dehydrogenation causes condensation of poly-aromatics exemplar of heavy oil.
- Ni enhanced the hydrogenating activity of the catalyst compared with Co.
- The rate of naphthalene hydroconversion is higher than tetralin.

1. Introduction

The demand for transportation fuels is rising with the major source of supply being declining crude oil reserves. To meet the demand-supply gap, the exploitation of lower quality but abundant deposits of heavy oil and bitumen is necessary, while waiting for the transition to renewable fuels. Partial upgrading of heavy oil can be achieved in situ through Toe-to-Heel Air Injection (THAI) and its catalytic variant CAPRI; however, to attain the required temperature in the catalytic zone necessitates a rapid heating method such as inductive heating [1].

Poly-aromatic hydrocarbons account for remarkable portion of heavy oil and bitumen, and give them high viscosity and low American Petroleum Institute (API) gravity. In the process of catalytic upgrading, the poly-aromatics are readily condensed to form coke, especially in a hydrogen limited environment which rapidly deactivates and plugs the catalyst pores [1,2].

The hydrocracking of poly-aromatics in heavy oils with inductive heating-assisted catalysis was studied. Typical hydrotreating catalysts (e.g., $NiMo/Al_2O_3$ and $CoMo/Al_2O_3$) were evaluated for hydrocracking reactions. The formation of coke based on the number of aromatic rings was also studied using naphthalene and tetralin. This study is conducted as part of the evaluation of incorporating inductive heating to augment the temperatures in the vicinity of the catalyst zone in the THAI-CAPRI process in order maximise catalyst performance and increase upgrading.

2. Methods

Commercial catalysts $NiMo/Al_2O_3$ and $CoMo/Al_2O_3$ quadra-lobe shaped (AkzoNobel) with dimensions (5 ± 2.1 mm × 1.4 mm × 1.21 mm) were used. The feedstock was naphthalene (99+%, Alfa Aesar), tetralin (99.5%), solvent n-hexadecane (99%, Alfa Aesar) and H_2 supplied by BOC, UK.

The inductive heating system comprises of a fixed bed reactor of quartz glass tube (440 mm × 20 mm i.d × 40 mm o.d) rated 20 bar pressure (Inductelec Ltd and assembled by C-Tech Innovation, UK). The height of the induction coil wound around the tube is 230 mm, which also represent the catalytic bed height. The catalyst bed is heated inductively by steel balls susceptors of size 3 mm mixed the catalyst in a volume ratio of 70% (v/v). The steel balls convert the electromagnetic field into heat, to heat the catalyst bed volumetrically. The reactants were preheated to 200 °C with the aid of trace heater cable wrapped around the line and mixed with hydrogen prior to being

delivered into the reactor from the top. A hydrogen flow rate of 200 mL.min^{-1}, temperature 300 ^{o}C, catalyst-to-steel balls ratio (CTSBR) 70% (v/v), pressure 18 barg, and LHSV 0.75 h^{-1} condition obtained from optimisation were used in the experiment.

The liquid product was analysed using an Agilent 6890N GC equipped with a capillary column HP-5 (30 m × 0.320 mm × 0.25 µm), and a thermogravimetric analyser, TGA (TG 209 F1 Iris® instrument, NETZSCH-Geratebau GmbH) was used to determine the amount of coke on the catalyst.

3. Results and discussion

Induction heating provided an effective means of heating the catalyst bed, with 70 %v/v CTSBR the bed could be heated to 250°C within about 3 minutes. In previous study with NiMo/Al_2O_3 alone, we found that with induction heating the catalytic activity was enhanced and the spent catalyst coke content was lower when compared to conventional heating. Figure 1 shows hydrogenation of naphthalene and tetralin. The NiMo/Al_2O_3 exhibited a superior hydrogenating activity than CoMo/Al_2O_3, which promoted further hydrogenation from tetralin to (*trans*/*cis*) decalins and thus significantly improved the selectivity to decalins (Figure 1a).

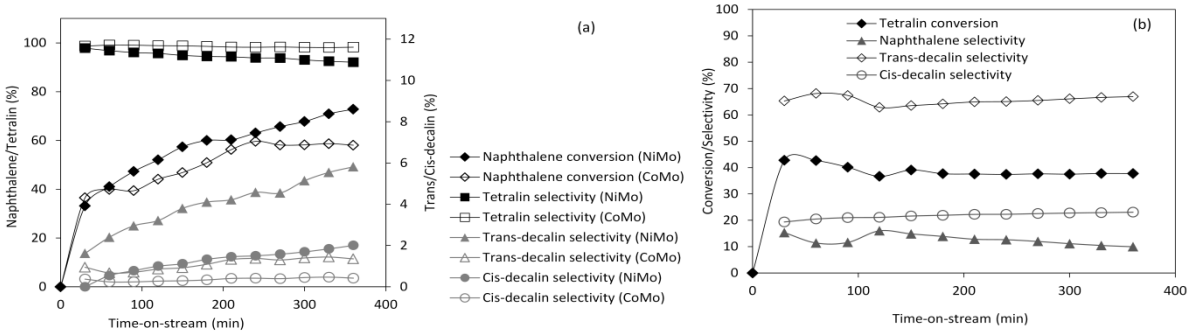

Figure 1. The hydrogenation of (a) naphthalene with NiMo/Al_2O_3 and CoMo/Al_2O_3 and (b) tetralin with NiMo/Al_2O_3 at 300 ^{o}C, 18 bar, 0.75 h-1 and CTSBR 70% (v/v).

The sequential reaction scheme shown in Figure 2, can be confirmed in Figures 1a and b, the intermediate tetralin can either undergo further hydrogenation to (*trans*/*cis*) decalins or dehydrogenation to naphthalene. However, the direction of the reaction is largely dependent on the catalyst type and the process conditions.

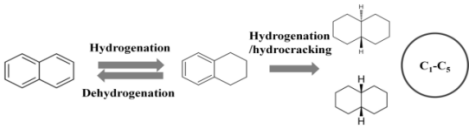

Figure 2. Reaction scheme

4. Conclusions

Induction heating of catalytic bed was studied for hydrogenation and hydrocracking of typical poly-aromatics found in heavy oil. Alumina supported NiMo and CoMo catalysts were investigated, while Ni increased the production of *trans*- and *cis*-decalins than Co, the rate of naphthalene hydroconversion was higher than tetralin for NiMo/Al_2O_3 catalyst.

Aqueous Oxidation of Xylose to Xylonic Acid and Xylaric Acid over Synergistic PtAu and PtCu Catalysts Using Molecular O_2.

Jie Ding[1], Mengyuan Liu[1], Tianqi Fang[1], Chaohe Yang[1], Jian Shen[2], Xin Jin[1*]

Highlights

- Selective oxidation of xylose using O_2 in base-free medium at 80 °C.
- Bimetallic PtAu and PtCu catalysts display synergistic performances.
- Combined selectivity towards xylonic and xylaric acid is approximately 85%.

1. Introduction

Carboxylic acids are important industrial chemicals for a variety of different everyday products. Catalytic conversion of inexpensive sugars to value-added acids provides an alternative route to fossil-based products. Xylaric acid ($ 2,650/g), produced from xylose ($ 0.07/g), has been identified as one of the top ten value-added chemicals for biomass conversion, with wide applications in fine chemicals, agriculture, medicine, and architecture [1].

Xylaric acid is conventionally produced using nitric acid as the oxidant, generating significant amounts of toxic by-products such as N_2O and NO. While oxidation of xylose to xylaric acid using molecular O_2 is environmental-friendly compared with mineral acid method, very limited work has been published on catalyst design for xylaric acid synthesis. One of the most recent results reported by Saha and colleagues showed that oxidation of xylose with O_2 to xylaric acid can be realized over supported monometallic Pt, Pd, Au, Ru and Cu catalysts with 64% yield [2]. The correlation of catalyst structures, including particle size, surface composition and metal-support interaction, with catalytic activity and selectivity, however, has yet to be fully understood in this area. Therefore, in this work, we reported a series of Pt-based mono- and bimetallic catalysts for effective oxidation of xylose to xylonic and xylaric acids. Influence of catalyst morphologies on conversion and selectivity will be particularly discussed in this work, with the aim to provide further insights into effective catalyst design for xylaric acid synthesis from xylose.

2. Methods

The catalysts were prepared by traditional method involving use of $NaBH_4$ as the reducing agent [3]. Metal loading was approximately 2wt%. In a typical oxidation experiment, 20 mL of aqueous xylose solution (0.07 mol/L) was added to the reactor and mixed with 0.05 g of catalyst. Reaction was conducted at 80 ℃ and 1 MPa O_2. The product solutions were analyzed by HPLC equipped with both RID-10A and SPD-20A detectors.

3. Results and discussion

Several TiO_2 supported Pt based mono and bimetallic catalysts were screened to evaluate their performances for xylose oxidation. Among other candidates, bimetallic PtAu catalyst shows enhanced conversion of xylose (X ~ 85%) and selectivity of xylaric acid (S ~ 18%, Figure 1a). PtCu catalysts also display interesting behaviors during xylose conversion. It is found that, $PtCu/ZrO_2$ catalyst exhibits higher conversion compared with $PtCu/TiO_2$, CeO_2, and AC with good selectivity towards xylaric acid being 19.6% at 80 °C. The preliminary results clearly suggest bimetallic catalysts show promising performances compared with monometallic ones.

We also observed other co-products such as tartaric, glyceric, glycolic and formic acids, suggesting that xylose and xylonic acid might undergo C_1-C_4 and C_2-C_3 cleavage during oxidation reactions. Therefore, in this presentation, the influence of particle size of bimetallic PtAu and PtCu catalysts, and metal-support interaction on catalytic activity and product distribution during xylose oxidation will be discussed in details. BET, XRD, TEM and XPS characterization data will be correlated with experimental results from batch studies to establish possible structure-performance relation.

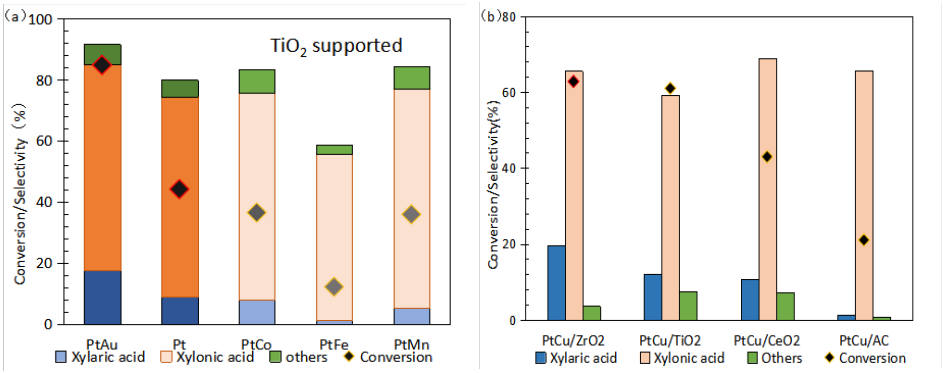

Figure 1. Activity and product distribution of Pt based mono and bimetallic catalysts (reaction conditions: 0.15 g xylose, 0.05g catalyst, 2wt.%, 2wt.%–2wt.% metal loading, 80 ℃, 10 h and 1 MPa O_2).

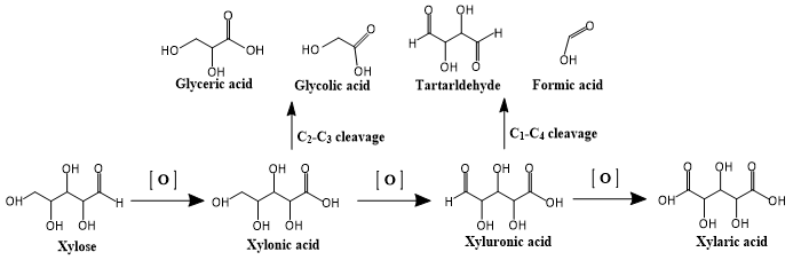

Scheme 1. Proposed reaction pathways of xylose Oxidation.

4. Conclusions

Bimetallic PtAu and PtCu catalysts exhibit synergistic catalytic performance in terms of activity and selectivity towards xylonic and xylaric acids during xylose oxidation.

Methanol Synthesis with Steel-Mill-Gases: Simulation and Practical Performance Investigations

Kai Girod*, Klaas Breitkreuz, Stefan Schlüter, Thomas Marzi, Stefan Kaluza

Fraunhofer UMSICHT, Osterfelder Straße 3, 46047 Oberhausen, Germany

**Corresponding author: kai.girod@umsicht.fraunhofer.de*

Highlights

- Impact of different syngases from steel mills on MeOH productivity
- Catalyst stability at high CO_2 and H_2O concentrations
- Synthesis in close-to-practice test reactor system with intrinsic heat gradients
- Optimization of test conditions by sophisticated process simulation

1. Introduction

State-of-the-art steel mills as large and highly integrated sites comprise different sources of CO_2, CO and hydrogen. Besides the current energetic utilization, these gases provide promising potential to be utilized as feedstock for bulk chemical production, while simultaneously reducing the CO_2 footprint of the steel mill. The commercial Cu-based catalyst applied in industrial methanol synthesis is optimized for constant gas streams of high purity and fixed composition. The scope of this work is to evaluate the possibility of applying a commercial methanol synthesis catalyst in the conversion of synthesis gas derived from steel mill exhaust gases exhibiting fluctuating compositions [1]. The present contribution deals with the influence of altering CO/CO_2-ratios as well as the influence of high water concentrations in the inlet gas stream on the performance of the catalyst. In addition, gas streams with specific compositions from different steel mill production sites are investigated, including CO_2- and nitrogen rich blast furnace gases as well as gas streams originating from steel processing (converter gas). These gas streams have to be enriched with H_2 from electrolysis or coke oven gas. The ongoing investigations were performed within the scope of the project Carbon2Chem®, funded by the German Federal Ministry of Education and Research (BMBF).

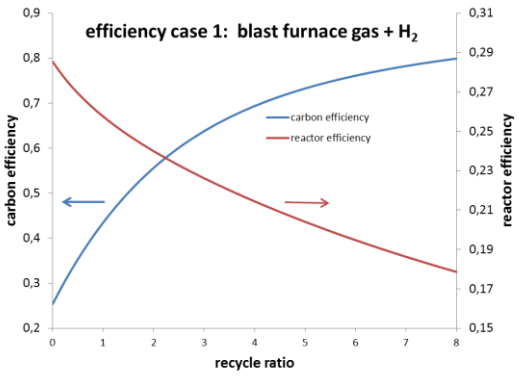
2. Methods

Catalyst development and testing is usually performed with rather small amounts of catalyst [2]. However, transferring the results about performance and lifetime of the catalyst to industrial relevant pilot-scale application is hardly feasible. Here, larger amounts of differently shaped catalyst particles are usually applied resulting in a non-ideal temperature distribution and transport phenomena that can influence the overall performance of the catalyst. In order to close the gap between lab-scale and large-scale catalyst testing a new test system was developed [3]. In addition, a large scale methanol synthesis process simulation was developed including a kinetic model for the heterogeneously catalyzed methanol synthesis reaction. The theoretically identified operating points were subsequently applied in practice using two different test facilities. The first system is

close to the industrially applied geometry. A second complementary test system with a total reactor volume of 15 ml is characterized by a higher grade of automatization.

3. Results and discussion

The ongoing research focuses on technically and economically feasible gas compositions and their impact on the overall catalyst performance. The carbon efficiency describes the total carbon utilization of the process and is shown in figure 1. The recycle ratio has to be kept in an economically reasonable range in order to enable high reactor efficiency. The CO_2/CO-ratio has a crucial effect on the catalyst performance.



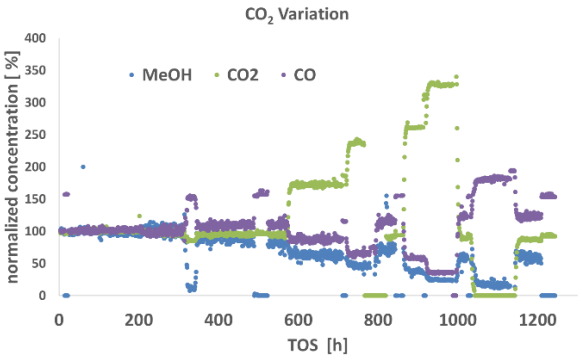


Figure 1: carbon and hydrogen process efficiency as a function of the recycle ratio (left)

Figure 2: MeOH formation depending on CO_2/CO (right)

As expected, the methanol productivity decreased with increasing CO_2 concentration (figure 2). A minimum CO_2 concentration is required for a high catalyst activity, as the lowest methanol productivity was obtained for pure CO. Apparently high water and CO_2-concentrations reduce the lifetime of the commercial MeOH-synthesis-catalyst.

4. Conclusions

The obtained results proof that methanol synthesis with H_2-enriched steel mill gases as feedstock is possible. However, for the same MeOH plant capacity a synthesis with steel mill gases requires a larger reactor due to lower catalyst productivity.

Model-based Solvent Screening for a Reductive Amination.

Fabian Huxoll[1], Jonas Bianga[2], Thomas Seidensticker[2], Dieter Vogt[2], Gabriele Sadowski[1]*

1 Laboratory of Thermodynamics, TU Dortmund University, 44227 Dortmund, Germany

Highlights

- Application of an activity coefficient-based approach for a fast solvent screening.
- Solvent influence on reaction equilibrium and reaction rate can be predicted.
- No experimental reaction data needed.
- Promising solvents could be confirmed by experiments.

1. Introduction

Reaction equilibrium and reaction rate of chemical reactions are significantly influenced by the solvent used. Therefore, to optimize the equilibrium position, to increase the selectivity towards the product of interest and to enhance the reaction rate, it is important to consider the solvent influence on a reaction [1, 2]. State-of-the-art lab screening is highly time-consuming and therewith cost-intensive.

In this work, the RA (reductive amination) of undecanal and diethylamine to DEAU (1-diethylamino-undecan) and water was investigated. Appropriate solvents were identified using a thermodynamic approach and subsequently validated by experiments.

2. Methods

The thermodynamic equilibrium constant K_a, which does NOT depend on the solvent nor on the reactant concentrations, was used as the starting point of this approach. K_a is the product of K_x, which contains the equilibrium concentrations x_i, and of K_γ, which contains the activity coefficients γ_i. As the activity coefficients may strongly depend on the solvent whereas K_a does not, K_x is also strongly influenced by the solvent.

According to equation 1, increasing activity coefficients of the reactants lead to an increase of product concentrations at the reaction equilibrium. Moreover, high activity coefficients of the reactants imply a high reaction rate (2). Accordingly, the aim of this approach is to identify solvents which lead to high activity coefficients of the reactants.

$$K_a = \frac{x_{Product,1} \cdot x_{Product,2}}{x_{Reactant,1} \cdot x_{Reactant,2}} \cdot \frac{\gamma_{Product,1} \cdot \gamma_{Product,2}}{\gamma_{Reactant,1} \cdot \gamma_{Reactant,2}} \quad (1)$$

$$r = k \cdot x_{Reactant,1} \cdot \gamma_{Reactant,1} \cdot x_{Reactant,2} \cdot \gamma_{Reactant,2} \quad (2)$$

For the solvent screening, a wide range of different solvents was investigated. Using the modified group contribution method UNIFAC [3], the activity coefficients were predicted without using any reaction data. Solvents were identified that lead to the highest possible reactant-activity coefficients. Afterwards, the most promising solvents of the screening were validated regarding reaction equilibrium and reaction rate.

3. Results and discussion

Based on the predicted activity coefficients, it could be shown that the applied solvents significantly influence the reaction rate and the reaction equilibrium. The activity coefficients of the reactants deviated from each other by a factor of up to 20. Out of 14 investigated solvents, methanol, DMF (*N,N*-dimethylformamide) and ACN (acetonitrile) turned out to be the most promising ones (see Figure 1).

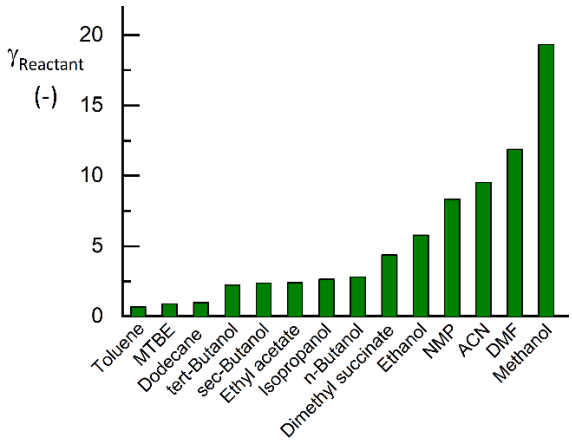

Figure 1. RA-reactant activity coefficient for reaction mixtures in different solvents.

To validate these results, experiments were performed in these solvents at 30 bar and 100 °C. Results showed that the highest product concentrations and reaction rates were indeed achieved in the three top solvents of the screening. Furthermore, using this approach it was possible to qualitatively predict the influence of initial substrate concentrations on reaction yield and kinetics.

4. Conclusions

Applying a thermodynamic approach allows a fast solvent screening without the need of any experimental reaction data for parameter estimations. Predictions and experimental results were in very good agreement, showcasing the advantages of thermodynamic models in order to screen possible solvents over the experimental and thus time and cost consuming lab screening.

An in Situ FTIR and Raman Study of MOF MIL-53(Al) Formation Under Solvothermal Conditions

Heidemarie Embrechts[1,2], Martin Kriesten[3], Wolfgang Peukert[1,2], Martin Hartmann[3], Monica Distaso[1,2]

[1] *Department of Chemical and Biological Engineering, Institute of Particle Technology, Cauerstr. 4, 91058 Erlangen, Germany* *heidemarie.embrechts@fau.de
[2] *Interdisciplinary Center for Functional Particle Systems, FAU Erlangen-Nürnberg, Haberstr. 9a, 91058 Erlangen, Germany*
[3] *Erlangen Catalysis Resource Center, Egerlandstr. 3, 91058 Erlangen, Germany*

Highlights

- The formation steps of the MOF MIL-53(Al) are studied with in situ FTIR and Raman spectroscopy in a specially designed solvothermal reactor.
- The formation of prenucleation building units, MIL-53 nuclei, MIL-53 formation, and the decomposition of the solvent DMF to formic acid are observed in situ.
- The MIL-53 particle size is linked to the accumulation of prenucleation building units which influences the supersaturation of MIL-53 prior to particle formation.

1. Introduction

Metal-organic frameworks (MOFs) are a class of porous coordination polymers formed by the self-assembly of polydentate bridging ligands and metal-oxo clusters.[1] Due to their remarkably high surface areas, highly-ordered microporous networks, and structural diversity, MOFs exhibit great promise in the fields of catalysis, sensing, drug delivery, gas separation, and gas storage.[2]

Although there has been much research on the properties of metal-organic frameworks and numerous novel structures have been synthesized to date, there are only few reports focusing on the MOF formation steps prior to precipitation. Optimization of MOF synthesis protocols has, in consequence, been largely governed by serendipity. An understanding of the individual formation steps would allow for the development of improved strategies for the targeted engineering of MOF materials with defined crystal structures tailor-made to fit a variety of specific applications.

2. Methods

Such mechanistic understanding is achieved by monitoring MOF synthesis with Raman and FTIR spectroscopy in a 1.5 L solvothermal reactor specially designed to enable in situ monitoring of the reaction solution.[3] MIL-53(Al), one of the most-studied MOFs with interesting breathing behaviour and high thermal stability, serves as a model system.[4] MIL-53(Al) is synthesized in N,N-Dimethylformamide/water mixtures from aluminum salts and terephthalic acid. In situ observations are complemented with detailed ex situ analysis of the synthesized MOFs with N_2 sorption, x-ray diffraction, SEM imaging, thermogravimetric analysis, and solid state FTIR measurements.

3. Results and discussion

The formation of prenucleation building units (PNBUs) consisting of one linker molecule and one aluminum atom, MIL-53(Al) nuclei, crystalline MIL-53(Al) and the decomposition of DMF to formic acid is followed over time.[3] By comparing the kinetic profiles of the PNBUs $[Al(H_2O)_4–HBDC]^{2+}$ and the solid MIL-53(Al) phase at various synthesis temperatures, the rearrangement of the PNBU to form the metal-organic framework is identified as the rate-limiting step of synthesis. The calculated activation energy of formation of the PNBU (65.5 kJ mol^{-1}) is significantly lower than that of MOF formation (90.4 kJ mol^{-1}). This information is used to contruct a proposed MIL-53 formation pathway (Figure 1).

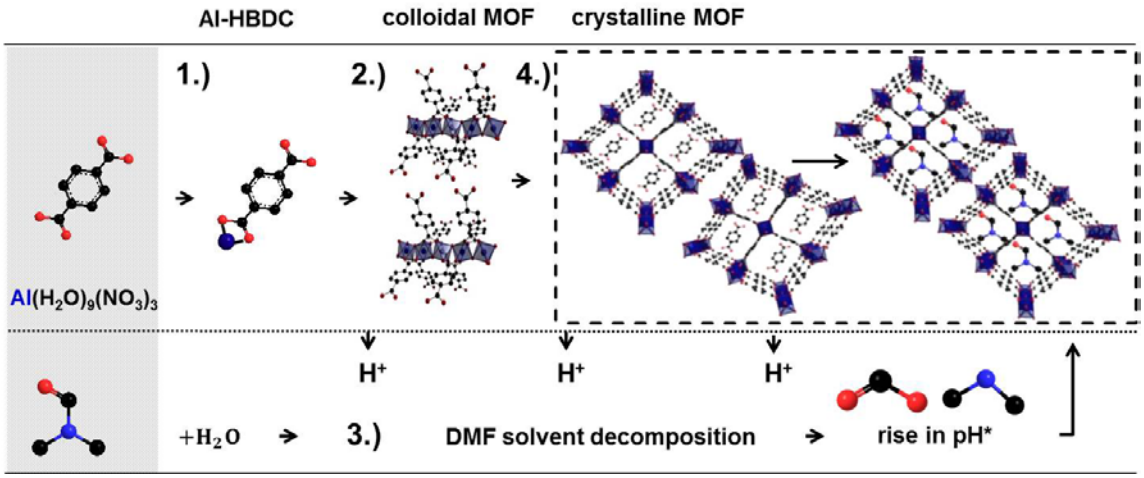

Figure 1. Proposed MIL-53 formation mechanism with reaction steps observed in situ.

The synthesized MIL-53 particle size is found to depend on the accumulation of prenucleation building units in solution prior to precipitation of the solid MIL-53(Al) phase. PNBU accumulation preferentially occurs when both the metal center and linker precursors are initially free to coordinate. A larger accumulation of prenucleation building units prior to MIL-53 precipitation results in a higher supersaturation, larger burst of nucleation, and the formation of nanoMOFs. Conditions less favorable to PNBU accumulation result in the formation of micron-sized particles.

4. Conclusions

This information gained from this study can be used as a tool to rationally understand the effect of various parameters on the MOF MIL-53(Al) formation process. The methodology described here could also be applied to rationally understand the formation of other MOF structures.

Kinetic analysis of the steam reforming of biomass derived oxygenates over Ni and Rh catalysts: Investigation of support effects

Marinela D. Zhurka, Panagiotis N. Kechagiopoulos*

Chemical and Materials Engineering Group, School of Engineering, University of Aberdeen, Aberdeen, AB24 3UE, UK.

**Corresponding author: p.kechagiopoulos@abdn.ac.uk*

Highlights

- Steam independent kinetic pathways over oxide supports for ethanol reforming
- Sepiolite's structure memory-effects revealed to influence rate determining step
- Rh shows an optimal performance in the steam reforming of phenolic compounds

1. Introduction

The steam reforming of oxygenates originating from biomass pyrolysis has received wide research attention in relation to the sustainable production of H_2. Bio-oil produced from biomass pyrolysis comprises of a complex mixture of organic compounds. Research to date has focused on reforming of model compounds of the aqueous phase of bio-oil, such as acetic acid, however much less work has been carried out in relation to lignin-derived aromatic compounds. In the current work, an extensive kinetic study of ethanol, phenol and hydroquinone reforming is presented over single metal (Ni and Rh) and bimetallic (Ni-Co) catalysts. Various supports, ranging from SiO_2 and γ-Al_2O_3, to mixed oxides of CeO_2, ZrO_2 and La_2O_3, to natural sepiolite, are utilized to probe support effects on the kinetic mechanism in combination with the active metal chosen.

2. Methods

The kinetic analysis was carried out using a fully automated reaction system by PID Eng & Tech (Micro Activity-effy unit). An HPLC pump (Gilson 307) was used to feed the water/organics mixture, the latter evaporated and mixed with N_2 prior reaching the catalyst bed. A stainless steel (SS316) fixed bed reactor (9.1 mm i.d, total length 304.8 mm) was used heated by a single-zone furnace. The gases were analyzed in an HP5890 GC equipped with a TCD detector and MS-5A and HS-T columns, while the liquids were analyzed in a Thermo Scientific TRACE 1300 GC using an FID detector and a WAXMS A column. Catalysts were prepared via wet impregnation.

3. Results and discussion

Concerning ethanol steam reforming, the effect of temperature for both Ni and Rh revealed dehydrogenation and decomposition reactions to be dominant at lower temperatures whereas higher temperatures promoted reforming and water gas shift reactions. Ni catalysts supported on SiO_2 and sepiolite showed a high methane selectivity at lower temperatures suggesting a metal-depended reaction pathway due to Ni's known methanation activity at these conditions [1]. On Rh no methane was detected, with the metal effectively promoting the dehydrogenation pathways of CH_x groups [2]. Identification of primary and secondary products on Ni catalysts revealed at lower temperatures acetaldehyde as a primary product, originating from ethanol dehydrogenation, with

CH_4 and CO being secondary products, emerging from acetaldehyde's decomposition, and CO_2 from the water gas shift reaction primarily and acetate species decomposition to a smaller degree. Strong support effects were observed in terms of the reaction pathway for ethanol reforming. A particularly low methane selectivity was observed over the CeO_2-ZrO_2-La_2O_3 mixed oxide supported catalysts, attributed to known activity of CeO_2 to form surface and bulk oxygen vacancies than can be replenished by water from the feed, hindering the development of CH_x to CH_4 and contributing to the elimination of the deposited carbon [3]. Interestingly, the catalyst supported on natural sepiolite exhibited a positive reaction order to water and negative to ethanol, in contrast to the rest of the supports. The calcination temperature of this catalyst was further revealed to have a critical impact on the reaction network, attributed to the memory-effect the structure of sepiolite exhibits when the mineral has not been exposed to temperatures higher than 530°C. Water preferentially adsorbs in sepiolite's structural channels, replacing the absent water and unfolding its structure, but also restricting the transfer of water from the support to the metal [4], resulting in steam activation being the rate determine step at low temperatures (Figure 1a). The lack of water derived species on the metal potentially further leads to a surface saturation by ethanol derived species explaining the negative order observed on ethanol (Figure 1b). Increasing the calcination temperature to 550°C (Figure 1c) or the reaction temperature to 500°C (Figure 1d) leads to the permanent collapse of sepiolite's structure, inhibiting water from entering its channels and facilitating the transfer of water to the metal for the promotion of the reforming reactions [5].

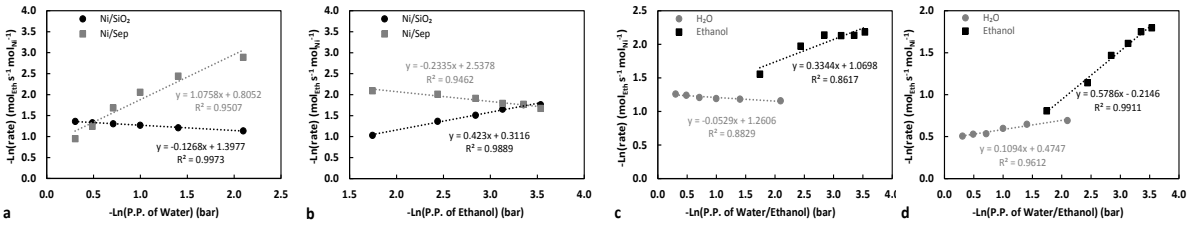

Figure 1. Partial reaction orders of ethanol steam reforming over Ni/SiO_2 and Ni/Sepiolite at 400°C (P = 0.9 bar, V_{tot} = 160 cm^3 min^{-1}) for (a) water and (b) ethanol. Partial reaction orders of ethanol steam reforming for water and ethanol at (c) 400°C on pre-treated Ni/Sepiolite catalyst at 550°C and (d) 500°C over untreated Ni/Sepiolite.

Reforming of phenol and hydroquinone, over Rh and Ni-Co catalysts supported on γ-Al_2O_3, revealed the effective conversion of the aromatic compounds to H_2 and CO_x at high temperatures (>500°C) and H_2O/C ratios (>8). Ongoing work at low temperatures focuses on liquid products analysis to elucidate the mechanistic pathways of these compounds.

4. Conclusions

The steam reforming reaction pathways of different classes of biomass derived oxygenates over a wide range of conditions and catalysts were investigated. For ethanol, the production of acetaldehyde is strongly related to the operating temperature. Ni promotes methanation reactions while Rh favors dehydrogenation reactions. On all oxide supports a steam-independent pathway is observed. Unique support effects are observed with sepiolite related to the interaction of water with the internal channels of the clay, restricting water from transferring to the metal and resulting on a steam-dependent kinetic mechanism. Current work extends the study to aromatic compounds.

Effect of temperature on $NiAl_2O_4$ catalyst stability in the steam reforming of raw bio-oil

Aingeru Remiro*, Naiara García-Gómez, Beatriz Valle, Lide Oar-Arteta, Javier Bilbao, Ana G. Gayubo

Dept. Chemical Engineering, University of the Basque Country, 48080 Bilbao, Spain

**Corresponding author: aingeru.remiro@ehu.eus*

Highlights

- 600 and 700 ºC are suitable temperatures for enhancing $NiAl_2O_4$ catalyst stability
- Ni sintering is avoided at 600 ºC and coking is minimized at 700 ºC
- Temperature significantly affects the nature of the coke and its impact on catalyst porous structure
- Coke deposition affects more severely the porous structure at 650 ºC, thus causing a faster deactivation

1. Introduction

Among the alternatives for sustainable hydrogen production, the steam reforming (SR) of bio-oil obtained by pyrolysis of lignocellulosic biomass is a promising route with a low environmental impact because of neutral CO_2 balance [1]. One of the main problems of bio-oil SR is the deposition of carbonaceous material that causes reaction equipment clogging and rapid catalyst deactivation. In order to improve its economic viability, research effort has been focused on the development of process strategies that improve the operability (minimizing clogging) and new catalysts with high resistance to deactivation and capability to be completely regenerated. In a previous work [2], the suitability of a bulk $NiAl_2O_4$ catalyst was highlighted, especially for its efficient regeneration at high temperature. The aim of this work is to establish an optimum reaction temperature for enhancing the H_2 production and attenuating deactivation of bulk $NiAl_2O_4$ catalyst in the SR of bio-oil.

2. Methods

The raw bio-oil, obtained by flash pyrolysis of pine sawdust, was supplied by BTG Bioliquids BV (The Netherlands). The bulk $NiAl_2O_4$ catalyst (with 33 wt% Ni) was synthesized by the co-precipitation method, calcined at 850 ºC for 4 h and sieved between 150-250 µm. Fresh and deactivated catalysts have been characterized by N_2 adsorption-desorption (porous structure), transmission electron microscopy (TEM) and X-ray diffraction (XRD) (metal properties) and temperature programmed oxidation (TPO) (amount and nature of the coke). The catalytic runs were performed in an automated reaction equipment (Microactivity Reference) provided with two steps (thermal +catalytic) in series [3]. The controlled deposition of pyrolytic lignin in the thermal step at 500 ºC minimizes operation problems and catalyst deactivation in the subsequent catalytic step. The latter has been carried out in a fluidized bed, with steam/carbon (S/C) molar ratio of 6 and space time of 0.15 $g_{catalyst}/g_{bio\text{-}oil}$. Prior to each reaction, the catalyst is reduced *in situ* (with 10% v/v of H_2 in N_2) for 4 h at 850 ºC.

3. Results and discussion

The evolution with time on stream (TOS) of bio-oil conversion and H_2 yield for different reaction temperatures (Figure 1a) show a slower and similar deactivation rate at 600 and 700 ºC, whereas the deactivation is faster at 650 ºC. This unusual result differs from that previously reported in bio-oil SR with Ni/La_2O_3-αAl_2O_3 supported catalyst [4], whose deactivation was attenuated by increasing temperature in the 600-700 ºC range. This different kinetic behavior suggests different deactivation mechanism for bulk $NiAl_2O_4$ catalyst and Ni/La_2O_3-αAl_2O_3 supported catalyst.

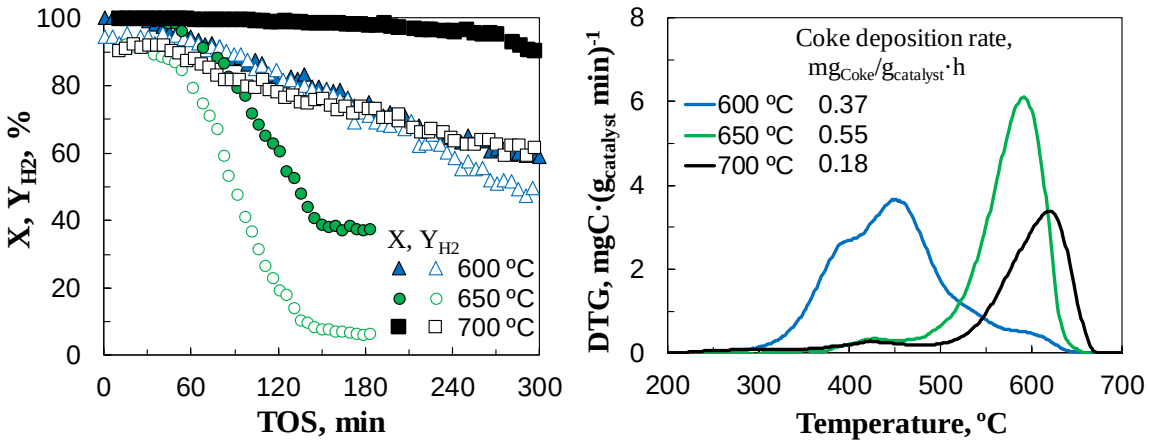

Figure 1. Effect of temperature on the evolution with TOS of conversion and H_2 yield (a) and on the TPO profile of the deactivated catalyst (b). Reaction conditions: S/C = 6, space time of 0.15 $g_{catalyst}/g_{bio\text{-}oil}$.

The XRD analysis of deactivated catalysts evidences that Ni sintering is incipient at 650 ºC and noticeable at 700 ºC. TPO analysis (Figure 1b) shows the formation of two different types of coke, which depends on the reaction temperature. An encapsulating coke that burns at low temperature is deposited at 600 ºC, whereas at 650 and 700 ºC a more condensed coke is deposited on the support, which partially blocks the porous structure. Both types of coke contribute to catalyst deactivation. The lower deactivation observed at 700 ºC compared to 650 ºC is explained by the promotion of coke gasification and a lower impact of coke on the porous structure of the catalyst.

4. Conclusions

The bulk $NiAl_2O_4$ catalyst undergoes greater deactivation during the SR of bio-oil at 650 ºC compared with that observed at 600 ºC and 700 ºC, because Ni sintering is avoided at 600 ºC, whereas coke deposition is attenuated at 700 ºC. It is concluded that 600 ºC is the optimum temperature for SR of bio-oil with bulk $NiAl_2O_4$ catalyst because it is suitable for attaining slightly higher H_2 yield than at 700 ºC (because of WGS promotion), with lower energy requirement, and moreover, it is also suitable for strategies that enhance H_2 selectivity (e.g., sorption enhanced steam reforming and membrane reactor).

Control of Temperature Uniformity for Exothermic Liquid Reaction in Structured Passages

Mohammed Msaed, Jordan MacInnes* and Annette Taylor

Chemical and Biological Engineering, University of Sheffield, Mappin Street, Sheffield S1 3JD

**Corresponding author: j.m.macinnes@sheffield.ac.uk*

Highlights

- Spatially-resolved temperature measurement using a fine-wire thermocouple
- Computation predicts the measured temperature profiles
- Buoyancy significant for the 5 mm passage size and flow rates used

1. Introduction

Exothermic reaction may cause temperature to exceed limits associated with preventing unwanted product formation or runaway reaction. Yet for efficient use of reactor volume it is important to operate as near to the temperature limit as possible to maximize reaction rate. Thus, an important engineering objective is minimizing temperature non-uniformity during the reaction process.

Reactors employing small-scale passages to increase relative heat transfer area have been widely advocated[1] but structuring the passage geometry to get the best performance out of a given size has received little attention. The present approach uses spatial temperature measurements within the flow passages, by traversing a fine-wire thermocouple, to assess the capability of predictive computation, thereby allowing probing at other scales and for other geometries than those used in the experiments. Spatial temperature measurement has not been attempted within the flow in small passages. Those reported are either of exterior temperature of the device, e.g. using infrared thermometry [2], or require sensor size approaching that of the passage, therefore not local and only at the passage walls[3,4].

The 'F' mixer geometry[5,6] shown in Fig. 1a is considered here. Only the first four elements of a multi-element reactor are studied as the first few elements are where the reactant streams mix, the largest concentrations prevail and hence the greatest challenge to thermal control occurs. The experiment uses relatively large passage size to enable accurate local resolution of temperature by the measurement. The size is large enough for buoyancy to be significant, although at the smaller size passages envisioned for best thermal control, buoyancy will have reduced importance.

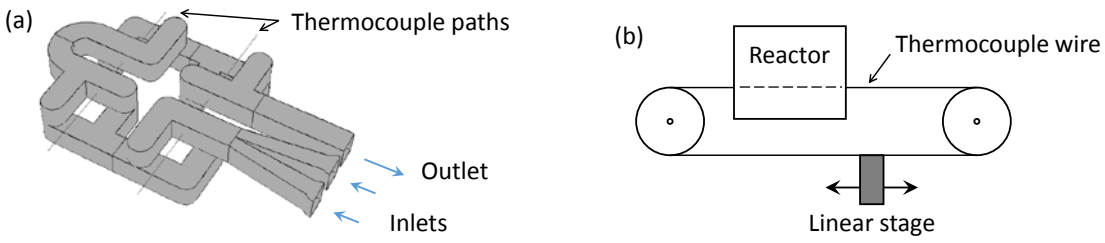

Figure 1. (a) Reactor geometry and (b) temperature measurement arrangement.

2. Methods

In the experiment, two separate streams are supplied at uniform temperature to four F elements placed in series. The element passages are milled from PEEK, covered top and bottom by 1 mm stainless steel sheets coated on the passage side with a thin PFA layer and sandwiched between two copper plates containing cooling water passages. Temperature profiles are measured along linear paths passing through the passages by traversing a 75 micron diameter butt-welded K-type thermocouple (Fig. 1b). Calculations of wire temperature in a flow with sinusoidal fluid temperature variation along the wire suggest conduction error is less than 1% of field temperature difference with this wire size. Computations use ANSYS 16 to solve the Navier-Stokes, energy and species equations in the experimental geometry, the domain including the solid regions surrounding the passage. Boundary conditions are uniform temperature, composition and velocity at the inlets, uniform temperature at the top and bottom boundaries (although with a heat transfer coefficient representing the thermal resistance of the PFA-coated cover sheet) and zero heat flux at other external boundaries. The apparatus is design to deliver these with good approximation.

3. Results and discussion

Fig. 2a shows a typical result for computed and measured temperature profile with water flow (no reaction). In this case a warm inlet (46 °C) is cooled by the top and bottom plates (25 °C). The importance of buoyancy is clear from the computed result with gravity switched off (dashed line). Fig. 2b shows successful measurement of temperature with reaction occurring (18 °C adiabatic temperature rise) from inlet reagent streams at 25 °C with plates at (35 °C). Computations of the reacting cases are underway and could provide a route to deducing models for reaction kinetics.

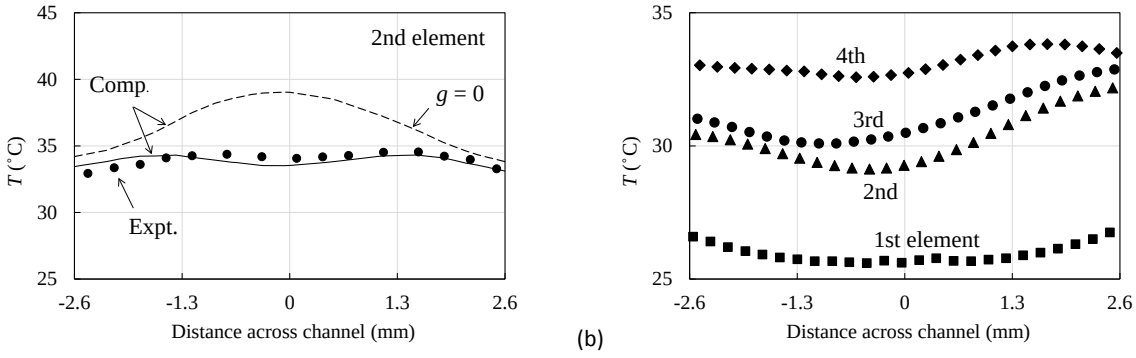

Figure 2. Temperature along wire path (a) in Element 2 for water flow with heating and (b) reaction of 0.35 M sodium chlorite and 0.10 M potassium tetrathionate with 0.002 M sodium hydroxide.

1. Introduction

The use of wood-based products in Europe is projected to increase threefold worldwide between 2010 and 2050. The need for innovative products from fewer resources to help reducing pressure on forests is attracting the attention of scientific community to provide a value-added use of wood-based products after their traditional service life. In this sense, cascading of wood is an efficient use of these resources from the point of view of natural resource higher value uses that allow the reuse and recycling of products and raw materials. In this work, heat-treated wood (*Pinus radiata* L., 212 ºC) after one year of weathering exposure was subjected to a multi-stage lignocellulosic fractioning following the cascading and the biorefinery principles. This fractioning allowed the obtaining of hemicelluloses and lignin as chemical precursors, which were analyzed in their yield and quality. To determine the quality of the obtained products, the same fractioning was done to natural wood and heat-treated wood with no weathering exposure, as well as the natural wood after being exposed to the same conditions.

2. Methods

Monterey pine (Pinus radiata D. Don) was harvested from the forest areas of the Basque Country (Spain) was debarked, sawed, stored and conditioned before the heat-treatment. Pine boards were thermally modified according to industrial production standards a heat-treatment chamber with steam presence and under inert N_2 atmosphere [1]. Monterrey pine samples (natural and thermally modified) were exposed to natural weather [2].

Organosolv process was conducted using a mixture of ethanol/water (65:35 v/v) as white liquor, at 200 ºC during 90 min and a fiber to liquid ratio of 1:10 (w/v) 0.05M MgSO4 was used as catalyst. Liquid fraction was separated via filtration and the solid fraction was washed several times until driving the remaining fibers to a neutral pH level. Lignin (L1) was precipitated by adding 2 volumes

of acidified water (pH 2), after which solid fraction was filtered with a 0.22 µm membrane. Filtrate was concentrated and then added to 4 volumes of ethanol and kept at 3 ºC during 24 h, precipitated solid (H2) was separated by centrifugation.

A Totally Chlorine Free Bleaching (TCF) sequence was selected, which was based on two alkaline oxygen stages, (E_O), one peroxide stage (P) with secondary chelating reaction (P_{OQ}) and an alkaline peroxide stage under oxygen atmosphere (P_O). Lignin was precipitated from the first liquor (L2) by acidifying them dropwise until pH ~2.

3. Results and discussion

Lignin yields showed a higher recovery of lignin during Organosolv process (Table 1) especially in the case of pine, either weathered or not. I In case of lignin from P extracted during organosolv, it can be seen that Pw has a lower recovery (~16% less) regarding the original mass. Organosolv lignin from thermotreated wood showed lower yields than that of normal pinewood in absolute values. Table 1 also presents the content of acid insoluble lignin (AIL), acid soluble lignin (ASL), carbohydrates, ashes, molecular weight (Mw) and polydispersity index (Mw Mn^{-1}).

Table 1. main purity indicators of the recovered lignins.

		Yield [%]	AIL [%]	ASL [%]	Carbohydrates [%]	Ashes [%]	Mw [g mol^{-1}]	Mw Mn^{-1}
Po	L1	17.92	93.37	0.88	1.84	1.13	5534	4.43
	L2	8.67	83.34	1.46	3.01	1.15	2772	2.94
Pw	L1	15.03	93.89	0.53	1.83	0.29	7401	5.32
	L2	5.29	93.05	1.20	4.44	0.65	10049	8.68
To	L1	8.54	93.36	0.74	1.73	0.51	1453	2.36
	L2	9.06	92.82	1.08	5.27	1.06	3477	4.16
Tw	L1	9.80	94.62	0.95	2.58	0.25	4307	3.71
	L2	7.14	89.92	1.29	6.11	0.49	3465	3.88

4. Conclusions

The recovery of lignin from Organosolv treatment and mild-alkaline bleaching sequence resulted in very different technical lignins, with different possible applications.

Highlights

- Noble metal-based catalysts with different acidities are employed
- Acidity plays a key role in the second stage of the LCO upgrading
- Lifespan of equilibrated FCC catalysts is extended

1. Introduction

Nowadays the oil market is especially volatile, thus the refining industry is working hard to find the most optimum way to process the heavier and sourer crude while maintaining its economics and profitability together with meeting the growing demand of high-quality fuels [1]. With the aim of intensifying the oil valorization, high efforts are being done to adapt the already installed and amortized units for the processing of non-conventional feedstocks, such as LCO. Considering the units available in the refineries, the best perspectives are focused on the usage of hydroprocessing units due to their multiple advantages [2]. Moreover, hydroprocessing in two stages, a first stage of hydrotreating (HT) with transition metal-based catalysts and a second stage of hydrocracking (HC) with noble metal-based catalysts, has proved to be a very suitable way of upgrading these streams [3]. In this work, the possibilities of using equilibrated FCC catalysts as support for catalysts used in the second hydrocracking stage of LCO valorization has been studied, extending, in this way, the life cycle of one of the highly produced residua of the refineries.

2. Methods

The feedstock consists of a previously hydrotreated light cycle oil (LCO_{HT}). Two in-house prepared catalyst have been used: (i) Pt-Pd/HY and (ii) Pt-Pd/HY-Al_2O_3, with the same Pt-Pd metal loading (0.5-0.5 wt%) and using as supports a HY ultra-stable zeolite (SiO_2/Al_2O_3 = 12) and an equilibrated commercial FCC catalyst (HY- Al_2O_3), respectively. In this work, apart from these two catalysts a physical mixture of them (50 wt%) has been employed, also. A deep characterization of the catalysts have been done [3]. Hydrocracking runs have been carried out in a down-flow fixed bed reactor in the following conditions: 400 °C; 65 bar; H_2/LCO_{HT} ratio, 1000 NmL_{H2} mL_{LCO}^{-1}; space velocity (WHSV), 0.21 h^{-1}; time on stream (TOS), 8 h. Products have been analyzed by chromatographic means.

3. Results and discussion

In the studied process, all the catalysts, before reaching a pseudo-equilibrium state, show an initial fast deactivation period as a consequence of both coke deposition and the stabilization of the metallic phases [4]. The length of this initial period has varied depending on the catalyst employed: the Pt-Pd/HY catalyst reached it after 2 h, whereas both Pt-Pd/HY-Al_2O_3 catalyst and the physical mixture of catalysts needed c.a. 4 h. Since the metallic phase is the same for the three catalysts, the coke formation rate seems to be related to the properties of the support, i.e., acidity and porous structure. Besides, as it has been widely demonstrated, the acidity of the catalyst is a key factor controlling the hydrocracking activity and selectivity of noble metal-based catalysts in the hydrocracking of secondary streams [5]. Figure 1 depicts the dependence between the hydrocracking (HC) and hydrodearomatization (HDA) conversions and the acidity of the catalyst employed. This way, the HC activity of the catalysts is linearly dependent of their acidity in the pseudo-stationary state, reaching for acidities higher than 0.16 $mmol_{NH3}$ g^{-1} total conversions at zero time of reaction. On the other hand, the HDA activity has not clear acidity dependence, so, for this route, porous structure appears to be a key factor. One more time, at zero time of reaction values of 100 % of HDA conversion are achieved. Comparing the performance of the different catalysts, the intermediate behavior of the physical mixture offers promising results, as the products stream is composed of c.a. 50 wt% of naphtha and diesel fractions with high HDA and HC activities. This fact reveals that adding a high acidity catalyst to the spent FCC catalyst is a good way of improving the behavior of the discarded FCC support and extending its lifespan.

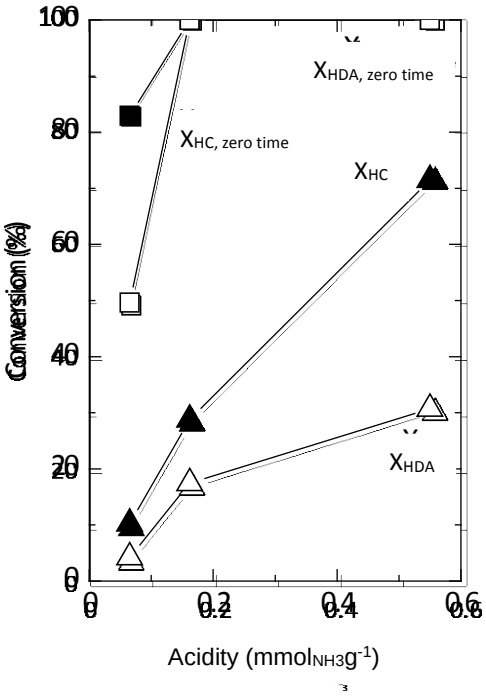

Figure 1. Dependence between the hydrodearomatization (HDA) and the hydrocracking (HC) conversions with the acidity of the catalysts.

4. Conclusions

Using the spent FCC catalyst mixed with a high acidic fresh catalyst in the second stage of hydrotreatment of LCO is a good way of extending the life cycle of highly produced residua of the refineries. The addition of this highly acidic catalyst leads to an enhancement of the acidity, which is the key factor controlling the hydrocracking activity and selectivity, producing a stream with a good quantity of naphtha and diesel. Besides, the hydrodearomatization activity, controlled also by other physical properties of the catalyst like pore volume, is improved.

CO_2-Reforming for production of CO rich synthesis gas at low steam to carbon ratio in industrial scale

Kim Aasberg-Petersen*, Peter Mølgaard Mortensen, Marené Rautenbach, Peter Seier Christensen

1: Haldor Topsøe A/S, Haldor Topsøes Allé 1, DK-2800 Lyngby, Denmark

**Corresponding author: kap@topsoe.com*

Highlights

- New process for CO_2-reforming
- Uses traditional Nickel catalysts
- Reduces size of steam reformer
- Almost any H_2/CO-ratio can be produced

1. Introduction

Many bulk chemicals such as methanol are produced in a multiple step process. The first step is normally conversion of natural gas or similar feedstock to produce hydrogen or synthesis gas (a mixture with mainly hydrogen and carbon monoxide) followed by the actual synthesis and purification. The synthesis gas production is often carried out by steam reforming of the feedstock with steam and carbon dioxide (in the following referred to as CO_2-reforming). Carbon dioxide reforming is an environmentally interesting process as it in theory offers a way of using CO_2, which in many industries is considered as a waste product and is a polluting greenhouse gas. Overall, CO_2-reforming is one of few chemical processes which can be designed with an overall negative CO_2-emission, as the process can be designed to utilize more CO_2 than what is produced from the process. The process could therefore play an important role in combination with CO_2 capture technologies, which are receiving much attention currently.

CO will make up a significant fraction of the produced synthesis gas when CO_2 is imported to the plant. Depending upon the process and amount of imported CO_2, synthesis gas with H_2/CO ratios in the range from 0.5-3 can be produced. Large amounts of CO are used within the chemical industry for example for production of higher alcohols, synthetic fuels, or acetic acid. There are also needs for carbon monoxide in especially the polymer industry in production of polycarbonates and polyurethane, among others.

A key challenge in the development of CO_2-reforming is to define (economical) operating conditions in combination with a suitable catalyst to avoid carbon formation. Carbon formation in a steam reformer is largely dictated by thermodynamics. In Fig. 1 the carbon limits are illustrated for various feed feed compositions with methane, steam, and CO_2. In the typical design of a reformer, it is a requirement that there is no affinity for carbon formation anywhere in the catalyst bed. This means that a sufficient amount of steam must be added to the process feed gas to avoid potential for carbon formation. In the case of the classical fired reformer, the process gas may enter the reformer at 450-600°C while leaving the reformer at an average temperature often

in the range 850-950°C. Hence, when designing a steam reformer, there must not be an affinity for carbon formation anywhere between 400°C and ca. 1000°C.

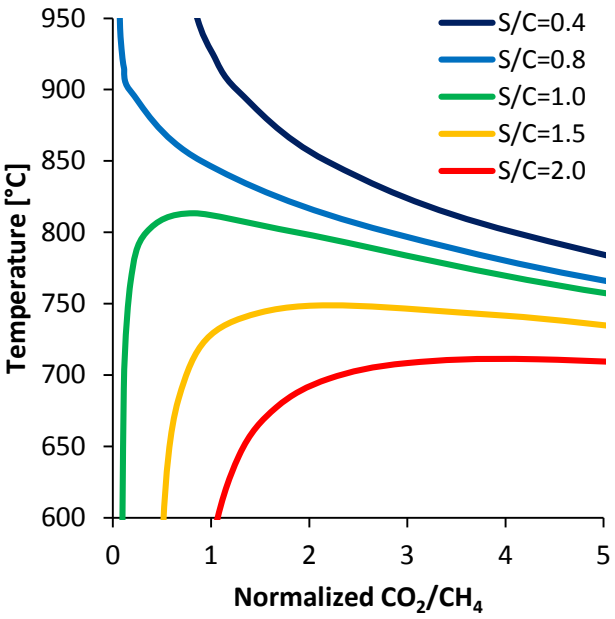

Fig. 1: Thermodynamic evaluation of carbon limit as a function of normalized H_2O/CH_4 (S/C), CO_2/CH_4, and temperature. A point placed below a curve in the graph will have a potential for carbon formation

In most cases, Nickel-based catalysts are used in a steam reformer. Nickel is relatively cheap compared to the alternative noble metals based catalyst. On the other hand, noble metals based catalysts have a lower affinity for carbon formation and a higher activity for steam and CO_2-reforming. However, very high raw material prices of these material makes them unattractive for extensive use in industrial scale. Consequently, nickel based catalyst are established as the preferred catalyst for industrial use for CO_2-reforming although the needed steam to avoid carbon formation is excessive compared to optimal design. This makes the process plants relatively expensive and there is an incentive to develop an improved concept still allowing for use of Nickel based catalysts.

2. New high temperature reactor for CO production

In the current work, a new reactor configuration is presented where hot CO_2 is added directly downstream a reformer and equilibrated in an adiabatic reactor. One possible configuration is illustrated in Fig. 2. This concept utilizes the high temperature of the reformer product gas and detailed understanding of the underlying thermodynamic and kinetic mechanisms to circumvent the carbon formation area. This allow for a method to tailor the product toward practically any H_2/CO ratio without the risk of carbon formation, while still using a cost-efficient nickel based catalyst. The adiabatic reactor may in principle be added downstream any reformer type and be used both for grassroot and revamp cases. Experiments have been carried out to demonstrate carbon free operation with the new reactor concept at significantly lower steam-to-carbon ratios than is possible with stand-alone CO_2-reforming. In Fig. 3 the gas composition profiles in the adiabatic reactor are provided illustrating significant conversion of CO_2 to CO and the resultant low H_2/CO-ratio in the product gas.

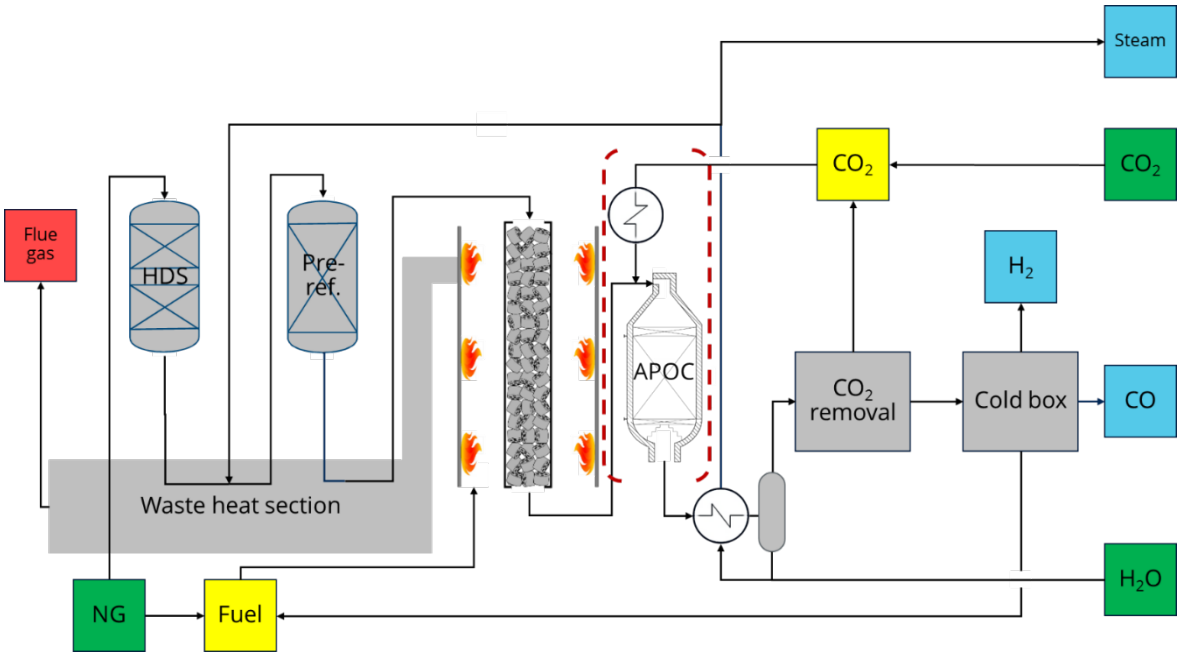

Fig. 2: Process concept with new technology utilizing an adiabatic reactor (APOC) downstream the steam reformer in a plant for producing CO and H_2.

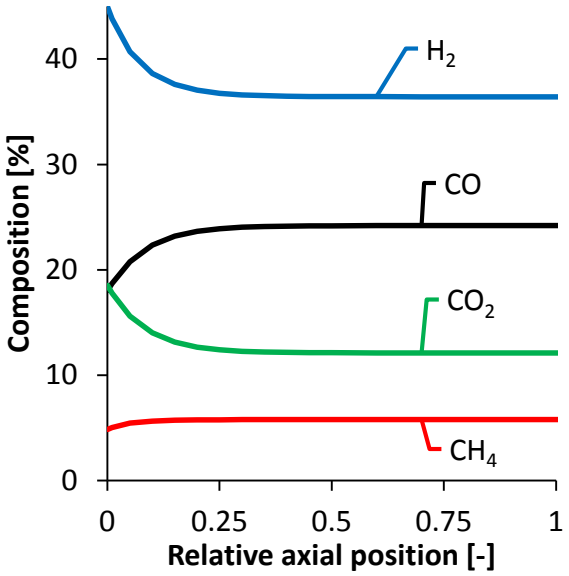

Fig. 3: Gas composition profiles in the adiabatic reactor (APOC) downstream the steam reformer

A series of process economic calculations have been carried out to illustrate the benefits of the new technology. Selected results include:

- The size of a steam reformer can be reduced by up to ca. 25%. Alternatively, the plant capacity can be boosted accordingly.

- The carbon for the CO product originates to a large extent from the CO_2 in the feed and the plant consequently has a large net use of CO_2.
- Practically any H_2/CO ratio can be supplied in the product synthesis gas.

3. Conclusion

In conclusion, the new high temperature CO production reactor is a promising technology for producing synthesis gas with a high content of CO at a low steam to carbon ratio. The technology can for example be used to retro-fit an existing production towards more CO production or included in new projects. In the presentation, the new technology will be described and the benefits will be illustrated with specific examples.

Superior performances of Fe-FER compare to Fe-ZSM5 in NO_x and N_2O abatements for Nitric acid plant

Michele Corbetta[1], Alberto Garbujo[1*], Roberto Lanza[2], Emmanuel Rohart[3], Arnaud Lahougue[3], Grégoire Gaudry[2], Raffaele Ostuni[1], Pierdomenico Biasi[1].

1 Casale SA, Lugano, Switzerland; 2 Verdant, Stockholm, Sweden; 3 Alsys, Ploemeur, France.
**Corresponding author: a.garbujo@casale.ch*

Highlights

- Fe-FER, CASALE and ALSYS catalyst, shows better catalytic activity then Fe-ZSM5.
- Fe-FER, CASALE and ALSYS catalyst, has lower deactivation than Fe-ZSM5 under aging treatment.
- The results obtained point out the Fe-FER as the best industrial solution for Nitric acid plant.

1. Introduction

Nitric acid is one of the most produced commodity worldwide. It is mainly used as a strategical chemical for the synthesis of fertilizers and in 2013 the production reached 78 million tons[1] [2]. In recent years, the higher awareness in the greenhouse effect and in the environmental pollution, have highlighted the importance of a new development in the nitric acid tail gas treatment, especially concerning the N_2O and NO_x species [1]. Many metal oxide and zeolite catalysts have been developed for N_2O and NO_x abetment, each one with benefits and drawbacks. The state of the art materials are based on Fe-zeolites which both show NO_x and N_2O abatement with the same catalyst. Many Fe zeolites have been explored, such as Ferrierite (FER), ZSM5 and BEA [3].

In this paper, the comparison of fresh and laboratory aged Fe-FER and Fe-ZSM5 industrial catalysts, both supplied by ALSYS, has been carried out. Fe-FER catalyst is a proprietary catalyst of CASALE and ALSYS and is used in nitric acid plants [4]. The results from field and laboratory showed that Fe-FER will allow customers to benefit from a higher catalytic activity and greater stability compare to the current commercial solution with Fe-ZSM5.

2. Methods

The extruded catalysts tested were prepared at industrial scale, from process production to quantity scale, by ALSYS. The catalytic tests were carried out in an Inconel reactor under industrial nitric acid plant conditions. The feed compositions are reported in figure 1 caption. The GHSV used was 25,000 h^{-1}. Very high space velocity was chosen with the purpose to highlight the differences in catalytic activity among the catalysts tested. The hydrothermal aging treatment was performed for 150h at ambient pressure at two temperatures (600 and 700°C) with a feed of 12% of O_2 and 6% of H_2O with a GHSV of 5000 h^{-1}. The detector used was FT-IR coupled with a lambda probe for oxygen measurement.

3. Results and discussion

Fe-FER and Fe-ZSM5 extruded catalysts have been subjected to a simulated aging procedure to investigate the catalytic behavior under stressed condition. The catalysts show a uniform cylindrical shape with a diameter close to 2 mm (with typical composition and shape of industrial catalyst). The catalytic tests were performed under relevant industrial deN_2O and deNO_x reaction conditions. The results (figure 1) display the higher catalytic activity of Fe-FER compared to Fe-ZSM5. The superior Fe-FER catalytic activity becomes particularly significant after the aging procedure where a different catalytic behavior is observed. Fe-FER, slightly decreased its activity, after the aging treatment, while the Fe-ZSM5 dramatically dropped its performances. In addition, N_2O formation is detected under deNO_x condition for Fe-ZSM5, while the Fe-FER does not exhibit any N_2O formation. The characterizations performed revealed that the reduced activity of Fe-ZSM5 compared to the Fe-FER is due to the Fe species present in the catalyst.

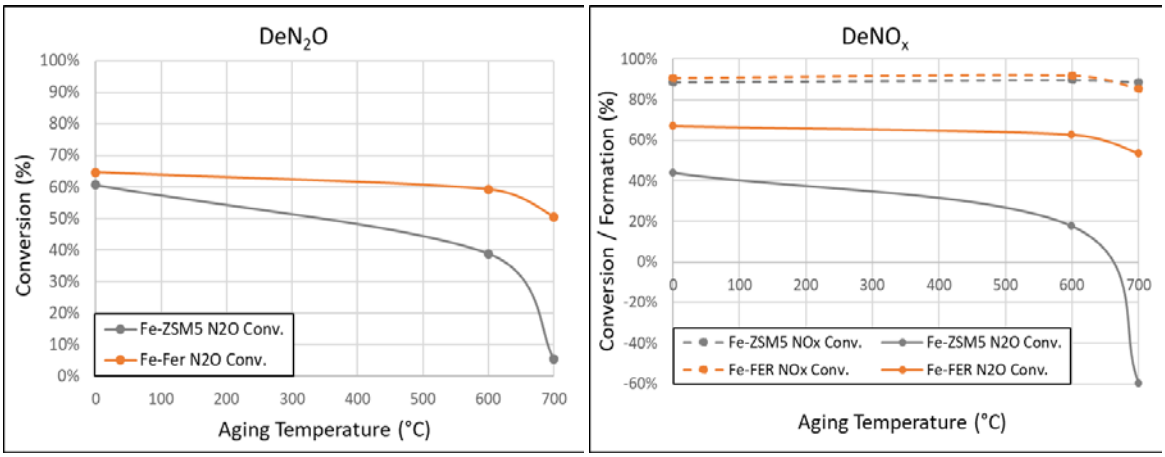

Figure 1. (Left) deN_2O condition: NO 70 ppm, NO_2 30 ppm, N_2O 900 ppm, O_2 3.0%, H_2O 0.3% and N_2 balance. (Right) deNO_x condition: NO 325 ppm, NO_2 325 ppm N_2O 40 ppm NH_3 650 ppm, O_2 3.0%, H_2O 0.3% and N_2 balance.

4. Conclusions

In this work, representative industrial catalysts were investigated in industrial conditions before and after severe aging treatments. Results showed that Fe-FER is the most stable catalyst and high performance that can be used for tail gas treatment in nitric acid plants. Moreover Fe-FER is extremely selective in N_2 even after severe aging while the Fe-ZSM5 exhibited a larger undesired N_2O formation. The Fe-FER catalyst for deN_2O and deNO_x applications has superior performances compared to the Fe-ZSM5.

Highlights

- 2D simplified dynamic system has been analytically resolved.
- 3D analysis has been developed in Comsol Multiphysics environment.

1. Introduction

Gasification is a well-known thermal conversion process, which in recent years has been applied to convert renewable feedstock such as biomass and waste. More specifically, gasification of Refuse Derived Fuel (RDF) in a high temperature melting gasifier has been employed for energy production, and applications for chemical production have been extensively studied [1-2]. Compared with biomass gasification, gasification of RDF faces several issues related to its intrinsic heterogeneity, such as the non-homogenous structure of the bed reactor, which entails a more significant solid particles release in the freeboard zone compared to the predictable occurrence. Once released, solid particles could be entrained with the gas flow or deposit on reactor wall producing crusts, as experimentally observed. This peculiar release of solid particle can be related to the occurrence of complex dynamic phenomena in the bed, for which solid particles could be released with an initial velocity higher than that of the gas [3]. In this work we introduce a discussion regarding conditions which may cause particle entrainment of deposition. The analysis has been developed in two steps: - a preliminary study to identify the conditions of entrainment of particles released with an initial velocity v_p^0 in a cylindrical gasifier, where gas moves upwards with a velocity v_g; - a more detailed model of particle behavior with the geometry and operating conditions of an industrial gasifier developed using Comsol Multiphysics.

2. Methods

2.1 Preliminary study

In order to gain some preliminary knowledge about the entrainment of solid particles ejected from the bed with an initial velocity, v_p^0, we firstly consider a very simple 2D model of a cylindrical gasifier, with a 3.4m diameter and 14 m height over the solid bed, working with a gas flow rate of 12.000 Nm^3 (see Fig.1-a). Two limit conditions have been considered based on the values of: particle diameter, d_p, density, ρ_p, and initial velocity, v_p^0. The first one is defined with reference to the terminal particle velocity, v_p^t: particles with $v_p^t > 0$ are always entrained by the gas and flow outside

the reactor; while, the destination of particles with $v_p^t < 0$ depends on dynamics. Thus, a second limit condition has been considered: for each pair of values (ρ_p, d_p) there exists an initial value of particle velocity, $v_p^{0,l}$, for which particles arrive at the top of the reactor with velocity equal to 0.

2.2 3D simulation

A more rigorous analysis accounting for the true reactor geometry and velocity field requires 3D simulation (see fig.1-b) for which Comsol Multiphysics has been used. A one-way approach has been followed: first the fluid dynamic of the syngas inside the reactor has been resolved, then the particle tracking module has been applied for particle dynamics. Interactions between particle and surfaces of the domain are described by sticky boundary condition.

3. Results and discussion

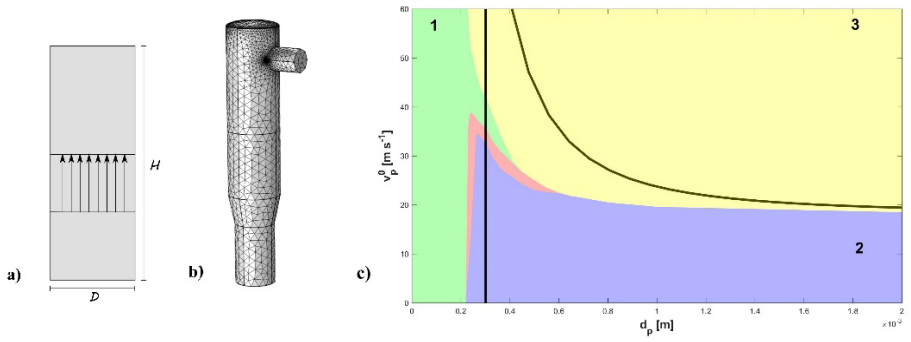

Figure 1. a) and b) Simulation domain, respectively, 2D and 3D; c) Comprehensive results representation (see text).

The analytical results show that particle density plays a less significant role compared to other parameters, so in what follows a mean particle density of 1500 kg m^{-3} has been considered.
With the analytically defined limiting conditions different particle behaviors can be recognized as a function of particle parameters (d_p , v_p^0). In fig.1-c black lines distinguish three characteristic zones resulting from the preliminary analysis. The one on the left (1) represents particles (v_p^t>0) entrained and flowing out with the gas; on the right side (v_p^t<0), the zone below the black curve (2) represents particles falling back on the bed, while the zone above (3) represents particles whose destination is strictly related to reactor geometry. Considering all the simplifying assumptions made, the preliminary results show good agreement with those from the 3D simulation, represented by the colored areas depicted in fig.1-c. Indeed, green and violet areas represent particles with the same behavior, respectively, to those in zones (1) and (2). Further distinctions can be made for other particles, which can stick on the upper (yellow) and lateral (pink) walls of the reactor.

4. Conclusions

Comparison of the results with experimental surveys from industrial gasifier can allow an assessment of the magnitude of particle “ejection” and provide a strategy for the reduction of particle entrainment and crusts formation.

Liquid-phase synthesis of *sec*-butyl levulinate by esterification of levulinic acid with 1-butene over Amberlyst-15

J.H. Badia, E. Ramírez*, R. Bringué, C. Fité, M. Iborra, J. Tejero, F. Cunill

Highlights

- Esterification of levulinic acid with 1-butene over Amberlyst-15 is technically feasible
- The proposed reaction pathway entails very low byproducts formation
- High temperature and excess of levulinic acid gives high yield of sec-butyl levulinate
- Amberlyst-15 is a promising catalyst for the *sec*-butyl levulinate production

1. Introduction

Liquid-phase synthesis of *sec*-butyl levulinate (SBL) by esterification reaction of levulinic acid with 1-butene over an acidic ion-exchange resin (Amberlyst 15) has been studied in a batch reactor. The use of SBL in transportation fuels formulation is of interest due to some of its properties, which make SBL a potential candidate for blending in both diesel and gasoline fuels. For instance, when blended in diesel, butyl levulinates reduce vapor pressure and improve the lubricity, conductivity, and cold flow properties of the fuel, which leads to cleaner combustion, and are completely soluble below the diesel cloud point (around −25.8 °C) [1]. However, levulinates exhibit low cetane numbers, which entails that their inclusion in diesel formulation requires additional cetane-enhancing additives. With respect to gasoline, high blending octane quality is achieved by adding butyl levulinates. For instance, blending values of RON and MON of 107 and 98, respectively, have been reported for 10 %vol. addition of SBL [2].

On the other hand, since levulinates are synthesized from levulinic acid (LA), which is a non-edible lignocellulose derivative, SBL can contribute in achieving the biofuel target in current EU legislation, which sets a minimum 10 %vol. of biomass-based oxygenates to improve fuel automobile quality by 2020 [3].

Conventional production of butyl levulinates is achieved by: 1) esterification of LA with butanol, 2) furfuryl alcohol-butanol alcoholysis, and 3) direct butanolysis of saccharides or polysaccharides; all of which are acid-catalyzed reactions. In most cases, ester formation is limited due to side reactions responsible for the formation of, for instance, dialkylether, water and polymerization products. Alternative pathway synthesis for butyl levulinates involves replacing the alcohol for an olefin as the esterification agent, which poses lower byproducts formation than conventional pathways. In addition, residual refinery streams containing “spent” C4 compounds, which are usually regarded as low-value streams, can be re-valorized by using them as the olefin source, taking advantage of the fact that these streams are usually rich in linear butenes, butane, and isobutane.

Therefore, and given the scarce number of literature references on the proposed synthesis reaction using ion-exchange resins as catalysts, the present work is aimed at determining the optimal reaction conditions for the batch-mode liquid-phase synthesis of *sec*-butyl levulinate over Amberlyst-15, in terms of temperature and initial reactants concentration.

2. Methods

Reactants were LA (>98 %wt., Across Organic) and 1-butene (>99.9 %GC, Air Liquide). Amberlyst-15 (The Dow Chemical Company) was used as the acidic ion-exchange resin catalyst (acid capacity of 4.81 meq H^+/g, BET surface area of 42.1 m^2/g, BET pore volume of 0.328 cm^3/g, and maximum operating temperature of 393 K).

Experiments were performed following a two-factor face-centered experimental design in which temperature ranged from 323 to 373 K and initial AL to olefin molar ratio was varied between 0.5 and 2.0. The catalyst load was set at 5 g (about 3 %wt.). All experiments were carried out in a 200 cm^3 stirred-tank reactor equipped with a six-blade magnetic stirrer operated in batch mode. The pressure was set at 2.5 MPa by means of N_2. Samples were taken in-line at different reaction times and analyzed by GC-MS using a capillary column (HP-PONA 19091S-001, J&W Scientific; 100% dimethylpoly-siloxane, 50m×0.20mm×0.50 µm). The typical duration for every experimental run was of 5 h, at least.

3. Results and discussion

Almost complete conversion of 1-butene was achieved in all of the experiments, whereas some LA remained unreacted at the end of the runs. In fact, 1-butene readily isomerizes to *cis*- and *trans*-2-butenes, which in turn react with LA to give the corresponding ester, SBL. Results showed only minimal side reactions extension regardless of the assayed experimental conditions, being the sum of all formed byproducts, mainly 2-butanol and olefin dimers, always below 5 %GC. Table 1 lists main results in terms of yield towards SBL from 1-butene. As seen in the table, higher yield is achieved at high temperature and high initial molar ratio.

Table 1. Yield (Y) of SBL from 1-butene.

***T* (K)**	***R*°$_{A/O}$**	Y [a] **(%)**
323	0.5	21
323	2.0	54 ± 6
373	0.5	88
373	2.0	98
348	1.0	89

[a] Yield calculation is based on GC areas.

4. Conclusions

The feasibility of the proposed chemical reaction pathway is strongly supported by the low amount of formed byproducts, which is the main drawback of conventional synthesis of butyl levulinates. The highest assayed temperature (373 K) and an excess of levulinic acid in the reactants mixture favors the formation of the desired product. Amberlyst-15 is a promising catalyst for the proposed reaction, since it allows high conversions at relatively low temperature while being an inexpensive catalyst.

Calcium looping for thermochemical energy storage: Kinetic modeling of limestone calcination

Athanasios Scaltsoyiannes[1], Andy Antzara[1], Tom Hills[2], Mark Sceats[2], Angeliki Lemonidou*[1]

[1] Department of Chemical Engineering, Aristotle University of Thessaloniki, University Campus, Thessaloniki, GR-54124, Greece; [2] Calix Europe Limited, Old Library Chambers, 21 Chipper Lane, Salisbury, SP1 1BG, UK

*Corresponding author: alemonidou@cheng.auth.gr

Highlights

- Kinetic experiments of calcination in a fixed-bed reactor.
- Calcination completed in less than 15 sec under conditions tested.
- A modified RPM (GRPM) describes adequately the reaction.

1. Introduction

Thermochemical energy storage (TCES) is of growing interest especially for concentrated solar power plants (CSP). The current technology is based on storage of sensible thermal energy using molten salts which "suffer" from short period storage, crystallization at temperatures lower than 200°C and degradation at temperatures higher than 550°C. A promising alternative is the calcium looping (CaL) due to the highly exothermic carbonation reaction and the higher operating temperatures (~850°C). Other advantages are the non-toxicity and availability of raw materials (e.g. limestone) and their capability to be stored for long periods at ambient conditions.

$$CaO + CO_2 \leftrightarrow CaCO_3 \qquad \Delta H = -178\ kJ/mol$$

Accordingly, the solar energy can drive the endothermic reaction in a calciner reactor while the reverse carbonation reaction will produce energy via a power cycle (e.g. Rankine cycle). The reaction kinetics is of great importance as it affects the overall efficiency of the process.
This work focuses on the kinetic measurements and modeling of the calcination reaction as well as on the deactivation evolution of limestone through the cycles. A fixed bed reactor flow unit was used for the experiments in order to achieve efficient gas-solid contact and eliminate the control by external transfer phenomena. A two stage mechanism was adopted for the kinetic modeling [1]. For comparison, two different models were used, namely a Prout Tompkins equation and a Generalized Random Pore Model (GRPM), which is a modified version of the RPM described by Gavalas [1, 2].The evolution of the deactivation through cycling was described with existing models [3].

2. Methods

The evaluation of reaction kinetics of the samples was performed in a bench scale laboratory unit operating near atmospheric pressure. The unit consists of the gas feed inlet section, a fixed bed quartz reactor (10mm ID) and a mass spectrometer (Omnistar TM GSD 320, PFEIFFER)). The material used was a limestone (Granicarb 0.1/0.8 provided by OMYA) with a particle size of 45-75μm. The tests were conducted using superficial velocity >12 cm/s to avoid the influence of mass

transfer to the observed rates. For the calcination kinetic experiment the sample was calcined under 20% CO_2/N_2 (GHSV=22500h^{-1}, P=1.5atm, T=950°C). The multicycle experiment (10 cycles, cycle time duration: 6min) for the deactivation assessment comprised carbonation under pure CO_2 flow (27000h^{-1}, P=1.7atm, T=890°C) and calcination under 20% CO_2 in N_2 (GHSV=22500h^{-1}, P=1.5atm, T=890°C).

3. Results and discussion

Figure 1 (A) presents the evolution of calcination expressed as a function of time. The calcination of limestone is very fast at 950°C and is completed in 15sec. Almost 80% of the conversion is achieved in less than 7sec. The two models provide good fitting to the experimental data obtained from a fixed bed reactor apparatus. The GRPM describes better the calcination reaction compared to the P-TM especially for low conversions. It is based on the evolution of the available surface area, so it is more realistic compared to the P-TM, which is a symmetrical sigmoidal curve. For both models the pre-exponential factor k_0 was the fitted parameter (GRPM: k_0=0.41m/s, P-TM: k_0=4.69 $10^9 s^{-1}$). Due to intense sintering, the multicycle performance deteriorates as the material loses 65% of initial capacity after 10 cycles (B). The deactivation was adequately described with a semi-empirical equation with a deactivation constant of k_d=0.48.

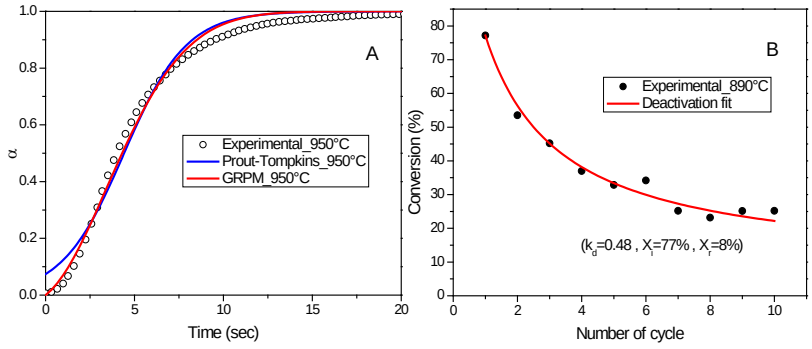

Figure 1. Calcination of limestone at 950°C along with P-TM and GRPM curves (A); Deactivation evolution of limestone through 10 cycles and modeling (B).

4. Conclusions

Calcination reaction as well as deactivation of limestone were studied experimentally in a fixed bed reactor unit and kinetically modeled. Two models were used for describing the experimental data. The GRPM better fits to the results compared to the P-TM. Calcination under the studied conditions is completed in a few seconds, rendering limestone appropriate as a solid heat carrier for CSP-TCES applications.

Design of the metal oxide catalysts for highly efficient and low temperature oxidation of VOCs

Marina Duplančić[1], Vesna Tomašić[1], Stanislav Kurajica[1], Zoran Gomzi[1], Albin Pintar[2]

1 University of Zagreb, Faculty of Chemical Engineering and Technology, Marulićev trg 19, Zagreb, Croatia;

2 National Institute of Chemistry, Department for Environmental Sciences and Engineering, Hajdrihova 19, Ljubljana, Slovenia

**marina.duplancic@fkit.hr*

Highlights

- Low temperature oxidation of VOCs.
- Mixed manganese and copper oxide catalyst.
- Fixed bed reactor *vs.* metal monolith reactor.
- Toluene as a model VOC component.

1. Introduction

The quality of the air and thus the quality of life is greatly affected by excessive emissions of volatile organic compounds (VOCs) which are recognized as the major contributors to global air pollution [1]. VOCs are emitted from different industrial plants and motor vehicles. Process intensification methodology, which most often involves the integration of catalytic and adsorption processes, and the development and application of structured catalysts, in particular monolith reactors, was used to develop highly efficient monolith reactors for low temperature oxidation of VOCs. The aim was to develop a metal monolith catalyst/reactor for catalytic oxidation of toluene as a representative volatile organic compound. Toluene was chosen as a model component because it is used in various industries (such as the automotive and pharmaceutical industries), and is often emitted in the environment as a result of the production and use of organic chemicals, solvents, dyes and similar products.

2. Methods

Mixed manganese and copper oxide in powder form ($MnCuO_x$) was prepared by the co-precipitation method [2]. Detailed characterization included the nitrogen adsorption-desorption analysis (BET), scanning electron microscopy (SEM), X-ray diffraction (XRD) analysis, differential scanning calorimetry (DSC) and Fourier Transform Infrared Spectroscopy (FTIR). Catalytic properties of the prepared catalyst were tested in a fixed bed reactor for toluene oxidation at various working conditions (temperature, reaction mixture flow rate).

Preparation of metal monolith catalysts/reactors included deposition of stabile catalytically active layer of $MnCuO_x$ on the surface of the corrugated metal monolith support (Al). In order to prepare metal monolith structure for a stable catalytic layer deposition, two-sided anodization of aluminum tiles was used. Catalytically active layer composed of manganese and copper oxides was

washcoated onto the metal monolith support (Al/Al_2O_3) [2]. The influence of working conditions, such as temperature and reaction mixture flow rate was tested.

Appropriate kinetic and reactor models for both, fixed bed and monolith reactor, were proposed and tested.

3. Results and discussion

The BET analysis showed textural properties of the prepared mixed oxide catalyst. With specific surface area of 23.7 $m^2 g^{-1}$, total pore volume of 0.10 $cm^3 g^{-1}$ and the average pore diameter of 16.5 nm the obtained catalyst can be classified as a mesoporous material, according to the IUPAC standards. The morphology of the $MnCuO_x$ oxide catalyst in powder form was further checked by the scanning electron microscopy (SEM) and it can be seen that the surface of the powder catalyst consists mostly of the spherical clusters with typical dimensions of about 1 micron. X-ray diffraction (XRD) of the powder $MnCuO_x$ mixed oxide identified four phases CuO, $CuMnO_4$, MnO_2 and Mn_2O_3. Differential scanning calorimetry over a wide range of temperatures (298-823 K) was used to investigate the thermal properties of $MnCuO_x$ mixed oxides it was found that in the temperature range from 523 K to ca. 655 K $MnCuO_x$ catalyst changes its crystalline structure which is accompanied by the release of energy of -209 J g^{-1}. In line with these observations before testing the catalyst activity for toluene oxidation the catalyst was pre-treated (calcined) at the temperature of 523 K for 2 h and then for 3 h at the temperature of 773 K. The DCS curve after pre-treatment shows no structural changes in the observed temperature range indicating that the catalyst obtained after pre-treatment is structurally stable in this temperature range and as such suitable for catalytic experiments. FTIR analysis confirmed that during the toluene oxidation over $MnCuO_x$ oxide catalyst there was no significant adsorption of possible reaction intermediates or reactants on the surface of the catalyst. Specific T_{90} values (90% toluene conversion) for powder $MnCuO_x$ vary from 431 to 480 K depending on the reaction mixture flow rate and T_{90} values for monolith catalysts, Al/Al_2O_3-$MnCuO_x$ are even lower, from 432 to 468 K depending on the reaction mixture flow rate.

4. Conclusions

Toluene oxidation over manganese and copper mixed oxide catalyst in powder and monolith form was studied. The high specific surface area, mesoporous structure along with high catalytic activity at relatively low temperatures demonstrates that this catalyst is suitable for the catalytic oxidation of toluene at different operation conditions.

The prepared powder $MnCuO_x$ and monolith Al/Al_2O_3-$MnCuO_x$ catalysts show extremely high activity for the toluene oxidation. It is particularly important to point out that the observed high conversions of toluene are achieved at relatively low temperatures (< 432 K) depending on the reaction mixture flow rate, which is important for the practical application of the catalyst in real systems. Applied mathematical models give satisfactory results for the oxidation of toluene in the experimental system described in this work.

Reactor concept for continuous milli-reactors

Marlies Moser, Esteban Rosasco, Norbert Merkel, Alain Georg

Fluitec mixing + reaction solutions AG, Seuzachstrasse 40, 8413 Neftenbach, Switzerland

**Corresponding author: mm@fluitec.ch*

Highlights

- Scale-up of exothermic reactions up to 2500 – 4300 t y^{-1}.
- Concept for a safe reactor design.
- Countercurrent safety purge system.
- Control system with a standard operating manual.

1. Introduction

Flow Chemistry at production and pilot scale presents new challenges to plant manufacturers. Scale-up of highly exothermic and fast reactions requires reliable safety measures. This work shows a reactor concept with safety elements for hazardous reactions including technical and electronic solutions to prevent an excessive temperature and pressure.

2. Methods

This pilot plant was designed and manufactured by Fluitec. Also, programming was done by Fluitec using Siemens PLC.

3. Results and discussion

The DN50 reference pilot plant for 2500 – 4300 t y^{-1} consists of two dosing systems, a tubular reactor containing static mixer heat exchangers [1], the safety purge system and a quench tank (Figure 1). Its underlying concept merges directives and standards of four fields: mechanical engineering (PED 2014/68/EU, MD 2006/42/EC, ATEX 2014/34/EU), chemical engineering (thermal safety concepts from F. Stoessel [2]), electrical engineering and safety (functional safety SIL according to EN 61511).

With this plant, three protection goals are met: dosing, inadmissible temperature and pressure. The devices are monitored by multiple mass flow meters, axial temperature sensors along the reactor, SIL approved temperature sensors and pressure sensors. In the case of a failure, the SIL approved safety purge system will empty out the reactor within a few seconds and direct the media to the quench tank, where it will be immediately inertised. This countercurrent safety purge was developed as an event preventing safety device. Besides this also damage limiting devices were installed such as rupture discs and a safety valve.

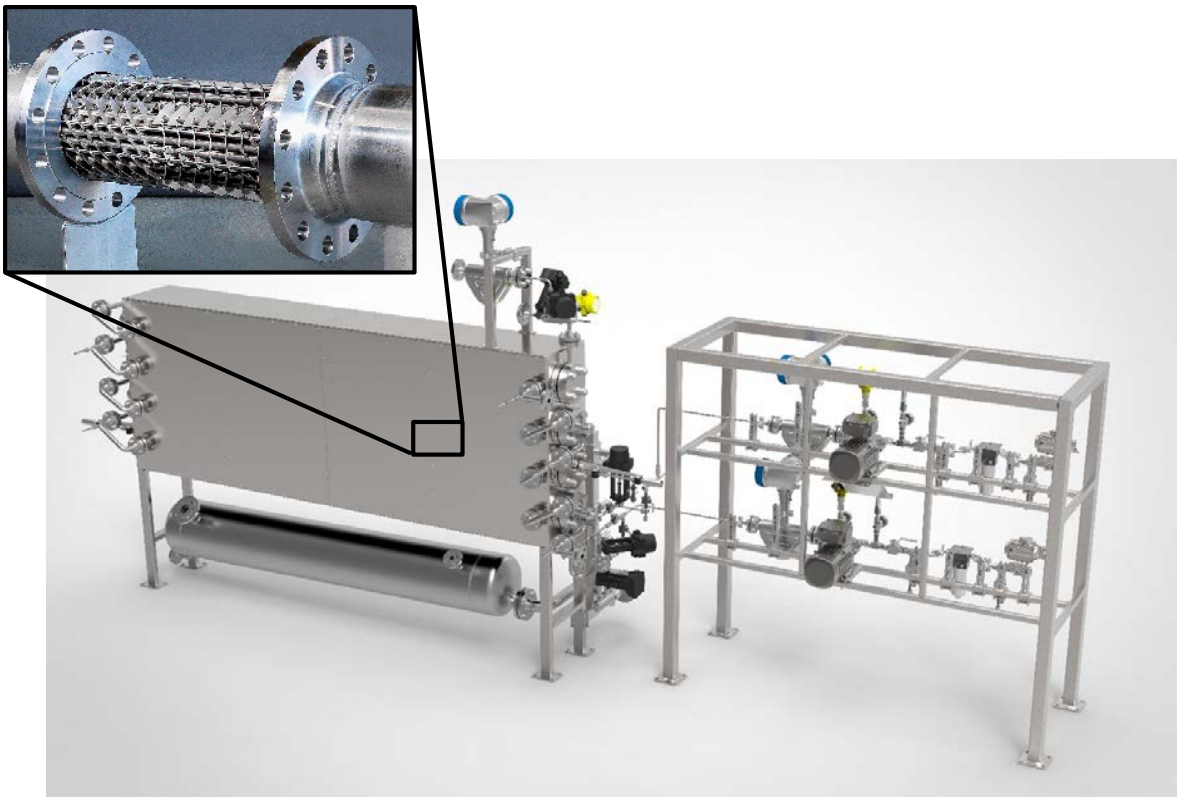

Figure 1. Reference pilot plant (2500 – 4300 t y^{-1}) containing two dosing systems, DN50 mixer heat exchangers and the safety purge system with quench tank.

4. Conclusions

This concept together with the scalable bundle mixer heat exchanger provides a way to tackle the scale-up problem of highly exothermic reactions in tubular reactors. The reactor and programming of the control system needs to be adjusted according to the characteristic temperature levels of the desired and decomposition reaction.

A Bayesian approach for continuous improvement of kinetic parameter estimates

Karsten H. G. Rätze[1], Kevin McBride[2], Kai Sundmacher[1,2]

1 Otto von Guericke University, Magdeburg; 2 Max Planck Institute for Dynamics of Complex Technical Systems, Magdeburg

**Corresponding author: raetze@mpi-magdeburg.mpg.de*

Highlights

- Optimal experimental design (OED) with Bayesian parameter estimation
- Continuous improvement of estimation quality via repeated OED and experiments
- Optimal control trajectories for parameter estimation of the Hydroformylation of 1-decene

1. Introduction

Estimation of kinetic model parameters requires experimental data which needs to be gathered over multiple experiments with varying reaction conditions. As a consequence, building a mechanistic reaction model is labor intensive and requires significant financial investments. Combining optimal experimental design (OED) with dynamic perturbation experiments [1] improves the data generation while reducing the overall experimental effort. By embedding the OED in a sequential approach of repeated experimental design, execution of experiments and subsequent parameter estimation, the amount of necessary experiments is reduced to a minimum. However, implementing the proposed procedure requires repeated usage and updates of prior information on the kinetic parameters. Bayesian parameter estimation is one possible solution by incorporating prior information of different sources in the parameter estimation process while simultaneously providing a measure of the estimation quality.

2. Methods

The parameter estimation procedure may be exemplified using four steps. Initially, a structurally viable, dynamic kinetic model is required with initial values for the model parameters. To improve the quality of the error bounds of the parameter estimations, measurment errors of the experimental equipment are required. Initially, OED generates dynamic control profiles respective to the chosen optimality criterion (A-, D- or E-optimality). Additionally, optimal measurement times need to be calculated that incorporate physical limitations of the experimental equipment and procedure. After performing the experiment, the prior information is used to perform the parameter estimation using Monte Carlo Marcov Chain simulations.

3. Results and discussion

To exemplify the proposed procedure, the hydroformylation of 1-decene is chosen as example reaction. Based on mechanistic models from literature [2] a selected set of unknown parameters

$p = [A_{\mathrm{Iso1}}, B_{\mathrm{Iso2}}]$ is chosen for parameter estimation. An initial guess is provided which deviates from the true parameter values $p_{\mathrm{true}} = [11.04, 18.53]$ found in [2]. Besides limiting the measurment data to two of the reactants, dodec-1-ene and dodec-2ene, the limitations of the experimental equipment are incorporated by enforcing a two minute time interval between measurments and limiting the rate of change of the reaction temperature $|\frac{\mathrm{d}T}{\mathrm{d}t}| \leq 2\,\mathrm{K/min}$. A normal distribution is chosen with $\mu = [10, 17]$ and $\sigma = [0.5, 0.5]$ as prior information for the parameters.

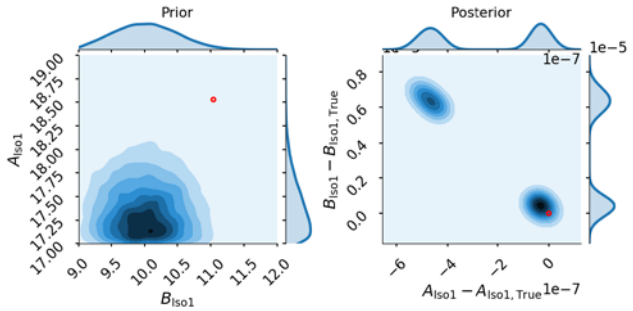

Figure 1. Probability density function improvement of A_{Iso1} and B_{Iso1} after one experiment.

Figure 1, depicts the improvement of the parameter probability density functions. In addition to the adequate approximation of the true parameter values via the density mean, the standard deviation of both probability density functions indicate a significant improvement of the estimation quality.

4. Conclusions

The proposed procedure shows a fast convergence to the true parameter values while simultaneously providing an indicator for the estimation quality. The standard deviation may be used as a stopping criterion for determining the necessary amount of experimental data, thereby reducing the development time for reaction kinetic models and improving economics.

CFD studies on the hydrodynamics in systems with open-cell foam internals

José D. Araújo*[1], João Barbosa[1], Manuel A. Alves[1] and João M. Campos[1]

[1] CEFT, Department of Chemical Engineering, Faculty of Engineering of the University of Porto

Rua Dr. Roberto Frias, 4200-465 Porto, Portugal

*Corresponding author: daraujo@fe.up.pt

Highlights

- Open-cell foams based on cubic cells with different tilt angles were investigated
- Residence time distribution was computed by CFD techniques
- Mass dispersion coefficients and pressure drop per unit length were estimated

1. Introduction

Fixed bed reactors are among the most relevant operation units in chemical industries, and the design of the internals is a subject that gathers particular attention. In the past, random or unstructured packings were mostly used which largely limited the freedom of design. Nowadays, this freedom is continuously increasing due to the application of more ordered structures, which can be even more potentiated by the implementation of 3D printing in the reactors intensification [1]. Following this trend, open-cell foams place themselves as a very attractive option suitable to enhance a wide range of industrial applications [2]. However, there is still a lack of detailed investigations about the hydrodynamics in fixed beds based on open-cell foams. Regarding chemical engineering, computational fluid dynamics (CFD) is widely used to simulate specific phenomena and also the combination of features that occurs on entire production units like chemical reactors. Overall, CFD tools can provide great flexibility for parametric studies and sufficient detail to describe different phenomena with distinct spatial and temporal characteristic scales.

The present work consists on a parametric and systematic study of the hydrodynamics of single phase flows through open-cell foams with cubic cell topology. CFD techniques are used to numerically replicate tracer experiments for the prediction of several characteristic parameters, such as mass dispersion and pressure drop.

2. Methods

The present numerical study was based on a CFD approach entirely open-source: OpenFOAM® CFD package to perform the numerical simulations; Blender® to generate the geometry/domain in the form of STL files; and SnappyHexMesh tool of OpenFOAM® to create the computational mesh. The domain under consideration (total length of 4.5 cm and diameter of 2.0 cm) is a portion of a cylindrical tube filled with ordered open-cell foam structure with different configurations derived from the repetition of unitary cubic cells. The space between struts (pore size) varied from 0.2 to 0.3 cm corresponding to porosities in the range of 0.60-0.95.

The simulated systems replicate tracer tests in order to produce residence time distribution data, i.e., it consists on liquid phase flow (water properties) through the foam with a feed of solute in the

core of the inlet cross-section (step input). The model includes the Navier-Stokes equations and the mass balance equation for the tracer. A large set of simulations was performed with different superficial velocities and cubic cells orientations.

3. Results and discussion

The main raw data to extract from the CFD simulations are the velocity, pressure and concentration fields. Based on this data for each simulation, it is possible to determine the pressure drop per unit length, produce the cumulative residence time distribution (Figure 1a) and estimate axial and radial mass dispersion coefficients (Figure 1b). These coefficients are obtained from fitting the numerical data to Danckwerts [3] and Hiby and Schummer [4] equations. The first step was to perform mesh independency tests to define a proper density (around 1300000 mesh elements) to apply throughout the work. It was verified that the mesh density affects mainly the dispersion coefficients results and the estimation of stagnant regions.

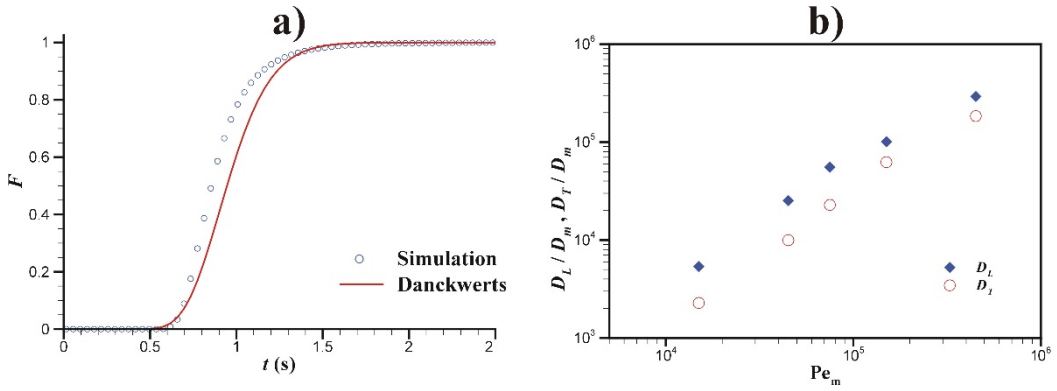

Figure 1. Cumulative residence time distribution for a system with a superficial velocity of 0.03 m/s (a) and dimensionless axial and radial dispersion coefficients as a function of molecular Peclet number (b).

The results in Figure 1 are illustrative of what will be obtained in this study, since the work is still under active development. More detailed and extensive results will be presented and comparisons will be made with available experimental and/or correlation data. Furthermore, there is the possibility of including a last set of simulations addressing illustrative homogeneous and surface reactions in some selected foam structures.

4. Conclusions

The implementation of open-source computational tools to simulate the flow inside tubes filled with open-cell foams was carried out. Single phase flow simulations were performed to replicate tracer experiments and produce important hydrodynamic information such as mass dispersion coefficients and pressure drop. A parametric study will be presented about the influence of the superficial velocity and tilt angles of the foam unitary cubic cells on the referred hydrodynamic parameters.

Gas-liquid hydrogenation in continuous flow for process intensification and rapid process optimization

Nikolay Cherkasov[1,2*], Evgeny V Rebrov[1,2]

1 Stoli Catalysts Ltd, Coventry, UK; 2 University of Warwick, Coventry, UK

**Corresponding author: n.cherkasov@stolicatalysts.com*

Highlights

- Catalyst-coated tube reactors provide no mass transfer limitations in hydrogenation
- Compared to packed-bed reactors, the coated tubes show 14-25 times higher throughput
- Quick mass transfer in catalyst-coated tubes provides excellent product selectivity
- Low-cost refractory sensors provide process automation and faster process development

1. Introduction

The fine chemicals industry relies on batch reactors which are inefficient in terms of space-time yield and safety. Flow chemistry solves these problems, provides a possibility for process intensification, and allows for production with lower capital requirements. Additionally, flow chemistry offers opportunities for process automation. In the work we present the application of catalyst-coated tube reactors in continuous flow hydrogenation of alkynes, alkanes, imines, and unsaturated aldehydes and their advantages compared to batch and fixed bed reactors in terms of mass transfer and product selectivity.

2. Methods

The tube reactors wall-coated with 12 wt% Pt/SiO2, 5 wt% Pd/ZnO, 5 wt% Pd/C catalysts were provided by Stoli Catalysts Ltd [1]. The solid catalysts were obtained by removal of the catalyst coatings. The reactions were performed in a flow system containing an HPLC pump for a substrate solution, mass flow controllers for H_2, an oven with the catalyst-coated tube, an Equilibar gas-liquid back-pressure controller downstream followed by a fraction collector. The reaction was operating autonomously using a pre-defined set of steps collecting samples for offline GC analysis controlled with OpenFlowChem automation platform [2].

3. Results and discussion

We studied the effect of mass transfer and residence time distribution on semi-hydrogenation reaction of alkyne (2-methyl-3-butyn-2-ol) and full hydrogenation of ethyl cinnamate. The catalyst-coated tube reactors showed no external mass transfer limitations, in contrast to packed beds, and a substantially narrower residence time distribution. The Peclet number in the tube reactor was above 100 indicating an ideal plug-flow behaviour in contrast to the packed-bed (Figure 1A). As a

result, the alkyne semi-hydrogenation in packed-bed reactors was a factor of 25 slower less selective (60% vs 95%). The full hydrogenation reaction was 14 times slower in packed-bed compared to catalyst-coated tube. Similarly, the packed-bed reactor filled with a 12 wt% Pt/SiO2 catalyst was inferior to the catalyst-coated tube with the selectivity towards unsaturated alcohol of 20% vs 90% likely due to elimination of mass transfer limitations and excellent control of residence time [3].

The continuous-flow hydrogenation can benefit from process automation. We demonstrated that low-cost (<10$) refractory liquid sensors can be used to accelerate process development and optimisation [4]. An example of dehydrolinanool hydrogenation in Figure 1B shows that the approach provides consistent and reproducible results.

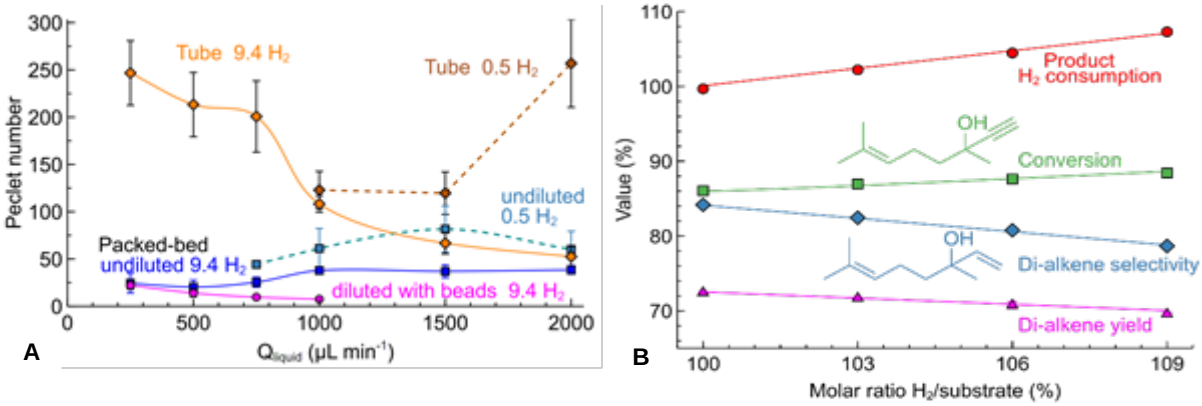

Figure 1. (A) Effect of the liquid flow rate on the Péclet number obtained in the tube and packed-bed reactors. (B) Dehydrolinalool semi-hydrogenation in a 2.3 wt% Pd/ZnO catalyst-coated tubes at various H_2/substrate feed ratios at 95% H2 absorption.

4. Conclusions

The results show that the catalyst-coated tube reactors provide excellent control of hydrogenation reaction conditions without external or internal mass transfer limitations. This results in a substantially higher throughput, a factor of 14-25 and higher selectivity in case of selective hydrogenation reactions. Using online analytics such accelerates the process development.

Continuous scalable synthesis of reactive intermediates: Grignard Reagents and Grignard Reaction

M. G. Menges-Flanagan*, E. Deitmann, L. Gössl, C. Hofmann, P. Löb

Fraunhofer Institute for Microengineering and Microsystems IMM, Carl-Zeiss-Str. 18-20, 55129 Mainz, Germany

**Corresponding author: Gabriele.menges-flanagan@imm.fraunhofer.de*

Highlights

- Continuous synthesis of industrially relevant Grignard reagents.
- Grignard reaction immediately following the reactive intermediate synthesis.
- Scalable processes allowing throughputs of tens of liters per hour.
- Improved product quality and flexible production to improve time-to-market.

1. Introduction

For over 100 years, Grignard reagents (RMgX) and their either simultaneous (Barbier reaction) or subsequent reaction (Grignard reaction) with other halides, aldehydes, ketones, etc. have been a most useful tool for process chemists seeking to form new C-C bonds.[1] However, drawbacks such as variable incubation periods for their initial formation, high exothermicity requiring effective heat management, as well as side reactions such as Wurtz coupling pose challenges to be overcome when aiming at large scale industrial production of such compounds. Here, continuous processing will benefit the Grignard reagent formation and Grignard reaction through improved heat management and the continuous provision of a large Mg excess with the aim to significantly suppress unwanted side product formation.

2. Methods

All solvents and reagents were purchased from commercial suppliers and were used without further purification. The set-up consists of Postnova syringe pumps while tempering of the reactors is achieved by the use of thermostatic baths. Progress of the reactions could be followed by recording the temperatures within the reactors. The family of reactors used for the continuous Grignard reagent formation spanning a wide range of accessible flow rates is given in Figure 1. Titration of the Grignard reagent was done following the method of Lin and Paquette[2] or Krasovskiy and Knochel[3].

3. Results and discussion

Initially, a laboratory scale reactor was established by 3D laser melting and tested for the continuous synthesis of a number of common Grignard reagents *via* processing of solid/liquid mixtures. In contrast to conventional processing of Grignard reagents, in this case a large excess of Mg within the reactor with integrated mechanical Mg activation, was used to suppress unwanted side reactions and allow for full halide conversion within one passage through the reactor with residence times on the order of 3-30 minutes depending on concentration and

reactivity. A broad applicability of this approach was established by synthesizing multiple alkyl and aryl Grignard reagents at varying concentrations in qualities comparable to commercially available products. Additionally, a number of Grignard reactions were also performed on the laboratory scale using freshly prepared Grignard reagents omitting the need for storage of these rather reactive intermediates. Lastly, results will be presented on scale-up efforts undertaken to build a larger scale pilot reactor set-up allowing for halide throughputs of up to 20l/h as well as again including an immediate second step (Grignard reaction) after online detection of Grignard reagent quality formed.

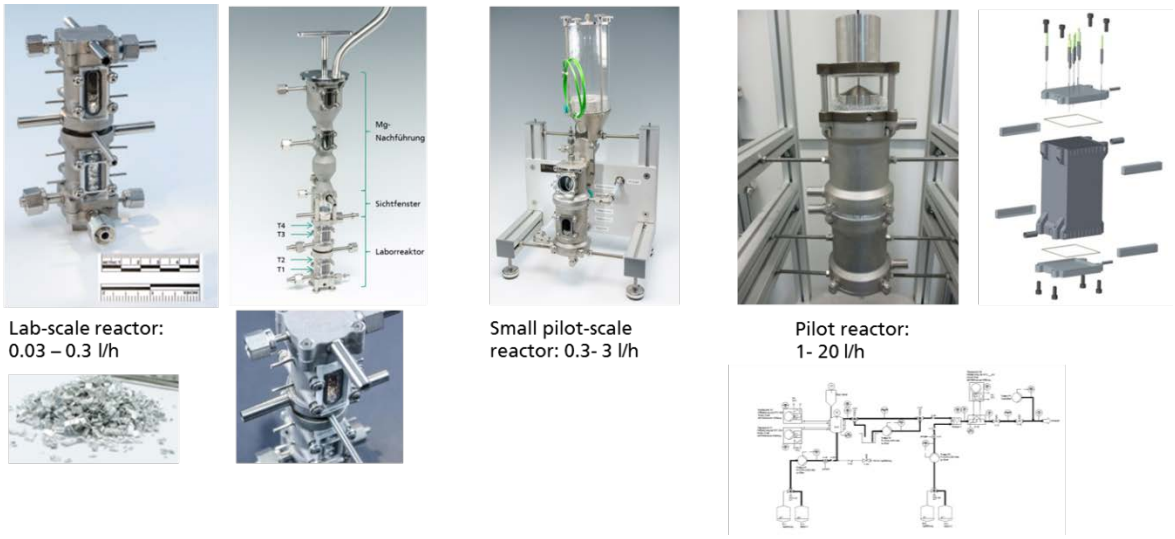

Figure 1. Family of scalable 3D laser sintered reactors for Grignard reagent formation and Grignard reaction.

4. Conclusions

In conclusion, a continuously operating laboratory set-up for Grignard reagent formation manufactured *via* 3D laser melting was established and tested in the optimization of process parameters for scalable continuous Grignard reagent formation. It was aimed at full halide conversion within a single reactor passage with the goal of achieving maximum throughput with minimal energy input (heating/cooling). After Grignard reagent formation was established continuously, it was immediately followed by Grignard reactions consuming the reactive intermediate omitting the need to store this reagent over prolonged time periods. Finally, efforts are underway to scale-up the two steps to pilot-scale throughputs to halide solution flow rates of up to 10-20l/h.

Highlights

- APR performed directly on sugar solutions has been a challenge hindering the development
- Experiments were performed with model solutions followed by actual hydrolysates
- 100% conversion was obtained with tailor made catalysts
- The selectivity of the process could be steered by choice of catalyst

1. Introduction

Currently, one of the key processing operations in the versatile utilization of biomolecules to value added products is hydrotreatment e.g. the stabilization and refining of bio-oils originating from biomass pyrolysis and liquefaction lead typically to different hydrotreatments and the valorization of "waste" lignin requires hydrotreatment in many pathways [1-2]. One potential source for the hydrogen used in the hydrotreatments is biohydrogen produced from waste wood and wood hydrolysates. In this study we investigate biohydrogen production applying first selective reactive/catalytic extraction of hemicellulose from waste wood to monosaccharides. After the reactive extraction we evaluate if the monosaccharides can be used directly, or first after hydrogenation to sugar alcohols, as a raw material to produce hydrogen using aqueous phase reforming (APR) over a solid catalyst. Aqueous phase reforming of sugar alcohols, and more generally polyols, to hydrogen and light alkanes can be performed over various supported metal catalysts at relatively mild operating conditions (ca. 225 °C, 30-50 bar) [3,4].

2. Methods

The reactive extraction experiments were performed using ground softwood (Pinus sylvestris) particles. Extraction solvent was a mixture of water and formic acid, which acted as the catalyst. The effects of operation conditions (reaction time, temperature and acid concentration) and particle size to the quality of the hydrolysate were investigated in an Accelerated Solvent Extraction equipment.

To enable initial evaluation of the characteristics and feasibility of the selected biohydrogen production route from wood hemicellulose, APR experiments were performed using a water

solution of xylitol, mixtures of xylitol and xylose, and finally with a mixture of xylose and formic acid. The actual extracts were tested after the evaluation with the model mixtures. Commercially available and tailor made catalysts were employed in the experiments. The effects of temperature, residence time and gas flow through the reactor on the conversion and selectivity to hydrogen and CO_2 were investigated. The fixed bed continuous reactor was operated in co-current trickle flow and the gas analysis was performed online with micro-GC while the liquid phase was analyzed with HPLC.

3. Results and discussion

Based on the reactive extraction experiments, formic acid catalyzed hemicellulose extraction results in the recovery of hemicellulose as monosaccharides with the efficiency ranging from 60%-75% at the optimal extraction time. Maximum recovery is relatively independent on the reaction temperature or formic acid concentration, when temperature is over 140 °C and formic acid concentration is over 4 wt-%.

In the APR experiments, it was observed that in order to achieve high conversion of xylitol the temperature should be preferably above 225°C. Additionally a three phase system with a flow of inert gas is very beneficial for increasing the conversion. No significant changes in selectivity to hydrogen was observed at different xylitol conversions obtained at varying experimental condition. Mixtures with different ratios of xylose and xylitol were tested in the same experimental conditions with the idea that the hydrogen produced from the xylitol could in situ hydrogenate the xylose and initiate the further APR reaction. All of the experiments resulted in the same conclusion; the mixture caramelized rapidly and blocked the reactor due to humine formation. Attempts to hydrogenate the sugar mixture were unsuccessful as the formic acid prevented the hydrogenation. Experiments were then performed with the xylose and formic acid mixtures. Promising results were obtained at relatively mild conditions, but even at higher temperatures the caramelization due to humine formation was avoided utilizing a tailor made catalyst and 100% conversion was obtained.

4. Conclusions

These results show that Aqueous phase reforming can be performed on actual hydrolysate sugar solutions directly, which is a significant advancement in the field. It enables the flexible supply of biohydrogen in locations that process biomass with side streams of sugars and .

Preparation of Hydrogen Source COx-free Fuel Cell by Ammonia Decomposition using ZA-5 Wustite Catalyst

Huazhang Liu, Chao Huo*

Institute of Industrial Catalysis, Zhejiang University of Technology, Hangzhou 310014, P.R. China

**Corresponding author: chaohc@zjut.edu.cn*

Highlights

- ammonia decomposition, ZA-5 $Fe_{1-x}O$ based catalyst, hydrogen fuel.
- The performance of ZA-5 wustite-based catalyst for ammonia decomposition to produce hydrogen is studied in this paper. The technology of ZA-5 wustite-based catalyst is ripe with low cost. Ammonia decomposition has obvious advantages in process technology, product composition and production cost.
- The ammonia conversion was over 99.9% and the hydrogen production rate reached 189.58 mol H_2/(gcat·h).

1. Introduction

Hydrogen is regarded as a clean energy source with broad application prospects. Hydrogen fuel cells are the most promising new generation energy supply system[1-3]. Currently, hydrogen production and storage technologies are solved by ammonia decomposition. In other word, storage of hydrogen is in liquid ammonia.

At present, the widely used catalysts for ammonia decomposition in industry are Ru or Ni catalysts supported on MgO and $A1_2O_3$. Although the Ru-based catalyst has high activity, it is costly and the Ni-based catalyst consumes a large amount of electricity and is severely corroded. Therefore, this paper uses a new low-temperature and high-efficiency ammonia synthesis ZA-5 $Fe_{1-x}O$ catalyst to study the performance of ammonia decomposition hydrogen production.

2. Methods

Promoters and fine magnetite powder and the reduced iron powder was mixed uniformly. Then the mixture is putted into the electric melting furnace at one time. After melting, the high temperature slurry is rapidly poured into the cooling tank with water jacket and cooled to room temperature, then broken and sifted to the desired particle size.

3. Results and discussion

The effect of the main factors of reaction temperature and space velocity on the ammonia decomposition activity of ZA-5 $Fe_{1-x}O$-based catalyst was carried out. The effects of temperature (450-600 °C) and space velocity (900-7800 h^{-1}) on the ammonia decomposition activity over ZA-5 $Fe_{1-x}O$- based catalyst were investigated.

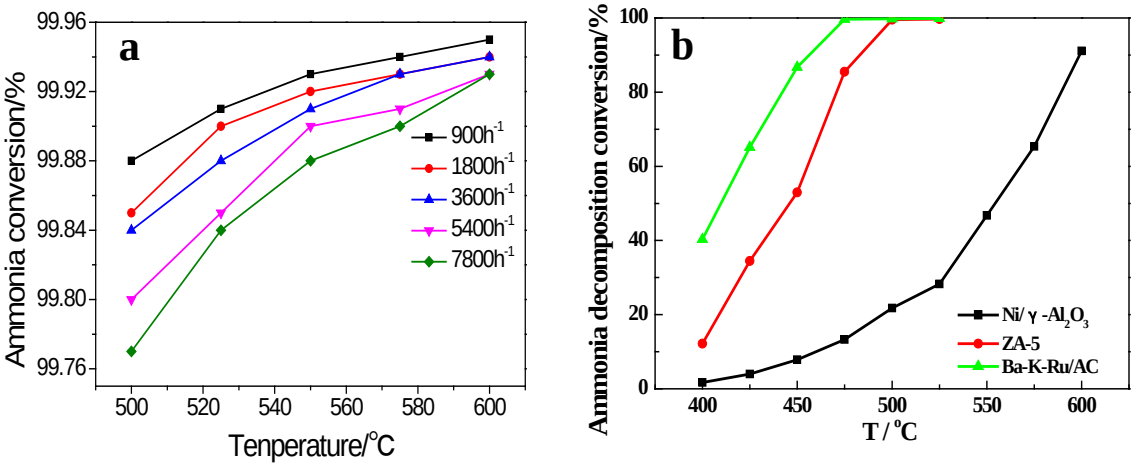

Figure. 1(a)The conversion of ammonia over ZA-5 $Fe_{1-x}O$-based catalyst as a function of reaction temperature at different space velocity; (b) Comparison of ammonia decomposition conversion for ZA-5, Ru/AC and Ni catalysts

It is observed from Figure.1a that the conversion of ammonia decomposition increases with the increase of temperature and decreases with the increase of space velocity. When the temperature reaches 500°C, the ammonia conversion reaches more than 99.7% at all investigated space velocity. If the temperature continues to rise, the ammonia conversion will have little difference, which because the ammonia conversion is close to the equilibrium conversion.

The activity of ZA-5, Ru/AC and Ni/γ-Al_2O_3 catalyst produced by an enterprise was determined under the same conditions. The conversion is shown in Figure.1b. It can be seen from Figure.1b that the low temperature activity of Ru/AC catalyst below 500 °C is obviously higher than that of ZA-5 catalyst, but the difference is not significant above 500 °C and the price is high. While the activity of Ni/ γ-Al_2O_3 catalyst is very bad.

4. Conclusions

The performance of ZA-5 $Fe_{1-x}O$ based catalyst for ammonia decomposition was studied. The results showed that the ammonia conversion was over 99.9 % and the hydrogen production rate reached 189.58 mol H_2/(gcat·h), and compared with Ru/AC and Ni catalysts. The cost of raw material, catalyst and investment cost of industrial plant for ammonia decomposition hydrogen production were analyzed. H_2 obtained from ammonia decomposition does not contain harmful substances such as CO_x, SO_x, NO_x. Ammonia is liquid at room temperature and 0.8 MPa with high energy density per unit volume. Therefore, the combination of ammonia and Fe catalysts with fuel cells is a perfect combination.

Evaluation of the Catalytic Activity of Red Mud for Olive Mill Wastewater Tretament by Fenton's Process

E. Domingues, J. Gomes, D. Lopes M..J. Quina, R. M. Quinta-Ferreira, R. C. Martins
[1]*CIEPQPF – Chemical Engineering Processes and Forest Products Research Center, Department of Chemical Engineering, Faculty of Sciences and Technology, University of Coimbra, Pólo II – Rua Sílvio Lima, 3030-790 Coimbra, Portugal, Portugal;* [2]*CICECO –Aveiro Institute of Materials, Department of Materials and Ceramic Engineering, University of Aveiro, 3810-193 Aveiro Portugal.*

Highlights

- Fenton, photo-Fenton, Red-mud, low cost catalyst

1. Introduction

Fresh OMW is considered phytotoxic because it has in its constitution phenolic compounds. The traditional physical chemical treatments only solve part of the problem since the contaminants are not destroyed but rather phase changed. Thus, an oxidation (chemical or biological) treatment is necessary to complete the treatment of the effluent. In this work, a low-cost catalyst, red mud, was applied in the Fenton process with the objective of reducing the costs of operation and reusing a waste that is currently produced in large quantities. Red-mud richness in iron and aluminium as well as some rare metals can enhance the Fenton´s process. In this context, the aim of the present research was to analyze the efficiency of red-mud as a solid catalyst in Fenton's process for OMW treatment.

2. Methods

Red mud was characterized morphologically by scanning electron microscopy (SEM) with a Hitachi S-4100 microscope. Particle size distribution was performed with a Coulter LS 230 (0.040 - 2000 µm). Specific surface area by the Brunauer-Emmett-Teller (BET) method was studied with a Micromeritics Germini 2380. X-ray diffraction was used to ascertain the crystallography of the powder with a PANalyticalXPert PRO diffractometer (2θ =10-80°, CuKα radiation), where a Panalytica lHigh Score Plus 4.1 (PDF-4) was used for phase identification.

The simulated OMW was prepared by dissolving 100 mg/L of each of the following phenolic acids in ultrapure water: trans-cinnamic, 3,4-dimethoxybenzoic, 4-hydroxybenzoic, 3,4,5-trimethoxybenzoic and 3,4-dihidroxybenzoic acid.

Dark and photo-Fenton's experiments were carried out in a glass spherical reactor (500 mL). A high-pressure sodium grow lamp (LUMATEK 600 W) was used for photo-Fenton's experiments.

3. Results and discussion

SEM images of RM are shown in Figure 1, where the waste seems to be formed by agglomerates with heterogeneous shape and size of particles (Figure 1 a)). Regardless the shape, the particles seem to be around 1.00 µm (Figure 1 b)), in average. Particle size analysis showed that the average size of particles is 1.10 µm, with a mean size (D_{50}) of 0.58 µm (Figure 2a), where 10% of particles have a particle diameter lower than 0.17 µm (D_{10}) and 90% of particles have a diameter lower than 2.86µm (D_{90}). The waste catalyst has a surface

area of BET of 10.57 m^2/g and 0.02cm^3/g of pore volume. XRD studies (Figure 2b) confirm the presence of several phases, in accordance with SEM results.

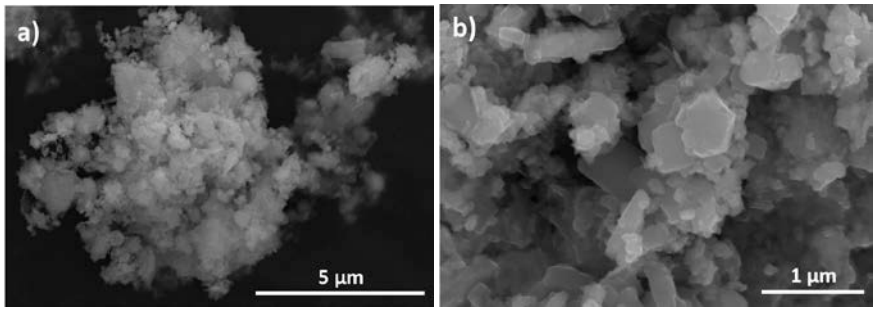

Figure 1. SEM of the red mud powder.

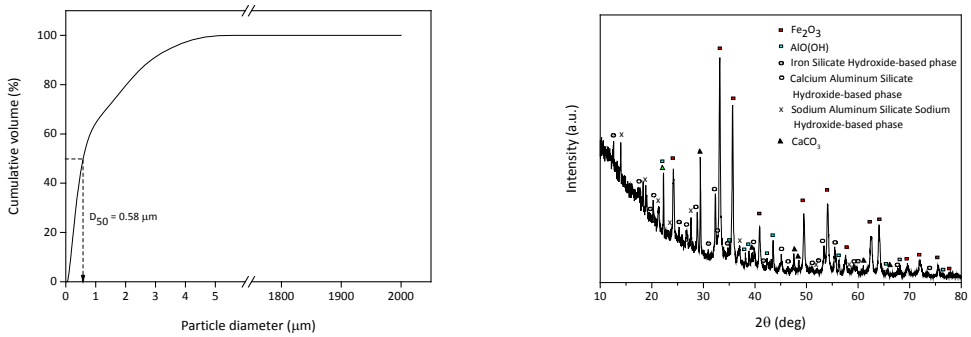

Figure 2. a) Cumulative volume (%) of red mud particles. b) XRD pattern of red mud.

Fenton's experiments showed that red mud is a suitable low-cost catalyst for the removal of the phenolic content. The operating parameters were optimized and the impact of Fenton's process over the treated wastewater ecotoxicity was evaluated.

4. Conclusions

Fe_2O_3 is the major constituent of RM, followed by AlO(OH) and an iron silicate hydroxide phase. Minor compositions of SiO_2, TiO_2, Ca_3SiO and $Al(OH)_3$ are present.

The presence of visible radiation in Fenton´s process decreased the efficiency of the process, probably led to the decomposition of hydrogen peroxide into non-reactive species with contaminants such as water and oxygen. The catalyst load above 1 g / L shows that the scavenger effect of the catalyst prevails. It has been found that increasing the concentration of hydrogen peroxide to 100 mg / L favors the process by increasing the rate of degradation of the phenolic acids.

Predictive Model of Delayed Coker Unit for Studying Variations in Feed.

Hala Kelani[1], Dr. Mohammad Abdur Rakib[2], Mohamed AL Musharfy[3]

[1,2,3] ADNOC Refining Research Center, PO Box 3593, ADNOC Refining

Abu Dhabi, United Arab Emirates

*Corresponding author: hkelani@adnoc.ae

Highlights

- *Delayed Coker*
- *Process Simulation*
- *Scenario studies*
- *Feed flexibility*

1. Introduction

Delayed Coking is a thermal process in which a residuum material from a vacuum distillation unit in a refinery is rapidly heated in a furnace and then thermally cracked in coke drums under appropriate conditions of temperature and pressure. Typical products from a Delayed Coker unit include Sour Off Gas, Sour LPG (C3s and C4s), full range of Stabilized Coker Naphtha, Light Coker Gas Oil (LCGO), Heavy Coker Gas Oil (HCGO), and Coke (Green Coke). In ADNOC Refining, the Delayed Coker Unit is designed for a feed blend of Vacuum Residue (VR) and Hydrotreated RFCC (Residue Fluidized Catalytic Cracker) Slurry. Depending on the availability of feed from its upstream units, and depending on dynamic market scenarios, the feed to a Delayed Coking unit might vary in terms of quality due to variation of blend ratios, as well as in feed rate. Hence, as reported in this present study, a predictive model was developed using a commercial simulation software to conduct scenario studies for various feeding scenarios (feed throughputs and blend ratios) to assess the expected impacts on the products yield and properties, prior to introducing these in real operations.

2. Methods

Delayed coking is a highly endothermic reaction with the furnace supplying the necessary heat of reaction. The exact mechanism of coking is quite complex and determination of the chemical reactions occurring would be quite challenging.

A commercial simulation software was utilized in the current study, whereby a base case was calibrated using a design case, denoted as Design Case 1. Data required for this calibration of the base model included: (a) Feed analysis for each stream in the feed blend, e.g. specific gravity, distillation curves, sulfur and metals content etc., (b) detailed operating conditions for each equipment of the unit including delayed coker furnace, coke drums, and the separation column, and (c) product analysis and yields for each product stream from the unit.

This calibrated model was validated by testing the model against another design scenario, denoted as Design Case 2, in addition to a set of operating data denoted as Scenario 3. The prediction for

these cases indicated a very good match, and henceforth the calibrated model was utilized for prediction of an additional scenario, denoted as Scenario 4. Feed for theese cases are as in Table 1.

Table 1: Feed blend percentage for each case

	Flow Rate Percentage (%)			
Feed	**Design Case 1**	**Design Case 2**	**Scenario 3**	**Scenario 4**
Vacuum Residue	85	85	83	85
RFCC Slurry (0.1 wt% S)	15	-	-	-
RFCC Slurry (0.2 wt% S)		15	-	-
Hydrotreated Atmospheric Residue	-	-	17	15

3. Results and discussion

Tabulated below are results for these predicted scenarios.

Table 2: Products yields simulation results for different feed scenarios compared to the calibrated case

	Yields (wt%)			
Products	**Design Case 1**	**Design Case 2**	**Scenario 3**	**Scenario 4**
Gas	4.7	4.7	4.21	4.191
LPG	4.82	4.82	5.64	5.596
Light Coker Naphtha	16.67	16.52	18.94	18.659
Heavy Coker Naphtha	8.71	8.623	9.8335	9.713
Light Coker Gas Oil	26.53	26.29	29.93	29.68
Heavy Coker Gas Oil	6.25	6.31	5.68	5.72
Coke	32.14	32.7	25.1	25.74

The presentation will include a detailed discussion of these results and the source of these variations of the individual yields.

4. Conclusions

A commercial Delayed Coker unit was simulated, whereby one set of design data were used to calibrate the model, and validated using a second set of design data and actual operating data. Parametric prediction cases were performed and validated directionally to provide operational guidelines to the refinery process engineers for assessing unit performance and limits of feed flexibility for the various feeding scenarios. The coke product yield has been significantly impacted while using hydrotreated atmospheric residue in the feed blend. These step-out predictions have also been made available for refinery production planning personnel to generate Linear Programming (LP) vectors for input for production planning software.

Fast Pyrolysis of Agricultural Eggplant Stalk Waste

Merve Atıl, H. Ferdi Gerçel

Department of Chemical Engineering, Eskişehir Technical University, Eskişehir 26555, Turkey

**Corresponding author: hfgercel@eskisehir.edu.tr*

Highlights

- Pyrolysis experiments of the eggplant stalk were carried out in the nitrogen gas atmosphere.
- The effects of pyrolysis temperature on the pyrolysis product yields were investigated.
- The highest liquid product yield was obtained as 28.16 wt.%.

1. Introduction

Pyrolysis is one of the thermochemical conversion methods of biomass, carried out in the complete or near complete absence of an oxidizing agent (air or oxygen), typically at 400–700°C to provide complex fractions of gases, condensable liquids (tars), and char (solid residue) [1]. Fast pyrolysis is the rapid thermal decomposition of biomass in the absence of oxygen. The main product of fast pyrolysis is a dark brown and viscous liquid, known as bio-oil [2, 3]. In this study, eggplant stalk was investigated as a source of biomass, pyrolysis was carried out in a nitrogen gas atmosphere and the effect of pyrolysis temperature on yields of the pyrolysis product was investigated.

2. Methods

Agricultural waste eggplant stalk was collected from Kızılinler village around the city of Eskisehir, which is located in central Anatolia, Turkey. Prior to use, the sample was dried at moisture free and shade conditions, ground with a high-speed rotary cutting mill and then sieved to a uniform size (0.425–0.6 mm). Pyrolysis experiments were carried out in a 310 stainless steel, fixed bed tubular reactor in an inert gas atmosphere. Pyrolysis of the eggplant stalk conducted in nitrogen atmosphere flowing at a rate of 100cm^3/min, at temperatures of 400, 450, 500, 550, 700°C with a heating rate of 300°C/min. After pyrolysis, the resulting solid char was separated, weighed and the char yield was calculated. The amount of water, collected from the liquid product-water mixture in the cooling containers, was determined. The tar was removed by washing with dichloromethane, then the solvent was removed in the rotary evaporator to calculate the liquid product yield and also the pyrolysis conversion from the weight loss in the reactor. Gas yield was calculated from the total mass balance. Chemical composition of liquid was determined by liquid column chromatographic fractionation. The liquid product was separated into two fractions as n-pentane soluble and insoluble compounds by using 100 mL pentane. The pentane soluble material was further separated on activated silica gel, pretreated at 105°C for 2 h prior to introduction into a 20 cm high and 25 mm i.d. column. The column was eluted with n-pentane, toluene, and methanol to produce

aliphatic, aromatic, and polar fractions successively. Chemical characterization of liquid, n-pentane eluate, toluene eluate and methanol eluate samples were carried out using potassium bromide (KBr) disks in a Fourier transform infrared spectrophotometer (FTIR, Perkin Elmer Frontier) in a scanning range of 4000-400 cm^{-1}.

3. Results and discussion

Pyrolysis product yields at different pyrolysis temperatures are presented in Figure 1. The highest overall conversion of 76.05 wt.% was obtained at the final pyrolysis temperature of 700°C under the nitrogen, flowing at a rate of 100 cm^3/min. The liquid yield also increased as pyrolysis temperature was raised from 400 to 500–550°C, although a decrease in the liquid yield was observed at higher pyrolysis temperature of 700°C.

FTIR spectra of the n-pentane, toluene, methanol eluate and the liquid product samples are presented in Figure 2. The O-H stretching vibrations between 3200 and 3400 cm^{-1} indicate the presence of phenols and alcohols; the C-H stretching vibrations, observed between 2800 and 3000 cm^{-1} and C-H deformation vibrations between 1350 and 1475 cm^{-1} indicate the presence of alkanes. The C=O stretching vibrations between 1650 and 1750 cm^{-1} indicate the presence of ketones or aldehydes. The absorbance peaks between 1575 and 1675 cm^{-1} represent C=C stretching vibrations are arising from the presence of alkenes and aromatics.

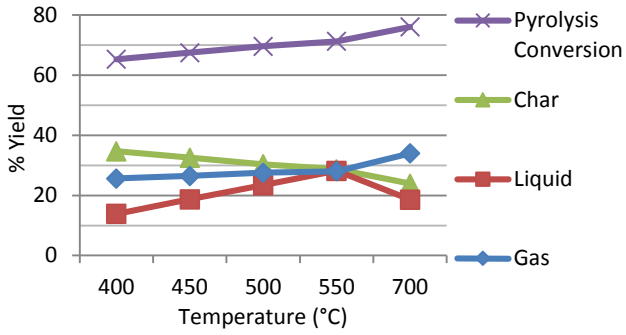

Figure 1. Pyrolysis product yields at different pyrolysis temperatures

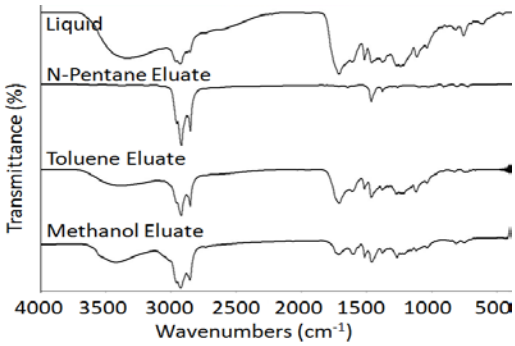

Figure 2. FTIR spectra of the n-pentane, toluene, methanol eluate and the liquid product samples.

4. Conclusions

FTIR spectra of the n-pentane, toluene, methanol eluate and the liquid product samples demonstrated that the functional groups of the liquids are consistent with those of the liquids and the chromatographic fractions obtained from eggplant stalk. The maximum liquid yield from eggplant stalk were achieved at the pyrolysis temperature of 550°C, under 100 cm^3/min nitrogen flow rate. The highest overall conversion of 76.05 wt.% was obtained at 700°C.

Catalytic Performance Investigations of the Direct DME Synthesis with Variable $CO/CO_2/H_2$ Feeds.

Stefan Wild[1], David Guse[2], Karla Herrera Delgado[1], Matthias Kind[2], Stephan Pitter[1], Sabrina Polierer[1] and Jörg Sauer[1]

1 Institute for Catalysis Research and Technology (IKFT); 2 Institute of Thermal Process Engineering (TVT) Karlsruhe Institute of Technology (KIT) D-76131 Karlsruhe/Germany

**Corresponding author: Stefan.wild@kit.edu*

Highlights

- Highly active CZZ/zeolite catalyst system with high CO_2 tolerance
- Good long-term stability under variable operating conditions

1. Introduction

Synthesis gas, a mixture of H_2, CO and CO_2 with variable composition, is the preliminary stage for many basic chemicals. Synthesis gas can be produced from a variety of feedstocks, resulting in a wide range of $CO/CO_2/H_2$ ratios[1]. Methanol (MeOH) and Dimethylether (DME) formed from synthesis gas are promising energy carriers in the "Power to Fuels" (PtF) concept[2]. Using CO_2 as a COx source would lead to a CO_2 recycle system and to CO_2-neutral fuels.

2. Methods

Within this study, the direct DME synthesis is investigated in a fixed-bed reactor aiming at dynamic processing with variable feed compositions. For initial methanol formation $Cu/ZnO/ZrO_2$ (CZZ) catalysts prepared at KIT-IKFT/TVT are used. Different solid-acid components such as γ-Al_2O_3, H-FER and H-MFI realize the dehydration of MeOH to DME. Experiments have been carried out under following reaction conditions: 483-523 K; 50 bar; gas hourly space velocity (GHSV) between 18.000 and 42.000 $ml_N/(g*h)$; initial $CO_2/(CO_2+CO)$ inlet-ratio between 0 and 1.

3. Results and discussion

Figure 1 (left) shows that CZZ catalyst enables up to 76 % higher DME productivity compared to a commercial $Cu/ZnO/Al_2O_3$ (CZA) sample material. DME productivity can be even increased at 503 K by raising the CO_2 content in the feed. At higher reaction temperature, the thermodynamic equilibrium becomes more noticeable, reflected by lower DME productivity for CO_2-rich feed compositions. More CO_2 in the feed generally favors water formation by reverse water-gas shift reaction, what also leads to a reduction of DME productivity[3]. In a long-time experiment over nearly 600 h time on stream (ToS) using a CZZ/H-FER catalyst system a total decrease of 29 % in DME yield is observed. Figure 1 (right) shows the deactivation during the first 100 h under constant reaction conditions, followed by periods of variable dynamic changes subjected to varying temperatures, residence times and feed compositions.

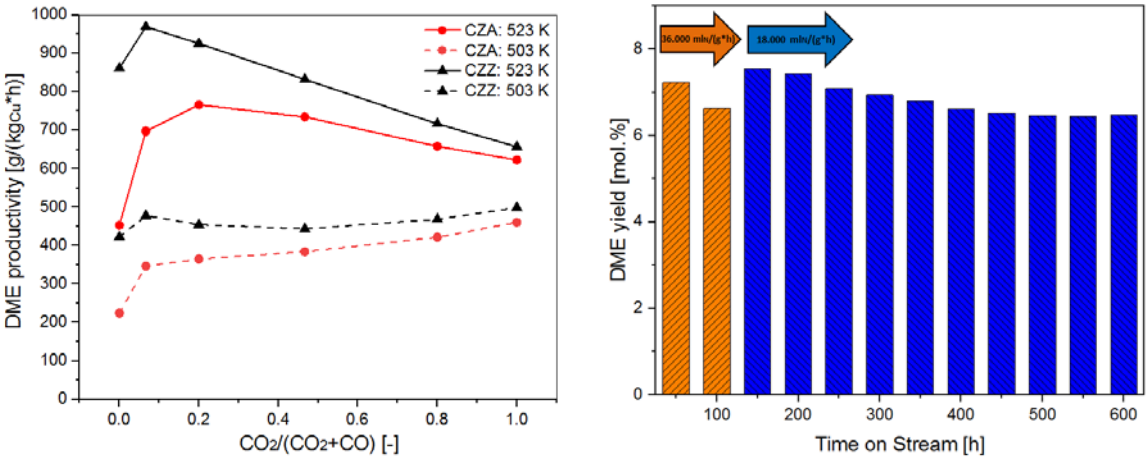

Figure 1. DME productivity of CZZ/H-FER and a commercial CZA/H-FER catalyst system (left). DME yield in a long time test of the CZZ/H-FER system (right).

4. Conclusions

The CZZ/H-FER system prepared at IKFT shows an enhanced performance compared to a commercial CZA/H-FER system and is a promising material for the conversion of syngas to DME with variable composition of $CO/CO_2/H_2$. With the appropriate choice of reaction conditions it is possible to make the DME productivity almost independent of the $CO_2/(CO_2+CO)$ inlet-ratio.

Highlights

- Experimental and ab-initio study of eugenol HDO over Pt, Pd, Rh, Ru on C.
- Micro-kinetics modelling of adsorption, desorption, bulk and surface reactions.
- The lowest hydrogenation/deoxygenation ratio found for Ru/C, the highest for Pd/C.
- Ru closest to the top of the volcano dependency: TOF vs. eugenol adsorption energy

1. Introduction

The present study represents an integrated theoretical and experimental assessment of the catalytic hydrotreatment of eugenol, a representative lignin monomer model compound, over the Ru/C catalyst. A micro-kinetic model has been developed to describe experimental observations at more fundamental level accompanied by DFT calculations.

2. Methods

Experiments have been performed in a cylindrical stainless steel slurry reactor (Autoclave Engineers) in a completely batch regime. A typical experiment was performed with 5 wt% (4.5 g) of eugenol, 0.2 wt% (0.2 g) of the Ru, Pd, Pt, Rh on C and 94.8 wt% (85.3 g) of the solvent (hexadecane) at 275 °Ca and 5 MPa of initial hydrogen pressure under vigorous mixing of 1000 min^{-1}. Reactions proceeded for 3 h at the final temperature (heating up period 30 – 45 min). During the experiment, sampling of the liquid and gas phase took place. Liquid samples were analyzed by using a gas chromatograph with flame ionization detector (GC–FID) coupled with a mass spectrometer detector (GC–MS), while gas samples were analyzed by using gas chromatography (GC) and Fourier Transform Infrared (FTIR) Spectroscopy.

Based on a reaction pathway network, proposed according to the experimentally-determined intermediates and DFT study, a microkinetic model of hydrotreatment in a three-phase slurry reactor has been developed, that includes the influence of i) thermodynamics, ii) hydrodynamics, iii) mass transfer (gas – liquid, liquid – solid surface), iv) adsorption and desorption kinetics, v) surface reaction kinetics, vi) reaction kinetics in bulk phase on the global reaction rate [1-3]. Mass balances for each component in every phase (gas, liquid, catalyst surface) have been written as a set of ordinary differential equations (ODE) and were solved numerically. Kinetic, mass transfer and thermodynamic parameters were obtained either by empirical correlations, DFT calculations or regression analysis.

Density functional theory calculations have been performed in a Quantum Espresso open-source software using computationally-cheap approaches, specifically; Plane-Wave DFT with Perdew–Burke–Ernzerhof functional (PBE) and Grimme-D2 for van der Waals interactions. Unit cell consisted of 96 Ru atoms (4x6x4). Approximately 500.000 core-hours were spent for 500 stable and transition-state structures search and optimization [2].

3. Results and discussion

Ru/C catalyzed hydrotreatment of eugenol yielded 2-methoxy-4-propylphenol (HMPB), 4-propylphenol (HPB), 2-methoxy-4-propylcyclohexanol (HMPC), 4-propylcyclohexanol (HPC), propylbenzene (PB), propylcyclopentane (PCP), propylcyclohexane (PC), 4-propylcyclohexanone (KPC), 4-propyl-1,2-cyclohexanediol (HHPC), trans-isoeugenol (IHMAB), 2-metyl-1-propylcyclopentate (MePCP) and 2-methoxy-4-propylcylohexanone (KMPC). Blank experiment reviled that allyl double bond isomerization and hydrogenation proceed also without the catalyst, what has been supported by DFT calculations. Reaction network of eugenol hydrotreatment over the Ru/C has been established based on the product evolution over the reaction time and experiments performed with intermediates [1]. The proposed reaction network has been confirmed by the DFT calculations.

Temperature variation influenced the product distribution the most significantly. Hydrogenation reactions took place predominantly at lower temperatures as a consequence of low activation energies (approx. 50 kJ mol^{-1}) estimated by the model. On the other side, deoxygenation reactions were significantly promoted at higher temperatures due to greater activation energies (approx. 100 kJ mol^{-1}). Pressure change affected primarily the yield of hydrogenated products. Agitation speed variation indicated absence of the external mass transfer limitations in the tested range. The catalyst loading promoted all reactions, as expected. Demethoxylation and dehydroxylation rate constants have been estimated 36- and 42-fold higher for aromatics relative to oxygen-containing cycloalkanes. Energy diagram, determined for HMPC deoxygenation by the DFT, has been provided in Fig 2a, while Fig. 2b demonstrats integrated experimental and micro-kinetic model results obtained for the experiment performed at 275 °C.

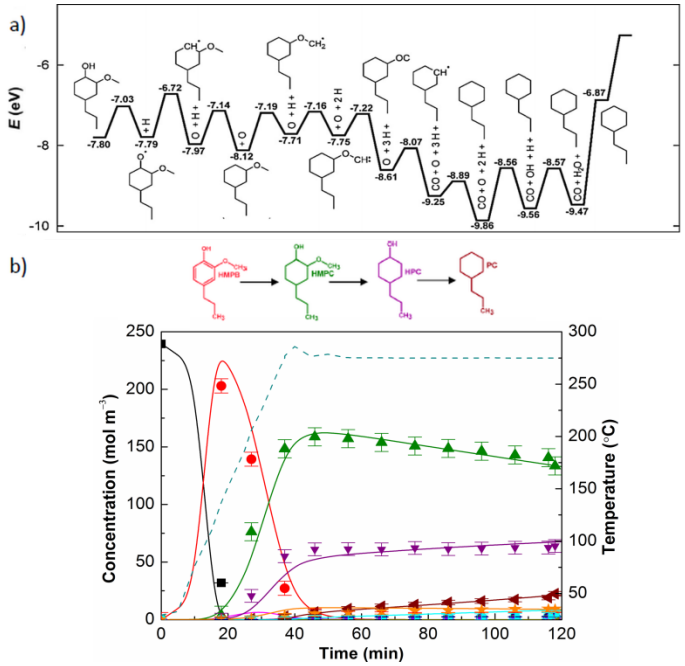

Figure 1. a) Potential energy surface for the minimum energy pathway of the HMPC deoxygenation obtained by the DFT b) eugenol hydrotreatment over the Ru/C at 5 MPa H_2.

Highlights

- Pretreatment of Lignocellulosic Biomass with Dilute Acid Pretreatment (DAc) vs. Liquid Hot Water Pretreatment (LHW)
- Design Optimization with Response Surface Methodology vs. Artificial Neural Network - Genetic Algorithm
- Predictive Modelling to use in Process Design for Sustainable Production of Xylitol

1. Introduction

Xylitol has manifold beneficial health properties, e.g. possessing a low insulin index, while tasting similarly to sucrose and thus being perfectly suitable as sugar substitute for diabetics [1]. Its currently predominant production process involves extensive purification and separation steps, which makes it highly cost-expensive [2]. The feedstock for this process is lignocellulosic biomass, whose hemicellulosic fraction consists to major parts of xylose. Rather than pursuing a chemical reaction, the xylose can also be converted to xylitol by fermentation. Consequently, a sustainable, biotechnological production process for xylitol represents a possible alternative [3]. One of the bottlenecks remains the pretreatment of the lignocellulosic biomass in order to partition the hemicellulosic fraction optimally from the biomass. Therefore, the scope of this work comprises a comprehensive analysis of a pretreatment experiment design: Two pretreatment methods are analyzed in two respective design of experiments. Furthermore, the design is optimized comparatively by means of a) Response Surface Methodology (RSM) and b) an Artificial Neural Network (ANN) coupled with a Genetic Algorithm (GA), in order to provide a statement on optimal process conditions for a maximal xylitol production. This is complemented by a sensitivity analysis of both approaches [4]. On basis of the optimized design, one of the pretreatments is chosen to be implemented as a model in order to serve in an overall process design routine.

2. Methods

The two methods Liquid Hot Water (LHW) pretreatment and Dilute Acid (DAc) pretreatment are considered as base cases. An experimental design with a fixed temperature range for both pretreatment methods is chosen and, subsequently, for each chosen temperature experiments with both pretreatments are done. The variable considered for LHW is time, and the variables

considered for DAc are time and the concentration of acid. The experiments are conducted with wheat straw as lignocellulosic biomass, chopped in a defined particle size interval. All experiments are conducted in stainless steel reactors under defined conditions. The acid used for DAc is sulfuric acid. Measured process variables are time, the concentration of xylose, glucose and the concentration of common inhibitors, such as furfural, HMF, acetic acid and phenolics [4].

The measured data from these experiments is then used to optimize the design with both RSM and the hybrid approach employing ANN-GA, with the twofold objective of a maximal xylose production and simultaneously low inhibitors formation. A local and global sensitivity analysis concludes the procedure. After the analysis of the optimized results, the pretreatment is then implemented as model based on the work of Prunescu et al. [6] and afterwards calibrated and validated with the experimental data.

3. Results and discussion

LHW tends to be conducted at higher temperatures than DAc. This is due to the reason of better solubility of the hemicellulosic fraction. With increasing temperature and/or acid concentration, DAc tends to yield higher concentrations of inhibitors during the course of pretreatment [5]. A main drawback of LHW is however the production of large amounts of oligomers instead of xylose monomers [4].

The main objective of the pretreatment is, as mentioned, the fractionation of the biomass. It should therefore yield a maximum amount of monomeric xylose. Other factors indicating the qualitative superiority of a pretreatment method is the amount of inhibitors produced, as well as the costs for heat and acid. In order to provide a sufficient answer for the choice of one pretreatment method or another, the design optimization gives a sufficient answer. The optimization of the design with RSM and respectively with the hybrid ANN-GA yields optimal process parameters for a maximal xylose production during the pretreatment. The comparison between both methodologies show certain differences in overall accuracy, sensitivity and optimal result. DAc yields higher amounts of monomeric xylose, although the use of acid involves cost, but still outruns LHW performance wise. The implemented, calibrated and validated model shows good predictive abilities.

4. Conclusions

The comprehensive analysis of the LHW and DAc pretreatment of wheat straw as lignocellulosic biomass yields ambiguous data in terms of favorability of one of them. The optimization of the design with RSM and with ANN/GA display different results considering their performance, but indicate that DAc should be chosen. This method is therefore supposed to be implemented as model for an overall process routine. Therefore, choosing DAc under optimal conditions for the pretreatment step for the biotechnological production of xylitol surmounts the bottleneck best, which makes it suitable for a sustainable process alternative.

Highlights

- Dolomite activity depends highly on temperature and changes composition of raw bio-oil
- H_2 yield is enhanced at 400 °C due to conversion of acids and levoglucosan into ketones
- Severe pre-reforming conditions lead to alkyl-phenols formation and faster deactivation

1. Introduction

Steam reforming (SR) of the bio-oil produced by fast pyrolysis of biomass is an interesting route for renewable and sustainable production of hydrogen [1]. However, direct valorization of raw bio-oil is hampered by its complex composition, high corrosivity and thermal instability. Poly-substituted phenols (e.g., catechols, guaiacols, syringols) are the main undesired components in bio-oil, which undergo condensation reactions leading to the formation of carbonaceous material, which may cause clogging of the reactor and severe catalyst deactivation [2]. Several Ni-based catalysts have been tested under a wide range of operating conditions, which despite achieving high yields of H_2 undergo a rapid deactivation. Selection of operating conditions and strategies that minimize catalyst deactivation is essential for the industrial feasibility of raw bio-oil SR. The on line two-step (thermal-catalytic) reaction system has proved to be effective for attenuating deactivation [3], and the use of dolomite as a pre-reforming catalyst has been addressed as a low-cost way of protecting the more expensive reforming catalysts [4].

In this work, the influence that temperature and dolomite space-time has on the subsequent reforming step has been studied with the aim of establishing optimal pre-reforming conditions with dolomite for enhancing H_2 production and attenuating deactivation.

2. Methods

Raw bio-oil (obtained by fast pyrolysis of pine sawdust) was continuously fed (0.1 ml/min) into the first thermal/pre-reforming unit (Pre-SR) where the previously calcined dolomite (at 850 °C for 5h) was located in a fixed bed reactor. The resulting volatile stream entered the fluidized bed reforming reactor (SR), where a Ni-spinel catalyst ($NiAl_2O_4$ with 33 wt % Ni) was located. The pre-reforming step was studied at 400-700 °C and two values of space-time (1.4 and 2.8 $g_{dolomite}h/g_{bio-oil}$), whereas conditions for steam reforming were settled at 700 °C and 0.15 $g_{catalyst}h/g_{bio-oil}$. Additional water was co-fed with bio-oil to have a steam-to-carbon ratio (S/C) of 3. Product stream was analyzed by on-line GC and GC/MS of the liquids collected at the outlet of the Pre-SR and SR reactors. The coke deposited on the $NiAl_2O_4$ catalyst was quantified by temperature-programmed oxidation (TPO).

3. Results and discussion

The effect of pre-reforming (Pre-SR) on the evolution with time on stream of the overall H_2 yield is studied in Figure 1, where the results are also compared with that obtained without dolomite in the first unit (black circles) and those corresponding to the Pre-SR unit outlet (dotted lines). For the same amount of dolomite (Figure 1a), the $NiAl_2O_4$ catalyst stability was enhanced when the pre-reforming was performed at 400 °C. Figure 1b also revealed that half the amount of dolomite was necessary to improve H_2 production (compared to the conventional SR) when the pre-SR was conducted at 700 °C. The faster catalyst deactivation observed as the pre-reforming temperature was raised from 400 to 700 °C was attributed to a higher coke deposition (from 4 to 18 wt %).

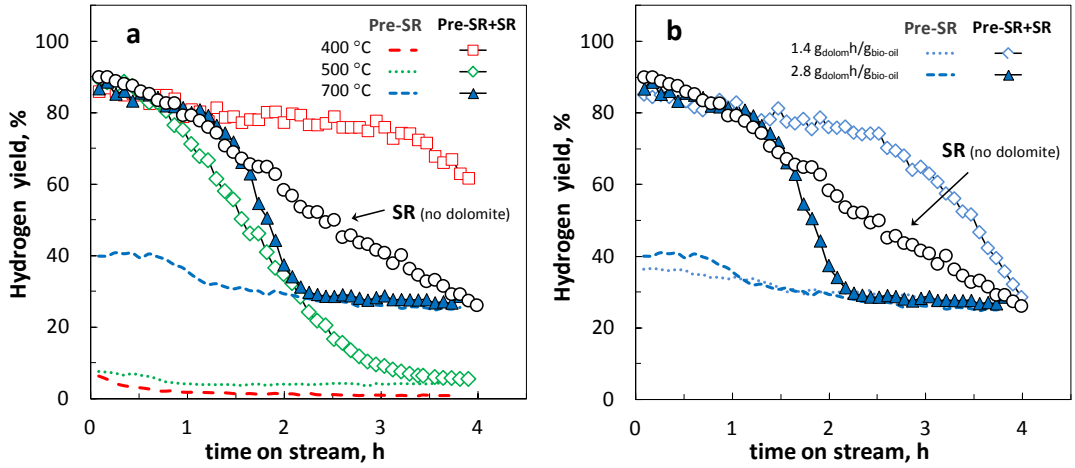

Figure 1. Effect of pre-reforming (Pre-SR) temperature (Graph a, 2.8 $g_{dolomite}h/g_{bio\text{-}oil}$) and dolomite space-time (Graph b, 700 °C) on the overall hydrogen yield. Conditions on the steam reforming (SR) step: 700 °C, 0.15 $g_{catalyst}h/g_{bio\text{-}oil}$.

These results were explained by differences in the composition of the oxygenated stream caused by the dolomite activity for ketonization, steam reforming, WGS, cracking and H_2 transfer reactions, whose relative prevalence depends on the operating conditions [5]. At 400 °C, acids and levoglucosan were mainly converted *via* ketonization leading to acetone, 2-butanone and cyclic ketones as majority compounds. Dolomite activity for reforming reactions was favored by temperature and space-time, although cracking and hydrodeoxygenation of poly-substituted phenols were also promoted, resulting in oxygenated stream with alkyl-phenols and aromatics as majority compounds.

4. Conclusions

The pre-reforming with dolomite at low temperature (400 °C) or low space-time is effective to attenuate the deactivation by coke of the Ni-spinel catalyst in the reforming step, due to the conversion of acids and levoglucosan contained in raw bio-oil into ketones, whereas more severe pre-reforming conditions promote formation of alkyl-phenols that cause faster deactivation.

Highlights

- Renewable energy has great potential but fluctuation and storage are always a challenge.
- Long-term storage of hydrogen can connect high-energy potential with demand.
- We propose a process to release hydrogen from LOHCs using solar energy.
- Concept and initial results are introduced.

1. Introduction

Potential for renewable energy based society is big but it cannot achieved without an appropriate energy storage infrastructure that copes with the fluctuating nature of the renewable sources [1-3].

Long-term hydrogen storage by means of Liquid Organic Hydrogen Carriers (LOHCs) is based on cycles of hydrogenation- dehydrogenation. This provides an option, which is potentially cheap, safe and easy to handle in order to connect regions with high-energy generation potential to regions with large energy demand. The sustainability of the process requires to recover the hydrogen using a heat source that do not emit CO_2 [4]. Solar light is an abundant resource that can be used for this purpose. Nevertheless the technology is not yet developed.

We make use of a plasmonic composite in order to capture the light energy and locally activate the dehydrogenation of LOHCs. For this, we have developed a dedicated reaction system, which will be described here.

2. Methods

2.1. Reaction setup and catalyst integration:

The reactor allows the illumination of the plasmonic composite while the flow and temperature of the LOHC is controlled. The plasmonic catalyst is deposited on the transparent slides by means of a layer-by-layer method. Optical profilometry and UV-Vis spectroscopy are used to characterize the surface. Electronic microscopy is used to study the catalytic nanostructure.

2.2. Reaction test:

The reactor is tested under white light with different flow rates. The production of hydrogen is followed by the degradation of the LOHC by means of refractometry.

3. Initial results

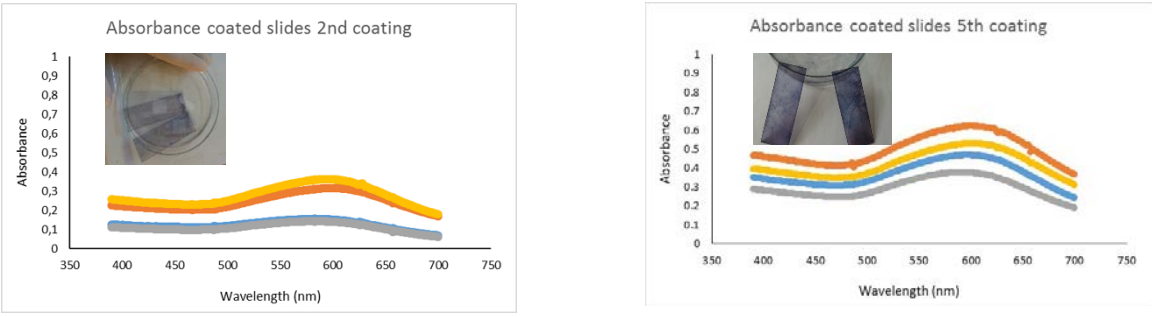

Figure 1. Catalyst deposition evolution.

The layer-by-layer method is appropriate to deposit catalyst with controlled optical characteristics that allow to absorb solar energy. This work provides evidence on the possibility of storing and releasing hydrogen using renewable energy during the storage-supply cycle. In particular, hydrogen could be recovered using solar energy in future processes based on LOHCs.

A Manganese Modified Fe_3O_4 Microsphere Catalyst with Effective Active Phase of Forming Light Olefins From Syngas.

Yi Zhang* and Yi Liu

1 [a]State Key Laboratory of Organic-Inorganic Composites, Beijing University of Chemical Technology, Beijing, 100029, China
**Corresponding author: yizhang@mail.buct.edu.cn*

Highlights

- The MnOx dispersed on the surface of Fe3O4 microsphere.
- The unique promoter-on-iron structure of obtained catalyst.
- The θ-Fe3C phase plays crucial roles in enhancing the light olefins selectivity.

1. Introduction

Light olefins (C_2-C_4) are key building blocks of the chemical industry and typically produced by steam cracking naphtha [1]. The direct conversion of syngas into light olefins via the Fischer-Tropsch synthesis (FTS) process is a promising route to meet the increasing demand for chemical feed-stocks [2]. It is well know that iron carbide is recognized as the active phase for the FTS reaction [3]. Herein, a manganese modified Fe_3O_4 microsphere catalyst was developed as illustrated in **Figure 1A**, where the MnOx dispersed on the surface of Fe_3O_4 microsphere to avoid the porous structure and solely modify the carburization of the catalysts.

2. Methods

The Fe_3O_4 microspheres were prepared by a solvothermal method [4]. For preparation of Mn/Fe_3O_4 catalyst, in order to improving the dispersion of supported Mn, an ethylene glycol solution of $Mn(NO_3)_2 \bullet 4H_2O$ was impregnated onto the Fe_3O_4 microspheres [5], followed by drying at 473 K under vacuum. The obtained catalysts were characterized by STEM-Mapping, HRTEM, XAFS, XPS, and Mössbauer spectroscopy.

3. Results and discussion

Figure 1B shows SEM image of the Fe_3O_4 microspheres, which possess uniformly spherical shape of ~300 nm. N_2 adsorption-desorption isotherms show representative type-Ⅱ curves, which is normally obtained with non-porous adsorbents [6]. Meanwhile, it was found that the MnO_x located at the edge of Fe_3O_4 microspheres as shown in **Figure 1C**. Hence, MnO_x should locate on the surface of the Fe_3O_4 microspheres as designed. It is considered that this unique promoter-on-iron structure of obtained catalyst would contribute to enhancing the promotional effects of manganese and clarifying the different role of iron carbides.

The prepared Fe_3O_4 microsphere catalysts were applied to FTS reaction for 50 h under 1.0 MPa, 593 K, and H_2/CO ratio of 1. The Mn/Fe_3O_4 catalyst with moderate amount of Mn (6 wt %) exhibits the best C_2-C_4 olefins selectivity (60.1 %) and lowest CH_4 selectivity (9.7 %) with better stability

compared with un-promoted Fe_3O_4 catalyst. The unprecedented efficiency of converting syngas to light olefins could be attributed to the special surface carbonaceous species, as confirmed by in situ XPS. The results on the activated catalysts show that the presence of significantly different surface carbonaceous species, and the charge of surface carbon atom was influenced by the Mn promoter. It is proposed that a specific carbide phase could be formed on the surface of Fe_3O_4 microsphere due to the presence of Mn promoter. This is also confirmed by Mössbauer spectroscopy and EXAFS. As shown in Mössbauer spectroscopy (Figure 2), a new carbide phase, identified as cementite (ϑ-Fe_3C), was discerned when Mn was added. Fourier transforms of the EXAFS spectra at the Fe K-edge **(Figure 1D)** show that, the Fe formed another carbide phase, ϑ-Fe_3C, in addition to χ-Fe_5C_2. Thus, it is reasonable to conclude that the ϑ-Fe_3C phase plays crucial roles in enhancing the light olefins selectivity.

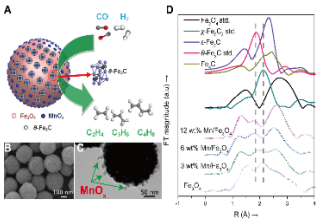

Figure 1 (A) Structural model for the Mn/Fe3O4 catalyst; (B) SEM images of the fresh Fe3O4 microspheres; (C) TEM images of the 6 wt % Mn/Fe3O4 catalyst after reduction; (D) Fourier transformed (FT) k3-weighted χ(k)-function of the EXAFS spectra. Solid lines denote reference samples of Fe3O4, χ-Fe5C2, ε-Fe3C, θ-Fe3C and Fe4C.

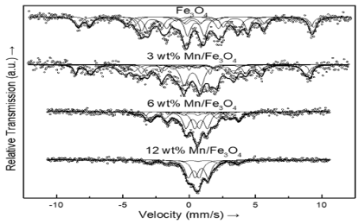

Figure 2 Mössbauer spectra of the iron-based catalysts after reduction.

4. Conclusions

The non-porous structure combined with dispersed manganese on the Fe_3O_4 microsphere surface contributes to enhancing the promotional effects of Mn and clarifying the different role of iron carbides. It was found that the ϑ-Fe_3C plays important role to enhance the selectivity of C_2-C_4 olefins during the FTS reaction.

Mathematical modeling of the hydrolysis process of sucrose

Vittorio Romano*[1], Brunella Ascione[1], Rino Apicella[1]

1 University of Salerno, Department of Industrial Engineering

**Corresponding author: vromano@unisa.it*

Highlights

- Hydrolysis process of sucrose
- Michaelis-Menten equation with enzymatic inhibitions
- Mathematical modeling
- Finite Element Method

1. Introduction

Simulations of the enzymatic hydrolysis of sucrose were conducted for a Michaelis-Menten kinetic with product and substrate inhibitions in a tubular reactor with axial and radial dispersion.

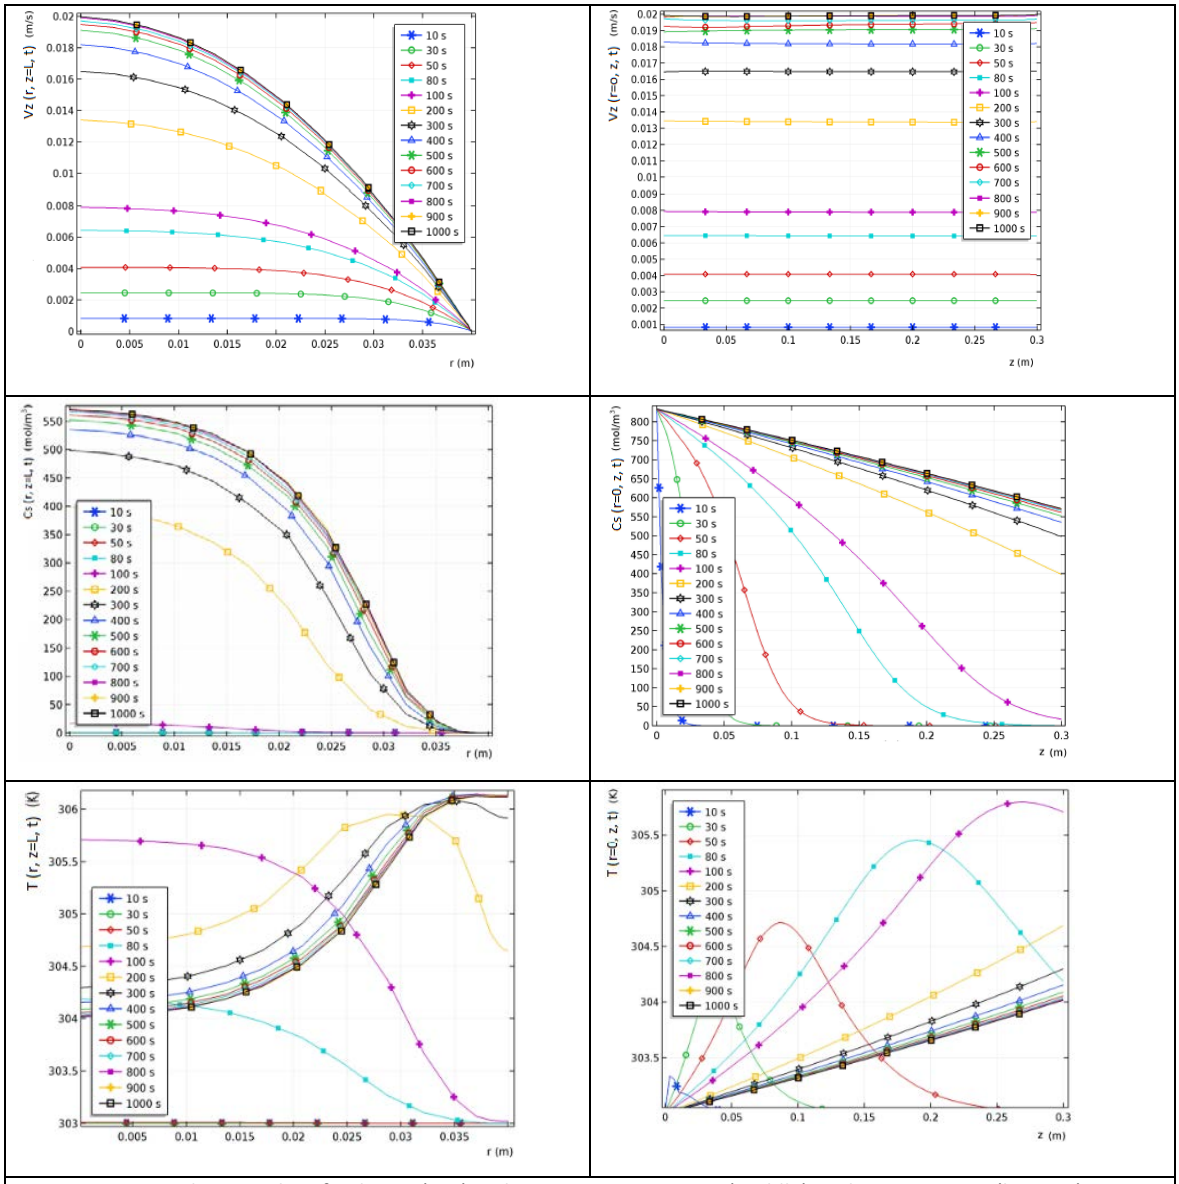
2. Methods

The sucrose enzymatic hydrolysis process was modeled as a laminar flow with average velocity v_m inside a tubular reactor of radius R=0.04 m and length L=0.3 m, triggered by a pressure drop between inlet and outlet sections, that generates a velocity component v_z (r,t). The transient sucrose concentration and temperature profiles result to be dependent both on the radial and the axial direction: Cs (r, z, t); T (r, z, t). The unsteady equations of mass and energy, including molecular and convective transport, were developed on a differential volume $\Delta V = 2\pi r\, \Delta r\, \Delta z$, considering a cylindrical coordinate system (r, θ, z).

$\mu\left(\frac{1}{r}\frac{\partial}{\partial r}\left(r\frac{\partial v_z}{\partial r}\right)\right)+\frac{P_{in}-P_{out}}{L}=\rho\frac{\partial v_z}{\partial t}$							
$-2v_m\left[1-\left(\frac{r}{R}\right)^2\right]\frac{\partial C_s}{\partial z}+\mathfrak{D}\frac{\partial^2 C_s}{\partial z^2}+\mathfrak{D}\left(\frac{1}{r}\frac{\partial C_s}{\partial r}+\frac{\partial^2 C_s}{\partial r^2}\right)-(-r_s)=\frac{\partial C_s}{\partial t}$							
$-2\rho c p v_m\left[1-\left(\frac{r}{R}\right)^2\right]\frac{\partial T}{\partial z}+k\frac{\partial^2 T}{\partial z^2}+k\left(\frac{1}{r}\frac{\partial T}{\partial r}+\frac{\partial^2 T}{\partial r^2}\right)-(-r_s)(-\Delta H_r)+16\mu {v_m}^2\frac{r^2}{R^4}=\rho c p\frac{\partial T}{\partial t}$							
$(-r_s)=\frac{K_3 C_{eT} C_S}{k_m\left(1+\frac{C_{S0}-C_S}{k_I}\right)+C_S+\frac{C_S^2}{k_{III}}}$							
$t=0$	$v_z=0$	$C_S=C_{S0}$	$T=T_0$				$\forall z, \forall r$
$r=0$	$\frac{\partial v_z}{\partial r}=0$	$\frac{\partial C_s}{\partial r}=0$	$\frac{\partial T}{\partial r}=0$	$r=R$	$v_z=0$	$\frac{\partial C_s}{\partial r}=0$	$\frac{\partial T}{\partial r}=0$	$\forall z, \forall t>0$
$z=0$	$C_s=C_{s0}$	$T=T_0$		$z=L$	$\frac{\partial C_s}{\partial z}=0$	$\frac{\partial T}{\partial z}=0$		$\forall r, \forall t>0$

The differential equations system was solved numerically by the finite element method.

3. Results and discussion



Time parametric line graphs of velocity (top), substrate concentration (middle) and temperature (bottom) against radial direction (left) and axial direction (right)

4. Conclusions

The radial concentration distribution is strongly influenced by the velocity profile, whereas along axial direction the only effect is due to the temporal evolution of the velocity. On the other hand, the temperature increasing for long times derives from the concentration consumption, considering that the reaction is exothermic.

BIONICO Project – A Case Study of Chemical Reactors Development & Prototyping at ICI Caldaie.

Carlo Tregambe

ICI Caldaie S.p.A. via G.Pascoli 38 , 37059 Campagnola di Zevio (VR) Italy

**Corresponding author: carlo.tregambe@icicaldaie.com*

Highlights

- Reactors development and prototyping
- Industrialization: from lab scale (TRL 4) to turnkey transportable reactors (TRL 9)
- Complete system integration and testing

1. Introduction

In the H2020 BIONICO project, a novel reactor concept that integrate H2 production and separation in a single vessel is been built by ICI Caldaie and will be demonstrated at TRL 6 at a real biogas plant, with a H2 production capacity of 100 kg/day. Main characteristics of the novel reactor are the utilization of fluidized bed catalyst for reforming reaction and Pd based membrane for pure H2 separation.

2. Methods

Synergies and deep cooperation between project partners were essential for the obtainment of the results.

Politecnico di Milano (coordinator): modelling and optimization of the innovative fuel processor - **TECNALIA:** Development of Pd-based supported membranes and membrane characterization - **Eindhoven Unversity of Technology:** Design, construction and testing of the lab scale membrane reformer - **Johnson Matthey:** development, characterization and testing of novel fluidizable reforming catalysts - **ICI Caldaie:** design, manufacturing and integration of the novel reactor at full size - **Quantis:** research on adapting environmental life cycle assessment (LCA) - **Rauschert:** Development of ceramic porous supports for the membranes - **ENC POWER:** field testing of the novel reactor in the ENC biogas plant.

3. Results and discussion

The activity of ICI Caldaie started 60 years ago in the business of high temperature and high pressure boilers (up to 950°C and 50 bar).

In the early 2000' ICI Caldaie became aware that chemical reactors were the proper and natural way to exploit the high level reached by its R&D department and started a dedicated laboratory called "ICI LAB".

Since the beginning of the activity “ICI LAB” created synergies between its academic partners and the industrial department of ICI CALDAIE, becoming a player able to have an holistic approach to the reactors business, starting from joint design solutions, through feasibility studies and up to the manufacturing, industrialization and integration of the reactors. Partnerships with universities, research centers and other industries all over the world have led to many projects (Internal 1, National 2,3, European 4,5) focused on the realization of chemical reactors and its integration in complex systems like CHP and production plant.

The first field of application was identified in the onsite hydrogen production from natural gas and Bio gas. Different reactors for hydrogen production were developed according to different sizes (from 3 to 50 Nm3/h) and different grades of purity for different hydrogen applications.

Together with hydrogen production and purification, the experience and knowhow acquired so far range from “CO2 capture and sequestration”, “gas to liquid reactors” to several other systems

Figure 1. BIONICO membrane reactor

Figure 2. Installation of H2FC cogeneration system prototype

4. Conclusions

Thanks to ICI manufacturing capability and proven ability of good knowledge transfer between industry and university, ICI is now screening new markets in reactor manufacturing business.

Highlights

- Oxygen stable Zn(II) complex used for the depolymerization.
- Main operating parameters identified through design of experiments.
- Reaction mechanism and kinetic modelling presented.
- Membrane separation process for product purification.

1. Introduction

Biodegradable-biorenewable polymers such as polylactic acid (PLA) are suitable candidates to replace synthetic oil-derived polymers. However, PLA can be still a potential source of environmental pollution. Chemical recycling presents an alternative to mechanical recycling or composting for end-of-life PLA that not only results in value-added products but that could also reduce production costs [1]. Although chemical recycling methods have been demonstrated in the literature (hydrolysis, acid-base depolymerization and transesterification) [2, 3], these processes are characterized for high temperatures (up to 260 °C). Milder operating conditions can be achieved in the transesterification reaction by using a complex metal catalyst. In this project, a Zn(**1**)$_2$ complex was used for the PLA degradation to produce methyl lactate (Me-La). Main operating parameters for the process were studied by a design of experiments. A preliminary evaluation of the use of membranes and distillation for the purification step is also presented.

2. Methods

Small Initial trials of the PLA degradation were performed in a Schlenk flask, with 0.25 g of PLA and 22.4 mg catalyst at 50 °C. THF was selected as the solvent whereas methanol as the reactant. Zn(**1**)$_2$ was first tested for oxygen stability. Me-La production was traced by GC and ^{1}H NMR. Polymer disappearance was confirmed by GPC. With the aim to show scalability of the process, reactions were then performed in a 300 mL SS-316 stirred batch reactor. Operating parameters for the Taguchi design of experiments were: polymer concentration, polymer molecular weight, catalyst concentration and reaction temperature. Additionally, mass transfer limitations of the process were studied by including polymer particle size and stirring speed. The effects studied were: PLA conversion, Me-La selectivity, Me-La yield and maximum amount of Me-La produced. Sensible values of the range of operating parameters were included in the model. The effects were statistically analyzed. The progress of all the reactions was traced by withdrawing samples at

different time intervals. Membrane separation studies were performed in a cross-flow system with a commercial membrane (Duramem 150), by varying pressure and temperature. Samples of the permeate were analyzed by GC and ^{1}H NMR.

3. Results and discussion

Zn(**1**)$_2$ was shown to be oxygen stable and easy to produce in large quantities. The statistical analysis of the results revealed that the main factors affecting conversion, selectivity and yield are temperature and catalyst concentration. No mass transfer limitations of the process were found. The maximum amount of Me-La produced only depends on the initial concentration of PLA. The observed experimental data was characteristic of two consecutive reactions showing formation of an intermediate and with the second reaction being reversible (Figure 1). The corresponding set of differential equations for the mass balance and rate equations were solved numerically coupled with a fitting procedure to get the kinetic constants for the different conditions studied. The temperature dependency of the kinetic constants for the PLA degradation step was evaluated by an Arrhenius type form. The activation energies obtained were in the range: 39 – 65 kJ/mol^{-1}, which are of the order of magnitude of other PLA degradation processes that require higher temperatures. Preliminary separation studies show the possibility of removing intermediate products by a commercial membrane. Solvent and alcohol can be recovered by distillation.

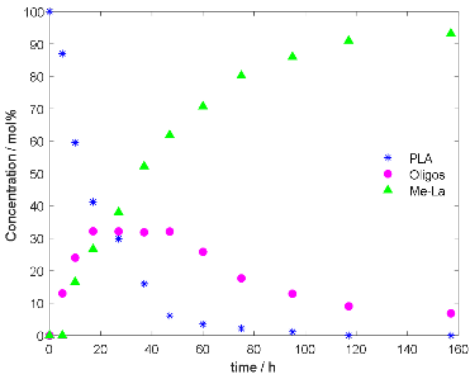

Figure 1. PLA degradation experimental data.

4. Conclusions

Complete degradation of PLA was demonstrated by the use of a metal complex catalyst which is stable in the presence of oxygen and that can be easily scalable. A valuable chemical (methyl lactate) was produced from this degradation. The main operating parameters of the process were identified and a kinetic model proposed. Kinetic constants and activation energies were calculated from the model that can be used for reactor design and optimization.

Highlights

- CO_2 as ammonium carbamate can be reduced to formic acid in hydrothermal media with a yield up to 38%
- Catalyst content, temperature and time are the relevant variables
- The formic acid yield is indirectly proportional to the initial concentration of carbamate
- The aluminum-water splitting reaction is feasible for reducing capture CO_2 without dry H_2

1. Introduction

The rapid population growing is making necessary the use of fossil fuels for the production of electricity, as well as fuel in the automotive industry, and will be still extended for many years [1]. This situation have encouraged to put the efforts in finding solutions concerning the mitigation of CO_2 emissions, such as CO_2 capture and storage technologies (CCS), and the Carbon Capture Utilization (CCU). The amine based CCS technology is one of the most attractive solutions nowadays, but the high cost of the desorption step entails to consider further possibilities. For instance, the French Company Alston developed a technology known as "Chilled Ammonia" [2]. In this technology, combustion gases are absorbed into an ammonia aqueous solution (28%wt) at low temperature (2-10˚C), to absorb CO_2 as carbonate, bicarbonate and carbamate of ammonia. Regeneration step consists also in desorption at temperatures between 100-150˚C, being less energetic than those from amines. Nevertheless, to completely avoid this step, our proposal is to reduce CO_2 captured in aqueous media as a carbamate with or without gaseous hydrogen. The last is achieved by the implementation of an environmentally friendly and economical hydrogen production technology like Aluminum-water splitting, and other reducers like zinc or biomass derivatives, which have proven to be effective in reducing sodium bicarbonate in hydrothermal media with efficiencies of up to 60% [3]. In the present work, the main product of the absorption of CO_2 in ammonia, the ammonium carbamate (AC), is transformed into formic acid in hydrothermal media, using metallic aluminum powder as reductant and Pd (5% wt) supported in activated carbon as catalyst, at temperatures from 80 to 200˚C and pressures above the saturation of water.

2. Methods

For stablishing the effect of the process variables on the production of formic acid (FA), several assays, under inert atmosphere of N_2, varying the temperature (80-300˚C), time (0.5-5 h), Al:AC molar ratio (3-9), catalysts content (7.5-60 wt% with respect to carbamate), liquid filling (50-85% of the total volume of the vessel) and initial concentration of aqueous AC solution (0.5-2.0M) were conducted in an stainless steel stirred reactor from Parr instruments, with autogenic pressure. The variation of the variables was performed based on a central point of reaction conditions (120˚C, 2h, Al:AC ratio of 6, 15% catalyst, 70% filling and 0.5 M of AC). The concentration of AC and FA were determined by means of HPLC (Waters, Alliance separation module e2695), using an Aminex 87H (Bio-Rad) column and RI detector (Waters, 2414 module).

3. Results and discussion

As observed in figure 1 (selectivity and conversion not disclosed), the time positively affects the yield, reaching 27% after 4 h of reaction and tends to level off, but with the depletion of selectivity. The highest selectivity (72%) is achieved at 0.5 h, indicating that the FA is formed faster than other possible compounds. The increase of initial concentration appears to not have a positive impact, since we observed a drop in the yield from 25% (0.5M) to 12% (2.0M). The temperature (not shown) presents a maximum yield of 20% between 120-150˚C. The catalyst content behaves similarly than time, allowing to obtain a yield as high as 38%, with a high selectivity of 85%, and conversion of 40% (not shown).

On the other hand, the Al:AC molar ratio does not have a great impact on the process. The liquid filling level also plays a positive effect over the process as the final autogenic pressure increases.

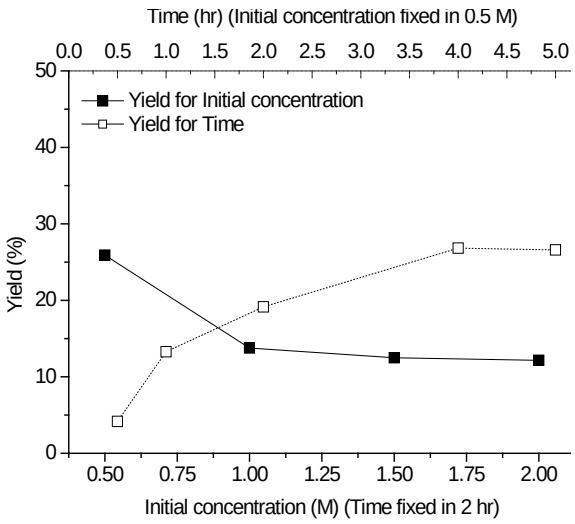

Figure 1. Effect of time and Initial concentration over Yield of FA

4. Conclusions

In the process to obtain formic acid, from the capture of CO_2 in aqueous ammonia solution, the variables that mostly affect the yield are the catalyst content, temperature and time. The reduction reaction can be achieved without the use of gaseous hydrogen with a yield up to 38% with an AC initial concentration of 0.5M. Scarce works have been found in the hydrothermal reduction of carbamates without dry hydrogen for producing value-added chemicals, representing a promising field of innovation.

Acknowledgments

This project has been funded by Junta de Castilla y León through project VA248P18. Juan Ignacio del Río acknowledges Universidad de Valladolid for the predoctoral fellowship. M. Dolores Bermejo thanks MINECO for Ramon y Cajal position.

Microstructured Reactor Development and Detailed Investigation into Catalyst Performance for Decentralized Power-To-Gas Applications.

Sarvenaz Farsi*, Wolfgang Olbrich, Peter Pfeifer, Roland Dittmeyer

Karlsruhe Institute of Technology, Eggenstein-Leopoldshafen/ Germany

**Corresponding author: Sarvenaz.farsi@kit.edu*

Highlights

- A detailed study of the methanation kinetics was carried out.
- A novel microreactor with internal cooling structure for hot spot control in methanation was developed and validated.
- Influence of different process parameters on reactor performance was studied.

1. Introduction

The growing interest in renewable energies calls for development of energy storage processes which support a balanced energy supply and demand and provide a stable power grid. In order to meet the problem of storing energy from renewable sources and to be carbon dioxide neutral, Power-to-Gas (PtG) applying CO_2 as carbon source is recognized as a promising future technology. The resulting synthetic natural gas (SNG) from methanation reaction can be either stored or injected without limits unlike H_2 into a natural gas grid, since the infrastructure for its transportation and storage already exists [1]. Moreover, steam generated from the highly exothermic methanation of carbon dioxide may be used for considerably increasing the overall process efficiency by feeding a steam electrolysis unit.

In the framework of Kopernikus project Power-to-X, we study the methanation reaction of carbon dioxide from both, reaction fundamentals as well as reactor development point of view.

2. Methods

To reveal the underlying kinetics of the methanation reaction, a microstructured packed bed reactor with highly efficient internal cross-flow cooling obtained at IMVT-KIT has been fabricated.

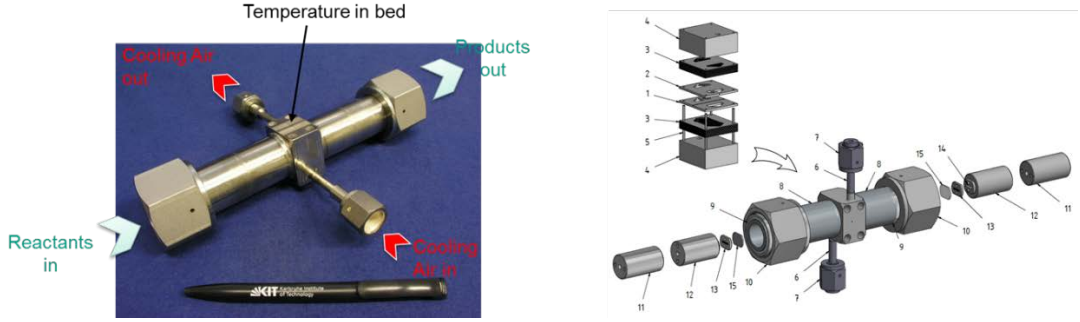

Figure 1 Packed-bed microstructured reactor used for kinetic measurements

Another focus of the work is dedicated to development and examination of a novel and compact evaporation cooled microstructured packed bed reactor for catalytic methanation of pure CO_2 for syngas throughputs of up to 2 Nm^3/h. The reactor (Figure 1) consists of two parallel reaction chambers in form of rectangular ducts. The heat management is accomplished by means of cooling channels above/below the reaction chambers and five heating cartridges between the reaction slits [2].

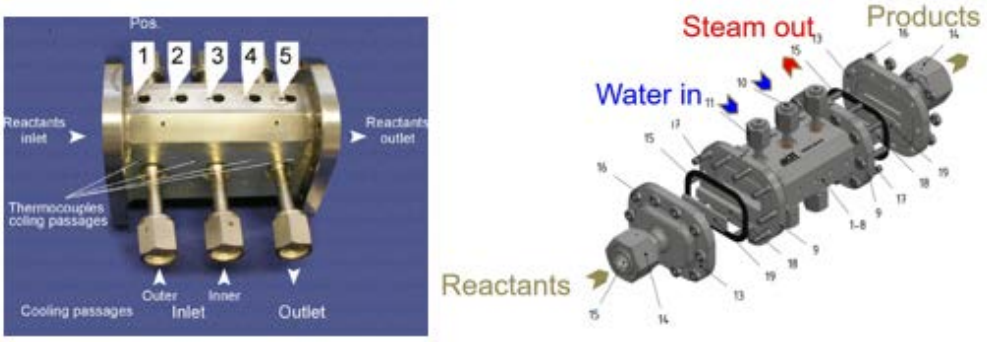

Figure 2 The microstructured reactor designed for methanation with two cooling inlets and one cooling outlet

3. Results and discussion

In the kinetic studies, the operation temperature, composition of the components in reaction and WHSV were varied to investigate their influence on reaction rate and stability of the catalyst. The results contributed to validation of the models for the catalytic methane production based on literature data for a stable and selective Ni_3Fe catalyst [3].

With regard to evaporation cooling, efficient heat removal and hot spot control by variation of the parameters of water feed were investigated. To assess the reactor behavior in cooperation with INERATEC GmbH, supply of pressurized water up to 20 bar to the cooling structures in different amount and distribution between the inlets was tested.

4. Conclusions

The in the current contribution parameters for reliable models for a wide range of process conditions are developed. The derived model can be applied to a microstructured reactor with internal evaporation cooling. The latter was also validated through this study.

Highlights

- A new chromatographic reactor model was developed.
- Methyl acetate hydrolysis was simulated.
- Full conversion and product separation were predicted.

1. Introduction

The esterification of carboxylic acid with alcohols is a hot topic of the modern bio-refinery, to produce, for example, solvents, plasticizers [1]. Nowadays, a lot of effort is in progress to optimize the synthesis of several esters. The right reactor should optimize the physical characteristics of the system that is, as before mentioned, a liquid-solid reaction: i.e. Mazzotti et al. [2], used the simulated moving bed reactor (SMBR) packed with Amberlyst-15 catalyst to perform acetic acid esterification to ethylacetate, demonstrating that the resin can be used both to catalyze the reaction and separate the stream. It is important to underline that to design such apparatus, accurate and reliable models are needed, involving profiles along different coordinates (time, reactor radius, reactor axis and catalyst radius) [3], the knowledge of physical and chemical properties, and powerful tools to reach a reliable solution. In the present work, the development of a reactor model, that can be used to interpret experimental data collected in chromatographic reactors will be presented. Methyl acetate hydrolysis catalyzed by DOWEX 50W-X8 catalyst was chosen as case study [4].

2. Methods

The developed model can be considered an advancement respect to the recent efforts published in the literature [4]. The breakthrough idea is to develop a model where no rate-determining-step is considered, writing the opportune mass balance equations on both the liquid bulk and intraparticle phases. All the physical parameters were calculated from existing correlations. The liquid bulk and intraparticle mass balance equations are respectively reported in Eqs. 1-2.

$$\frac{\partial C_{i,B}}{\partial t} = -u\frac{\partial C_{i,B}}{\partial z} + D_z\frac{\partial^2 C_{i,B}}{\partial z^2} - k_m a_{sp}\left(C_{B,i} - C_{i,L}\big|_{r_P=R_P}\right) \quad (1)$$

$$\varepsilon\frac{\partial C_{i,L}}{\partial t} + (1-\varepsilon)K_i\frac{\partial C_{i,L}}{\partial t} = \varepsilon\frac{D_P}{r_P^s}\frac{\partial}{\partial r_P}\left(r_P^s\frac{\partial C_{i,L}}{\partial r_P}\right) + (1-\varepsilon)\frac{D_S}{r_P^s}\frac{\partial}{\partial r_P}\left(r_P^s\frac{\partial K_i C_{i,L}}{\partial r_P}\right) + (1-\varepsilon)\nu_{ij}r_j \quad (2)$$

The model was implemented in gPROMS ModelBuilder v.4 software, solving the axial and particle radial partial derivatives with a centered finite difference method with respectively 150 and 25 discretization points.

3. Results and discussion

Methyl acetate (MA) hydrolysis kinetic rate laws with related parameters are fixed and directly taken from literature [4]: the authors carried out different experiments by fixing the flow-rate at 0.75 mL/min and injecting pulses of 100 µL of a 0.5 mol/L solution of methyl acetate in water, at different temperatures (from 298 to 328 K). The results are reported in Fig. 1-left, together with the model predictions. As revealed, a temperature increase corresponds to an increase of the reaction conversion (the MA area decreases) with the related formation of the two products (M and A). Parameter estimation was carried out to obtain the surface diffusivity for each component, obtaining that the surface diffusivity values follow the order MA>M>A. The trend is due to the different acidity of each component, interacting with the acid solid phase. A parametric investigation was conducted evaluating the effect of different operation conditions on both the acid conversion and product separation (Fig. 1-right). It was possible to achieve complete MA conversion and product separation fixing the reactor length to L=2.50 m and T=323K, demonstrating high performances of the chromatographic reactor.

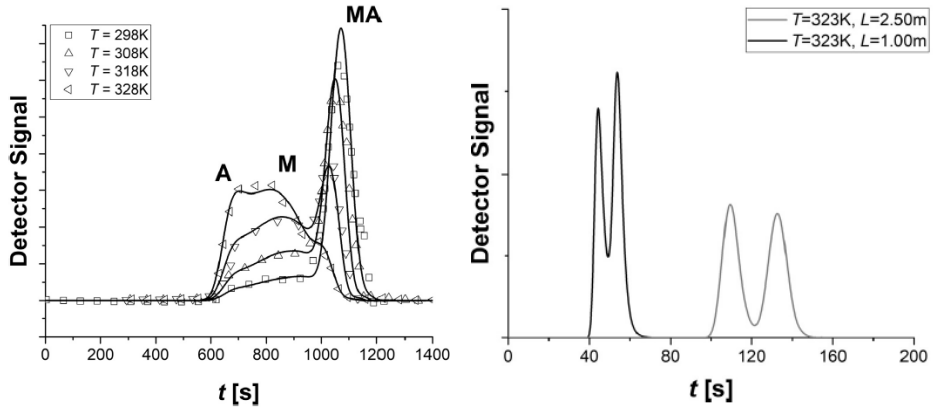

Figure 1. (Left) Description of experimental data taken from literature [4]: symbols are experimental data, lines the model description. (Right) Simulation of full conversion and total product separation.

4. Conclusions

A novel chromatographic reactor model was developed to interpret experimental data dealing both with the esterification of carboxylic acids and with the hydrolysis of organic esters. The model is advanced respect to the state of the art because no rate-determining steps are considered. All the physical and chemical phenomena are considered. In perspective, the model can be applied in optimizing the esterification/hydrolysis processes.

Highlights

- 2G ethanol bioconversion process still needs to overcome process challenges.
- Inhibitors from lignin degradation hinder the biochemical reactions.
- Removal of soluble inhibitors improved the conversion of the hydrolysis.

1. Introduction

The large scale production of 2G ethanol is still under development and needs to overcome obstacles such as high solids loading in the reactors, in addition to inhibitors impairing the biochemical reactions (1). Inhibitors released from both chemical degradation of lignin and cellulose/hemicellulose during the pretreatment process negatively impacts the subsequent steps (2). During enzymatic hydrolysis of biomass, the phenolic inhibitors from lignin degradation deactivate and/or inhibit the biological catalysts (3-4), increasing the amount of enzymes required. In this context, the configuration of the overall processes with a detoxification of soluble inhibitors is a possible strategy for contributing to the feasibility of large-scale process (3). Washing the pretreated biomass with hot water, for instance, has been shown a high removal of inhibitors from steam pretreated hardwood (5). Thus, the purpose of this work was to investigate a feasible protocol for washing pretreated sugarcane bagasse in order to improve the enzymatic hydrolysis process.

2. Methods

Hydrothermal pretreatment of sugarcane bagasse was carried out at 195 ° C, 10 minutes and 15% solids (w:w). The washing protocols were carried out using hot water at 90 °C. The first procedure consisted in homogenization of the mixture water and biomass at 10% solids (t_{MIX} < 1 minute), followed by filtration for 2 and 3 washing steps. The second washing process was conducted using a batch with 3% solids during 10 minutes for 6 washing steps (assuring the stabilization of the pH of the washing water). Subsequently, the enzymatic hydrolysis was performed at 50°C, 15% solids (w:w) and 10 FPU/g of dry bagasse in sodium citrate buffer (50 mM, pH = 5.0). Glucose was determined using a D-glucose enzymatic assay kit (Liquiform®, Brazil).

3. Results and discussion

The enzymatic hydrolysis conversion of washed pretreated biomass from first washing procedure with 2 washing steps removed the soluble inhibitors and improved up to 30.2% the conversion during enzymatic hydrolysis.

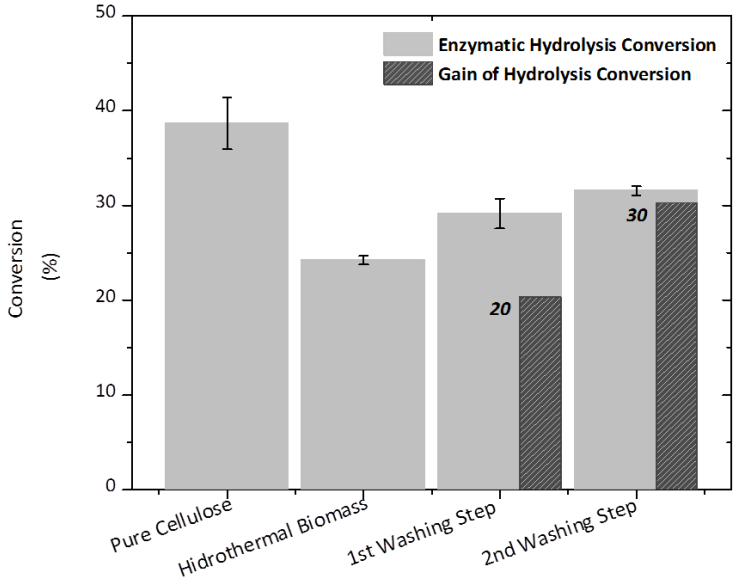

Figure 1. Conversion in the hydrolysis stage for each biomass processing and the conversion gain for the unwashed hydrothermal bagasse (52.41 % of cellulose).

On the other hand, the severe conditions of time and the many stages of washing with a lower solids loading (3% w:w) showed a negative impact on the enzymatic hydrolysis reaction (second protocol). This washing procedure not only removed the soluble inhibitors, but also helped to solubilize and disperse the remaining lignin in the biomass, resulting in the blocking of biomass to the action of the enzymes.

4. Conclusions

The results suggest that for improving the enzymatic conversion, the study of different washing proceedings is crucial to optimize the removal of soluble inhibitors during the production of 2G ethanol.

Reaction pathway network and kinetic model development for catalytic HDO of furfural over Ru/C and Rh/C

Rok Šivec[1], Miha Grilc[1], Blaž Likozar[1]

1 Department of Catalysis and Chemical Reaction Engineering, National Institute of Chemistry, Hajdrihova 19, 1000 Ljubljana, Slovenia

**Corresponding author: Miha.Grilc@ki.si*

Highlights

- Furfural is used as a renewable source for value added product production.
- Hydrodeoxygenation of furfural was carried out in a stirred three-phase reactor.
- Ru/C and Rh/C catalysts were used.
- A microkinetic model was developed and fitted to experimental data.

1. Introduction

Furfural is a very promising platform chemical, which can be produced from renewable sources, such as lignocellulosic (LC) biomass. The use of LC materials is increasing due to demand, and so are its residues (wastes), which are produced in millions of tons annually. [1] As a result, furfural is already produced in large quantities (close to 300 kTon annually). Furfural can be used as a valuable bio-derived source for many value added chemicals and biofuels. [2]

The hydrodeoxygenation (HDO) reaction of furfural with gaseous hydrogen was studied, by using different heterogeneous catalysts, such as Ru/C and Rh/C, in a high-pressure three-phase batch reactor system. Neat furfural and its iso-propanol solutions were used and various process parameters were varied. Furthermore, the reaction mechanism is being studied and a microkinetic model developed. The model will be fitted to experimental data. The use of different catalysts will also be compared.

2. Methods

A three-phase batch reactor was used, consisting of a 300 mL vessel, Rushton turbine stirrer and sampling lines for liquid and gaseous phase. 100 mL of liquid medium was used, composed of pure furfural as the main reactant or furfural dissolved in iso-propanol, while the latter has not only the role of a solvent but also participates in the reaction as a hydrogen donor. A solid catalyst (Ru/C or Rh/C) was added afterwards. The reaction vessel was closed, flushed with N_2 and pressurized under pure hydrogen at high pressure (50 bar at room temperature). The convective heat and mass transfer was assisted with vigorous stirring at 500 rpm. The reaction mixture was heated-up with a heat-up rate of 5 K min^{-1} to the temperatures of plateau at 175 °C, 200 °C and 250 °C, respectively. Liquid and gas samples were taken during the experiment and analysed by GC-MS/FID and NMR (liquid samples), and by GC-FID/TCD and FTIR (gaseous samples). At the end of the experiment, the reaction vessel was rapidly cooled down and flushed with N_2.The microkinetic model is being developed in Matlab software according to the proposed reaction sheme in Figure 1.

3. Results and discussion

100% conversion of furfural was achieved during the reaction (Figure 2), leading to numerous intermediates and products, such as Furfuryl alcohol, 2-methylfuran, 2-methyltetrahydrofuran, Tetrahydrofurfuryl Alcohol, 2,2'-[oxybis(methylene)]difuran and others. According to the microkinetic model, furfural is firstly hydrogenated to furfuryl alcohol. Three parallel reactions occur afterwards: a) furfuryl alcohol hydrogenation to tetrahydrofurfuryl alcohol and subsequent hydrodeoxygenation to 2-methyltetrahydrofuran, b) furfuryl alcohol hydrodeoxygenation to 2-methylfuran and subsequent hydrogenation to 2-methyltetrahydrofuran and c) furfuryl alcohol oligomerization to 2,2'-[oxybis(methylene)]difuran with subsequent hydrogenation to furfuryl alcohol and 2-methylfuran, which are further converted as already mentioned.

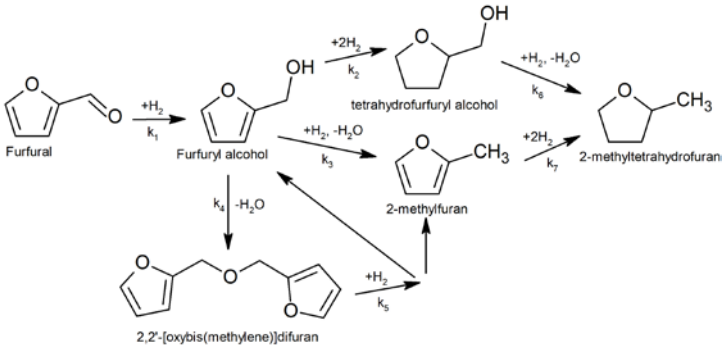

Figure 1. Proposed reaction scheme.

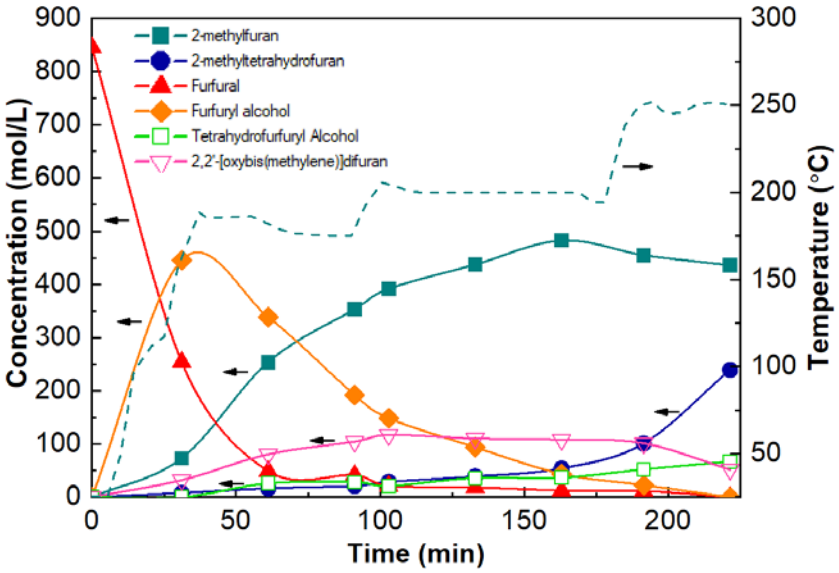

Figure 2. Experimental data of furfural conversion over Rh/C catalyst.

4. Conclusions

Experiments of furfural hydrodeoxygenation were carried out with the use of Ru/C and Rh/C catalyst. The results are promising for 2-methylfuran and 2-methyltetrahyfdrofuran production. The developed microkinetic model will be fitted to experimental data points and used to predict the reaction at different conditions.

Highlights

- The theory for the total pressure method applied on the study of heterogeneously catalyzed kinetics was presented
- Experiments on methanol synthesis was carried out in a intensively stirred batch reactor
- The reaction-diffusion model for porous particles were used to interpret the data and to determine the kinetic parameters
- The applicability of the total pressure method was demonstrated for methanol synthesis and generic examples

1. Introduction

The total pressure method is well-known for the measurement of the kinetics of homogeneous gas-phase reactions. If the number of molecules change in a gas-phase process, the total pressure in a closed reactor vessel changes indicating the progress of the reaction. The total pressure method can be applied to heterogeneously catalyzed gas-phase reactions, too. In this work, the general theory for the interpretation of kinetic data in stirred batch reactors is presented. The concept was applied to the synthesis of methanol from carbon monoxide and hydrogen on a commercial copper-based catalyst.

2. Methods

The catalyst particles were placed in a spinning impeller which rotated at high speed, typically 300-600 rpm. The volumes of the autoclave reactor and the gas phase were constant. Catalyst particles of equal sizes were used in all the experiments and isothermal conditions prevailed. The reaction temperatures and pressures were 150-250ºC and 10-30 bar, respectively. The classical modelling approach, based on simultaneous chemical reactions and diffusion in porous media was applied. This implies that that separate mass balances are valid for the gas-phase components in the gas bulk and in the catalyst pores. The catalyst particles were presumed to be chemically (activity, number of active sites) and physically (particle size, porosity, tortuosity, surface area) equal. Thus the aspects of particle size distribution and chemical inhomogeneity of the catalyst surface were ignored.

The model for the catalyst particles in the rotating device is

$$\varepsilon_P \frac{dc_i}{dt} = \frac{D_{ei}}{R^2}\left(\frac{d^2c_i}{dx^2} + \frac{s}{x}\frac{dc_i}{dx}\right) + r_i\rho_P$$

where x = the dimensionless particle coordinate, R = particle radius, s = shape factor, r_i= the generation rate of component i, ρ_P = particle density, ϵ_P = particle porosity, D_{ei} = effective diffusion coefficient. For the gas bulk surrounding the spinning impeller, the balance equation is given by

$$\frac{dc'_i}{dt} = -\frac{D_{ei}}{V_G R}\left(\frac{dc_i}{dx}\right)_{x=1} n_P A_P$$

where n_P and A_P denote the number of particles and their outer surface area, respectively. V_G is the gas volume. The model was solved numerically and the parameters were estimated from collected total pressure data.

3. Results and discussion

The results of the sensitivity analysis of the model revealed that the increase of the kinetic constant leads to a faster decrease of the overall pressure. The initial pressure plays an activating role on the reaction kinetics as well. By working at higher H_2/CO ratio, a lower rate is observed. Examples of the intraparticle profiles of carbon monoxide and hydrogen are displayed in Figure 1, which confirms the role of the internal diffusion effect in the catalyst pores as concentration gradients appear inside the particles.

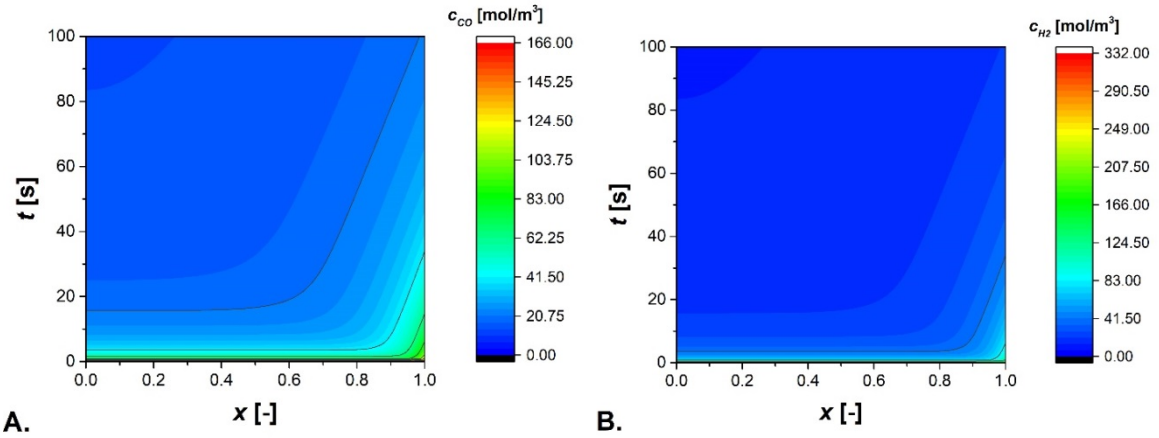

Figure 1. CO (A) and H_2 (B) concentration profiles inside the catalyst particle.

4. Conclusions

Rapid methods are very valuable in the determination of the kinetic and mass transfer effects for heterogeneously catalyzed reactions. The total pressure method is a classical tool in the measurement of the kinetics of gas-phase reactions. It can be successfully applied to the kinetics of gas-phase processes enhanced by solid catalysts. A general theory for the analysis of heterogeneously catalyzed gas-phase kinetics in stirred batch reactors was presented for the case of the kinetic control and combined kinetic-diffusion control. The concept was successfully applied to gas-phase synthesis of methanol from carbon monoxide and hydrogen.

Highlights

- The degradation of ibuprofen by catalytic ozonation was studied.
- A kinetic model was developed.
- The model gave a valid description of data.

1. Introduction

Pharmaceuticals are continuously entering surface waters due to the growing worldwide consumption which is a health risk to humans as well as the environment [1]. Hundreds of different compounds – painkillers, inflammatory mediators, hormones and antibiotics are eluted to the seas, because conventional water treatment plants cannot eliminate these compounds from wastewaters. Ozonation is a good treatment upon removal of micropollutants; however, low mineralization, peril by-products, limited ozone solubility and low stability in water are the main shortcomings of ozonation. The limitations of using ozone alone can be avoided by combining solid catalysts with ozonation which promotes the of ozone reactivity and the formation of hydroxyl radicals, and eventually a complete mineralization becomes possible [2]. In order to progress towards process design, a detailed mathematical model for the three-phase system is required.

2. Methods

Semibatch ozonation experiments were conducted in a double jacketed glass reactor (1100 ml) connected to an ozone generator (Fig. 1). The experiments were managed in a gas-liquid reactor system which consisted of the aqueous phase containing IBU, ethanol and deionized water in batch, while the gas mixture containing ozone was continuously bubbled from the bottom into the solution through a disperser. In case a catalyst was used, it was immobilized inside the stirrer, which is a special mixing device (Spinchem™ Rotating Bed Reactor) that maximizes the mass transfer between all phases. The operating conditions were: concentration of ibuprofen (IBU): 10 mg/L, ethanol 10ml/L, gas flow range: 250-1100 ml/min, mixing rate: 900-1070 rpm, temperature: 5-30˚C and the reaction time was typically 2-4 h. For the catalytic experiments, a preset amount of 0.25-0.5 g catalyst (zeolites) were used in a rotating mixer.

3. Results and discussion

The kinetic model for catalytic ozonation of IBU was implemented in gPROMS, which helped to describe and evaluate the reaction kinetics. The dissolved ozone concentration and the kinetic parameters were modeled based on the experimental data, and the data were utilized to model the ibuprofen decomposition using a number of experiments performed under various conditions. An improved understanding on the complex behavior of the reaction system was successfully achieved thanks to the model.

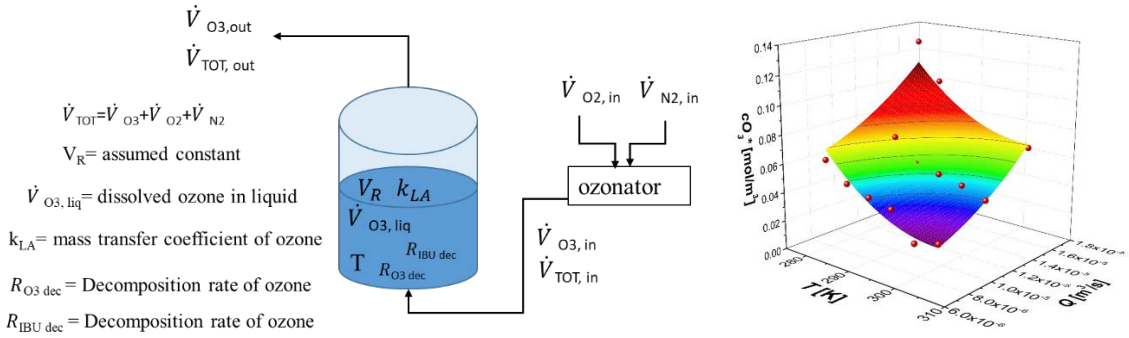

Figure 1. Left: The reactor setup and considered parameters for modeling. Right: fitting of the dissolved ozone concentration vs T(°C) and gas flow rate.

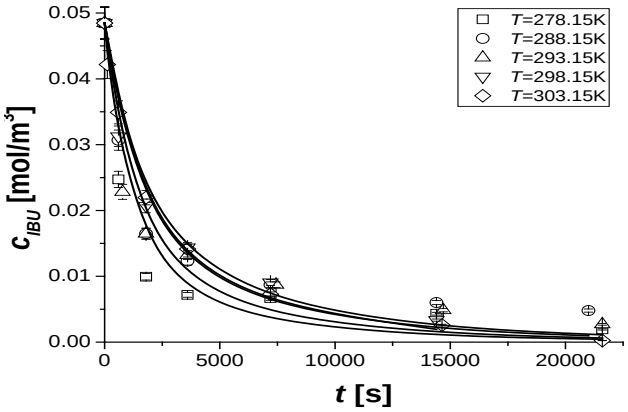

Figure 2. IBU ozonation experiments conducted at different temperatures without heterogeneous catalyst. Symbols represent the experimental data, lines the calculated profiles.

A preliminary interpretation was achieved to describe the experiments conducted in the absence of heterogeneous catalysts. The calculations were performed by fixing a power-law rate expression, finding apparent reaction orders of 1.5 for ibuprofen and 3 for ozone, suggesting a complex reaction mechanism. The activation energy was determined to 100kJ/mol. The results are portrayed in Figure 2. As revealed, a good fit was obtained. The model was further developed to describe the ozonation system in the presence of heterogeneous catalysts, where the catalyst amount, the mixing intensity and the active metal species were shown to have an important role.

Conclusions

An extensive study of ibuprofen removal was carried out. The ozonation system and the ibuprofen decomposition with and without heterogeneous catalyst was successfully modeled.

Highlights

- Efficient fractionation method with organic solvents widely used in industry and with low boiling point
- Obtaining of different molecular weight fractions
- Lignin fractionated with different structure and properties

1. Introduction

In current times, the utilization of materials from renewable resources has been severely promoted, as well as the revalorization of industrial wastes for the production of high added value materials. Therefore, biorefineries of lignocellulosic materials are key not only for the pollution reduction, but also for the sustainable development, being the means of obtaining fuels, chemicals and renewable materials[1]. For all these reasons, it can be predicted that all the main components of biomass (lignin, hemicellulose and cellulose) will significantly contribute to the global bioeconomy[2].

Lignin is one of the most interesting components of lignocellulosic materials. It is the most abundant aromatic compound on earth as well as having high availability and low price. However, it has great heterogeneity, and its properties, linked with composition and structure, also vary. Consequently, its uses are limited and in order to incorporate lignin in added value applications, its fractionation is an essential requirement to be used as feedstock in the industry[3].

One of the most promising methods is the use of organic solvents. This method allows separating lignin in different fractions to obtain fractions with specific properties by the successive utilization of different organic solvents. Apart from that, it was also taken in consideration the fact that these organic solvents were environmentally friendly and they could be bio-derived[4]. Therefore, the main objective of this work was to study the fractionation of industrial kraft lignin, as well as organosolv lignin, to separate it in more homogeneous fractions and characterize their structure and composition.

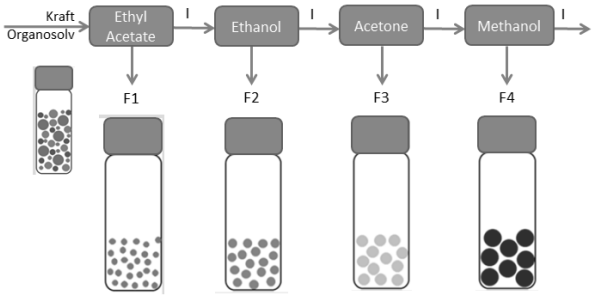
2. Methods

The fractionation was conducted using two types of lignin, kraft (from local industrial waste) and organosolv (commercial provided by *chemicalpoint*). They were dissolved firstly in ethyl acetate, the organic solvent with the lowest capacity to dissolve lignin. The insoluble fraction was obtained by filtration whilst the soluble fraction (F1) was obtained by rotavaporation of the solvent. The

next step was followed with the insoluble fraction with the next solvent with the lowest solubility, ethanol. The same procedure was followed, except for the fact that the soluble fraction (F2) was obtained by precipitation with acidified water. The sequence was finished after using acetone and methanol, respectively, to obtain the two remaining fractions (F3 and F4).

The obtained fractions were analyzed to determine their structural and thermal properties. Gel Permeation Chromatography (GPC) was conducted to know the molecular weight of both lignins and their fractions. Fourier Transformed Infrared was also performed, as well as the spectrophotometric method of Folin-Ciocalteau to calculate the total phenolic content, Py-GC-MS to identify the main components, and the glass transition temperature and thermal stability were determined.

3. Results and discussion



Mw		F1	<	F2	<	F3	<	F4
OH content		F1	>	F2	>	F3	>	F4
Py	S/G	F1	>	F2	>	F3	>	F4
	Purity	F1	>	F2	>	F3	>	F4

Figure 1. Schematic representation of the fractionation process and summary of the results obtained.

Although the kraft and the organosolv lignin have different characteristic, the same tendency could be observed during the fractionation process, obtaining molecules of the smallest molecular weights first and the biggest ones last.

It can also be observed the influence of the fractionation in the total phenolic content, since the molecules with the smallest weight had the largest phenolic content. From the pyrolysis analysis it was noticed that the purity increased after the fractionation method and that he first fractions (F1 and F2) contained a higher syringil derived components quantity.

4. Conclusions

It can be concluded that the fractionation method is efficient. First of all, it could be observed that the molecular weights of the fractions increased along the solubility parameter of the organic solvent used. Moreover, the content of phenolic hydroxyl groups diminished, which leads to an increase in the content of condensed compounds.

Highlights

- Propyl-sulfonic acid functionalized SBA-15 catalyst was synthesized.
- The catalyst characterization was performed.
- The esterification reaction of myristic acid with methanol was conducted.
- Kinetic parameters of the reaction were determined.

1. Introduction

Acid catalysis is one of the most important catalytic processes in the chemical industry. Industrially important organic transformations include esterifications and transesterifications [1,2]. Solid acid catalysts present an alternative to dangerous and corrosive mineral acid catalysts used in the industry. They contain more environmentally benign components, while providing higher activity and selectivity in comparison with existing homogeneous catalysts.

Mesoporous silicas, a type of solid acid catalyst, are solid inorganic carriers with large surface areas and relatively large ordered pores. Catalysts based on silica are inexpensive, simple to synthesize, and insoluble in most organic solvents, which allow them to be recycled. One type is modified mesoporous silica SBA-15, which is applicable for a wide variety of organic reactions [3].

In this study, mesoporous silica SBA-15 was functionalized with sulfonic acid, a very suitable catalyst for acid-catalyzed reactions. We used a slightly modified single-step synthesis based on simultaneous hydrolysis and condensation. After extensive characterization, the catalyst was tested performing the esterification reaction of myristic acid with methanol.

2. Methods

Propyl-sulfonic acid functionalized SBA-15 was synthesized by the one-step co-condensation procedure. The catalyst characterization was performed applying XL-30 scanning electron microscope from Philips and ZetaSizer Nanoseries from Nano, a Tristar II 3020 porosimeter from Micromeritics, FTIR IRAffinity-1 from Shimadzu and TA4000 from Mettler Toledo.

All experiments were performed in a batch reactor at different temperatures, ϑ = (55, 60 and 64.5) ºC and stirrer speed, f_s = 600 min^{-1}, loading of the catalyst, m = (0.2, 0.4 and 0.6) g and 10 mL of myristic acid solution in methanol with an initial concentration, γ = 15 g/L. The analyses of myristic acid were performed on a Shimadzu GC-2010 equipped with an autosampler AOC-20s and a flame ionization detector (FID).

3. Results and discussion

The myristic acid conversion was calculated from determined concentration of myristic acid in the reaction medium. The results at 55 °C are presented in Fig. 1. At 55 °C the conversion of myristic acid after 1 h was 49.9, 68.2, 81.7 % and 93.7, 98.7, 99.0 % after 5 h, applying 0.2, 0.4 and 0.6 g of the catalyst, respectively. We can observe that at the beginning of the reaction the conversion is highly dependent on the amount of catalyst used, while at the end those differences are not so pronounced.

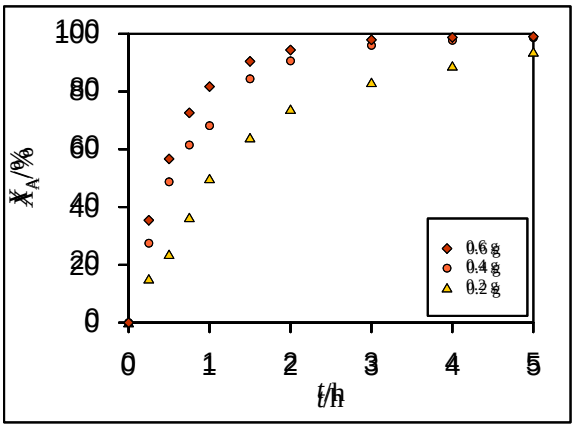

Figure 1. Conversion of myristic acid versus time at different catalyst loadings, ϑ = 55 °C and f_s = 600 min^{-1}.

In order to calculate reaction rate constants, the Langmuir-Hinshelwood-Hougen-Watson model was applied. The plots $\ln((M - X_A)/M\,(1 - X_A))$ versus t were constructed for all sets of experimental data. The reaction rate constants were then obtained from the slopes of the lines divided by c_{A0} $(M - 1)$ term. The Arrhenius equation was used to calculate activation energies and pre-exponential factors form the determined values of reaction rate constants at different temperatures. The average activation energy for myristic acid esterification was found to be E_a = 32.2 kJ/mol.

Three subsequent reactions were performed with each batch of the catalyst to test the deactivation between individual repeated reaction. The results revealed that used catalyst is highly resistant to deactivation, because there were practically no differences in the conversion for the 1st, 2nd or 3rd reaction.

4. Conclusions

Functionalized mesoporous silica SBA-15 containing sulfonic groups was synthesized with a modified one-step procedure. The results of catalyst characterization reveal that SO_3H functional groups are incorporated in the structure of homogenous particles with a random distribution. The catalyst has high catalytic activity in esterification reaction and is easily separated from the reaction medium. We confirmed the high potential of the catalyst's reuse with no significant loss of activity between consecutive reactions. Additionally, the kinetic parameters of the reaction were determined and they are in accordance with the literature data.

Highlights

- 3D structured catalysts show promising performance and low pressure drop
- Examined correlation between pressure profile and reactor performance
- Performance of a scaled up reactor for OCM demonstrated

1. Introduction

Powdered catalysts in most cases offer high reactivity and specific surface area, both for oxidative coupling of methane (OCM) and other gas phase reactions. However, powdered catalysts have significant drawbacks too. Their use often results in high specific pressure drops and they are difficult to handle and maintain. This is the reason that powdered catalysts are rarely used in large-scale applications. On the other hand, pelletized catalysts are conventionally used, as they are easier to work with and show a decent compromise between reactivity and pressure drop. The use of modern 3D printers opens up the possibility to print catalyst material directly. 3D printed catalysts represent a real alternative to pellets with tuneable porosity, high surface area, low pressure drop and improved heat and mass transfer.

The aim of this work is a comparative investigation into powdered, pelletized and 3D structured catalysts on a miniplant scale using the example of the oxidative coupling of methane.

The OCM reaction is a promising way to produce ethylene directly from natural gas or biogas. It presents an attractive alternative to naphtha cracking as it can utilizes different and more widely available feedstock.

2. Methods

For all the experiments that were carried out, MnNa2WO4/SiO2, provided by Johnson Matthey, was used as catalyst for the OCM reaction testing. The powder was first pressed and subsequently ground to obtain a particle size range of dp=400-600µm. The pellets, provided by Johnson Matthey too, were produced through extrusion with a particle size of 2.7mm. The catalyst powder was printed by VITO into catalyst structures with periodic lattices, using a direct write technique that offers a high degree of control over the composition, surface area and geometry.

The structures, pellets and source powder (Figure 1) were tested in a miniplant scale reactor at TU Berlin with a total reactor volume of 1.8l. The performance in terms of C2 yield was assessed under different temperatures and feed rates. Other parameters, such as the CH_4 to O_2 ratio, pressure and dilution were kept constant.

In order to examine the possible loss of reactivity due to the fabrication process, a second set of experiments was performed. The pellets and structures were ground back to a powder with the same particle size as the source material. Subsequently, the three powder samples were tested in a smaller size fixed bed reactor under the same operating conditions.

Figure 1. MnNa2WO4/SiO2 catalysts for OCM reaction tests; powdered (left), pelletized (middle), 3D printed structures (right)

3. Results and discussion

The main design considerations in the scaled-up reactor were (1.) facilitating the stacking of the 3D printed structures and (2.) ensuring a robust seal between the perimeter of the structures and the inner wall of the reactor tube in order to prevent gas from bypassing along the length of the reactor. The resulting scaled-up reactor demonstrates the design modularity and ability to perform OCM reactions in applications that are larger than lab scale.

The preliminary results of testing the structured catalysts are promising when compared to the conventional packed bed configurations. The influence of the different catalyst shapes on the pressure drop along the reactor was examined and quantified showing a correlation between the specific surface area and the reactivity, or C2 yield. Furthermore, it can be seen to what extent the production process of the pellets and 3D printed structures influence the reactivity of the catalyst.

4. Conclusions

In this work, the different shapes of OCM catalysts and their influence on C2 yield have been quantified and compared. It has been shown that 3D printed structures have the potential to provide tailor-made catalysts for large-scale applications, offering increased accessibility of the active sites within their engineered porosity.

Continuous reactive distillation for the esterification between glycolic acid and butan-1-ol

Carole Mutschler[1], Clémence Nikitine[1], Pascal Fongarland[1]

1 Laboratoire de Génie des Procédés Catalytiques, Université Claude Bernard Lyon 1, CPE Lyon, CNRS,43 bd du 11 novembre 1918, B.P. 82077, 69616 Villeurbanne cedex, FRANCE

**Corresponding author: cmu@lgpc.cpe.fr*

Highlights

- Characterization of a reactive distillation column
- Reaction between glycolic acid and butanol in a continuous reactive distillation in the transient state

1. Introduction

The production of bio-based carboxylic acids have aroused considerable interest in industrial field as intermediate products. By oxidizing glycerol in aqueous phase, formic acid, oxalic acid and alpha hydroxy acids such as lactic, glycolic, glyceric and tartronic acids were obtained [1,2]. These acids have low volatility with each other, and some of them are subject to thermal degradation at higher temperature (tartronic acid, glycolic acid …). Hence, their separation tend to be difficult by simple distillation. To overcome that issue it has been decided to esterify those acids with an alcohol. Using reactive distillation to esterify alpha hydroxy acids has already been developed in order to remove water and then shift the chemical equilibrium [3,4].
In first instance, it has been decided to focus our research on the esterification of glycolic acid with butan-1-ol by reactive distillation in order to get butyl glycolate and water as presented in Figure 1

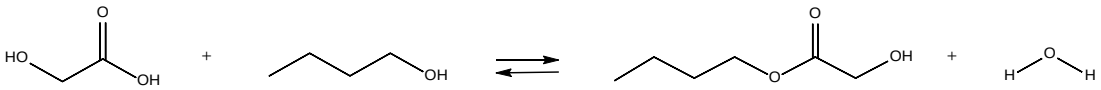

Figure 1 : Esterification between glycolic acid and butan-1-ol

2. Methods

A preliminary study was carried out in order to evaluate the feasibility of producing butyl glycolate through reactive distillation. A model of reactive residue curve maps was developed on Matlab®. In these reactive residue curve maps, the butyl glycolate is a stable node. A residue highly concentrated in butyl glycolate can therefore be obtained. However, a distillation boundary split the area into two regions. In order to get a residue of mainly butyl glycolate the feed should be in large excess of butanol.
Experiments were conducted in a laboratory distillation column of 1m high and with an internal diameter of 32mm designed by Pignat® (Figure 2). The column is divided into three different sections filled with random packing (glass bead

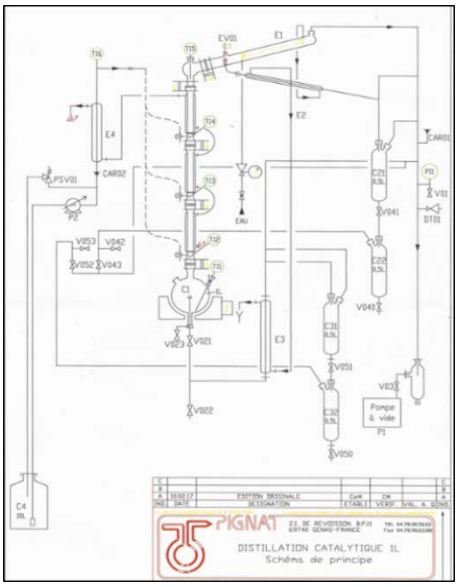

Figure 2 : Catalytic distillation column designed by Pignat®

of 7 mm) or foam. Catalysts (amberlyst36 or TiO_2-WOx) used are directly filled in those sections or coated on a foam.

The column was first characterize. The number of theoretical plates of the column was determined by a mixture of isopropanol and ethanol at atmospheric pressure and infinite reflux in batch mode. Three theoretical plates are counted (4 if the boiler is considered). The heat supplied to the boiler was determined by the evaporation of pure water with no reflux and is about 71 W. Simulations with Prosim Plus® have given the same results as the characterization.

Esterification experiments were conducted continuously at 390mbar with a feed composed of glycolic acid and butanol 1:10 wt./wt. The boiler was first filled with pure butan-1-ol. The analysis of both distillate and residue was operated by HPLC with a Phenomenex® Kinetex XB-C18 column, equipped with a Refractive Index (RI) and an UV detector.

3. Results and discussion

Results shown in Figure 3 correspond to a reaction carried out without any catalyst. After 3h of reaction, the steady state is not achieved as the composition of the residue is still evolving, but the mass balance has been established. However, the ester is produced through the operation even without any catalyst. In order to get the steady state quicker, it will be needed to start the reactive distillation with a composition at the boiler close to the steady-state composition of the residue.

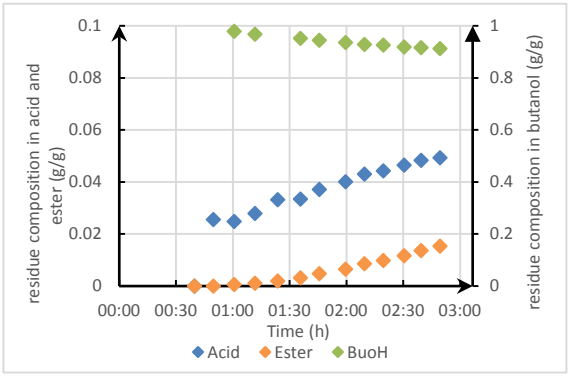

Figure 3 : Composition at the residue in butan-1-ol, glycolic acid and butyl glycolate

In one hour batch distillation, 22% and 88% of acid conversion have been observed without and with catalyst respectively. Moreover, simulations with Prosim Plus© showed that acid conversion is close to 100 % after one theoretical plate. So, it is possible to obtain a residue concentrated in butyl glycolate by using catalysts in one section of the column. Hydrodynamic and liquid-gas contact with foam or glass bed packing are similar. Hence, foam coated on TiO_2-WOx is a proper catalyst for this reaction in this process.

4. Conclusions

To conclude, our column has been characterized and first tests for the esterification of glycolic acid with butan-1-ol in reactive distillation have been performed. It shown that the production of butyl glycolate through reactive distillation is feasible without any by-product. Different catalytic packing (Amberlyst 36 beds, TiO_2-WOx pellets or coated on foam) are tried which represent a commonly known issue in reactive distillation as it needs to be efficient in both distillation (G/L contact, pressure drop) and reaction (good conversion). Results in simulation always show a good conversion (more than 90%) and separation of the products.

Kinetic modeling of catalyst deactivation in the rhodium diphosphite catalyzed hydroformylation of long chain olefins

Martin Gerlach[1]*, Maximilian Wendt[1], Andreas Seidel-Morgenstern[1,2], Christof Hamel[1,3]

1 Otto von Guericke University, Institute of Process Engineering, Magdeburg, Germany; 2 Max Planck Institute for Dynamics of Complex Technical Systems, Magdeburg, Germany; 3 Anhalt University of Applied Sciences, Department of Applied Biosciences and Process Engineering, Köthen, Germany

**Corresponding author: martin.gerlach@ovgu.de*

Highlights

- Kinetic study of industrially relevant impurities
- Detailed experimental investigation of deactivation kinetics
- Operando FTIR spectroscopic validation of catalyst deactivation
- Extension of mechanistic kinetic models by deactivation model

1. Introduction

In the Collaborative Research Center Transregio 63 of the German Research Foundation the concept of thermomorphic multi component solvent systems (TMS systems) is investigated for the Rh/BIPHEPHOS-catalyzed hydroformylation of long chain olefins and esters. For a TMS system consisting of *N,N*-dimethylformamide (DMF), decane and 1-dodecene reaction kinetics and solvent effects on the chemical equilibrium were investigated in detail [1,2,3]. Previous studies on feed impurities revealed a significant kinetic influence of hydroperoxides on the isomerizing hydroformylation network of long chain olefins [4]. In particular, a loss of active ligand specific n- to iso-aldehyde production could be correlated to the decomposition of the diphosphite ligand which was observed by ^{31}P NMR [4]. In parallel, industry is facing reduced aldehyde space-time yield and selectivity by decomposition of catalyst due to unavoidable traces of peroxides in the olefin feed [5]. This work aims to contribute to a better understanding of the deactivation kinetics which is necessary to be optimized in the rhodium catalyzed hydroformylation process using highly active diphosphite ligands.

2. Methods

Hydroformylation experiments were carried out in a high pressure reactor system equipped with temperature and pressure controllers. The TMS system consisted of 1-dodecene ($c^0_{substrate}$ = 0.9 mol L^{-1}), decane and DMF. Rh(acac)(CO)$_2$ and BIPHEPHOS were used as catalyst precursor and ligand (Rh/ligand = 1:3, c_{cat} = 13 ppm), respectively. Two hydroperoxide species, *tert*-butyl hydroperoxide and a mixture of unsaturated hydroperoxides, generated by autoxidation of 1-dodecene, were used as model and substrate derivative hydroperoxides, respectively. These hydroperoxides were separately spiked to 1-dodecene according to different peroxide/ligand ratios. The hydroformylation was performed at temperatures ranging from 95 °C to 115 °C at a constant CO/H$_2$ (1:1) pressure of 30 bar. In addition, operando FTIR hydroformylation experiments were conducted at 60 °C and 10 bar CO/H$_2$ (1:1) in toluene using an increased catalyst concentration of c_{cat} = 500 ppm.

3. Results and discussion

The kinetic influences of hydroperoxides on the hydroformylation of terminal olefins were investigated at different temperatures and different hydroperoxide to ligand ratios (Fig. 1a). Both hydroperoxide species revealed different activity in the hydroformylation experiments.

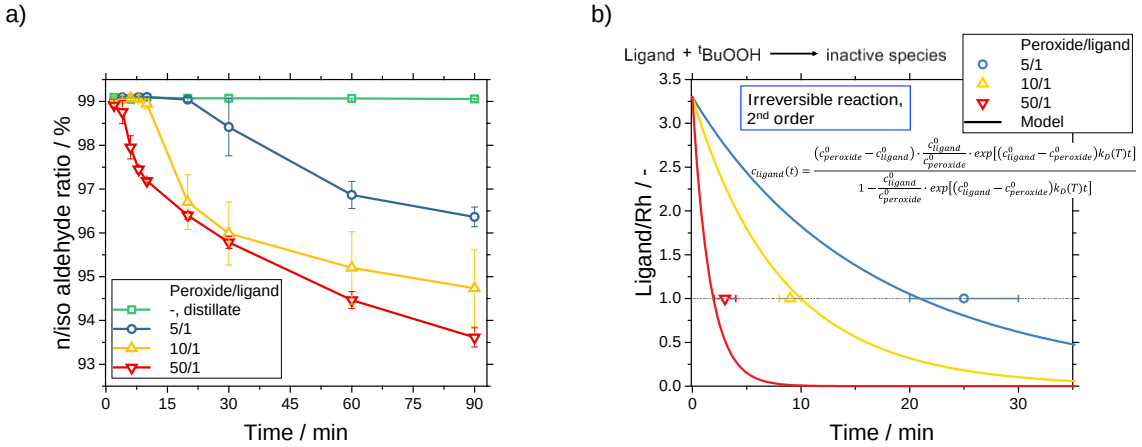

Figure 1. Results of the kinetic deactivation study for the Rh/BIPHEPHOS-catalyzed hydroformylation of 1-dodecene at 105 °C and 30 bar CO/H_2 (1:1) for different peroxide/ligand ratios: a) n/iso Aldehyde regioselectivity, b) Simulation of ligand decomposition

The decomposition of the ligand BIPHEPHOS by hydroperoxides was assumed to proceed as a second order irreversible reaction. Thus, a kinetic model for the decomposition could be derived and parameterized. The resulting simulation of ligand/Rh ratio shows a good correlation to the experimental findings (Fig. 1b) whereas a decline of the ligand/Rh ratio below 1 is supposed to significantly change the regio- and chemoselectivity of the catalysis. In addition, a change of the catalytic species could be observed during the decomposition using FTIR spectroscopy.

4. Conclusions

The kinetic influence of industrially relevant hydroperoxides was studied in detailed kinetic experiments. The kinetic data was used to derive and parameterize a kinetic model for a mathematical description of decomposition of the ligand as well as the corresponding deactivation of the catalyst. Thus, already existing mechanistic kinetic models for Rh/BIPHEPHOS-catalyzed hydroformylation could be extended to an improved prediction of the reaction kinetics allowing a description, simulation and optimization of the reactor behaviour using real feedstocks in industry.

Highlights

- Mass transfer study
- Kinetic modelling for hydrogenation of levulinic acid and its esters.
- Relationships between reactivity and structure.

1. Introduction

Nowadays, biomass valorization has attracted great interests as its products have shown potential to substitute the fossil-oriented products. Conversion of biomass to biofuels and chemicals is one of the hot topic in chemical engineering. Levulinic acid (LA) is regarded as one of the top 12 building-block molecules from biomass. Besides, hydrogenation of levulinic acid and its esters leads to γ-valerolactone (GVL) [1], which is also another important platform molecule for biofuel production and industrial applications. GVL can also be used as industrial solvent, fuel additives, food and pharmaceutical industries.

From our previous research, the safe operation conditions for hydrogenation of levulinic acid to γ-valerolactone were determined from thermal risk assessment, which could provide an operational guide for further study of this process [2]. However, as LA is corrosive to the reactor system, a comparison of kinetic for hydrogenation of LA and its esters, such as methyl levulinate (ML), ethyle levulinate (EL) and butyl levulinate (BL) which could be obtained by alcoholysis of cellulose, is important for a better optimization of GVL synthesis.

The hydrogenation process of LA and its esters in GVL has two steps: the first step is the hydrogenation of the ketone group to the intermediates and the second step is the intra-molecule cyclization to get the final product GVL and its corresponding water or alcohol. The objective of this study is to study the kinetic modelling for hydrogenation of levulinic acid and its esters. Then, we will determine a relationship between the structure of the different substrates and their kinetics.

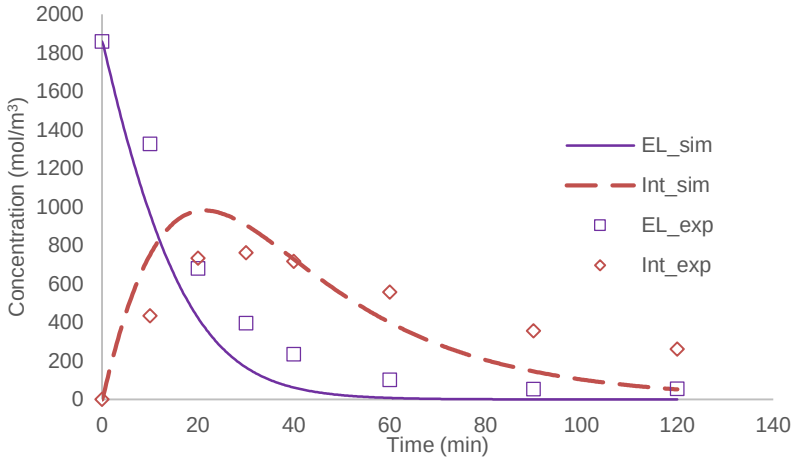
2. Methods

Experiments were performed in a Parr reactor equipped with efficient gas entrainment impeller, hydrogen reservoir, pressure and temperature recording system. GC-MS and GC were used to identify and quantify the compositions of the sample.

3. Results and discussion

Due to space limitation, we did not include the mass transfer study. Based on this study, we were able to determine the value of the mass transfer coefficient and Henry's constants at different temperature.

For the kinetic study, different parameters such as substrate concentration, catalyst loading, pressure and temperature were studied for hydrogenation of levulinic acid and its esters to GVL. Figure 1 shows the good fit of simulated data to the experimental data.



Figures 1. The fit of simulated data to experimental data for Ethyl levulinate hydrogenation. Reaction conditions: EL 2mol/L, Ru/C catalyst 1.4g, Hydrogen pressure 20bar, Temperature 413K, stirring speed 1000rpm.

4. Conclusion

Figure 1 shows that the simulated data from kinetic model could fit the experimental data. The continuation of this work is to compare the kinetic between the different substrates to find a more efficient hydrogenation process and look for a possible relationship between the reactivity and structure.

Highlights

- Dehydration of fructose to produce 5-hydroxymethylfurfural.
- Supported triazolium-based ionic liquid catalysts.
- Click chemistry for the synthesis of triazolium salts.

1. Introduction

5-hydroxymethylfurfural (5-HMF) is considered a furan-type platform chemical derived from the dehydration of hexoses, along with being a versatile and critical intermediate in biofuel chemistry and an important building block to produce plenty of chemical compounds, such as dimethylfuran (DMF), 2,5-diformylfuran (DFF) among others. Nevertheless, the reaction to produce 5-HMF shows the disadvantage of promoting side-reactions with undesired by-products. Furthermore, the rehydration of 5-HMF takes place frequently forming levulinic and formic acid. In order to produce 5-HMF, a wide range of conditions has been assessed, from homogeneous to heterogeneous catalyst as well as the use of monophasic or biphasic systems that are coupled with different separation techniques. The main technical challenge is to achieve the efficient production of 5-HMF through cleaner and greener chemical reactions and separation steps, due to the exponential growth of the green chemistry and its benefits to chemical processes [1]. In this framework, ionic liquids (ILs) are one of the most promising green solvents, specially triazolium-based ionic liquids, which are synthesized under click chemistry concepts by 1,3 dipolar cycloadditions, acting as a chemically supported Bronsted acidic ILs [2]. This work is based on the study of a new family of triazolium-based ionic liquids supported on silica or alumina to be used as a catalyst in the dehydration of fructose. Moreover, the 5-HMF production yield was quantified in this work as well as the reaction kinetic in order to identify the best-operating conditions.

2. Methods

Synthesis of supported triazolium-based ionic liquids: a first triazolium salt was synthesized pouring together sodium azide and benzyl bromide in water (2mL); meanwhile, iodo tris(triphenylphosphine) copper (I) was used as catalyst. After stirring of 30 min, 3-butyn-sulfonate was added, and the reaction was kept at room temperature for 24h. A second triazolium salt was also synthesized pouring together the 3-azidopropane sulfonate and phenylacetylene at the same conditions, using the same reaction solvent and catalyst of the previous reaction. The anchoring of triazolium salt was carried out putting the triazolium salt together (iodobutyl) trimethylsilane-functionalized silica or alumina (the triazolium salt mass corresponded to 20% with respect to

support mass) refluxing in toluene for three days. The obtained product was a supported triazolium-based ionic liquid. Finally, to functionalize the ionic liquid with $[HSO_4]^-$, H_2SO_4 was used according to the procedure reported by Zhang and coworkers [3].

Dehydration reaction of fructose: 2%(w/w) of fructose was pouring in DMSO (4mL) and 20%(w/w) of supported triazolium-based ionic liquid catalyst with respect to the fructose. The reaction was left at 100°C for 2h. The produced 5-HMF was quantified by UV-HPLC.

3. Results and discussion

The main idea for synthesizing this new type of ILs considers that the 1,2,3-triazolium salts can be produced under click chemistry concepts, being greener, cleaner and closer to green chemistry processes. As far as the reaction of fructose is concerned, this is carried out under acid conditions; this characteristic is provided by the $[HSO_4]^-$ anion, which was functionalized with the ionic liquids, owing to its acid characteristics. Figure 1 and 2 show the structures of both catalysts, which were supported in SiO_2. For the case of Al_2O_3 support, the same ILs were anchored. The chosen solvent was DMSO as it is highly polar and capable to stabilize 5-HMF [4]. Therefore, it allows comparing the catalysts with each other avoiding the rehydration reaction to some extent.

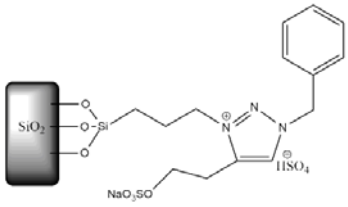

Figure 1. First supported triazolium-based ionic liquid, TR1-Si-HSO_4

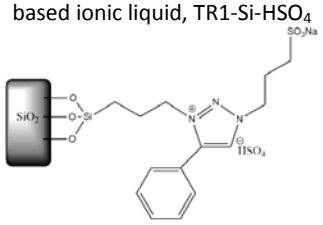

Figure 2. Second supported triazolium-based ionic liquid, TR2-Si-HSO_4

The results presented in figure 3 show that the silica support allows obtaining better yields than alumina support after 2h, being of 80% and slightly lower than 70%, respectively, in comparison with the others, which around 60%. Moreover, the kinetic reaction was faster using silica support.

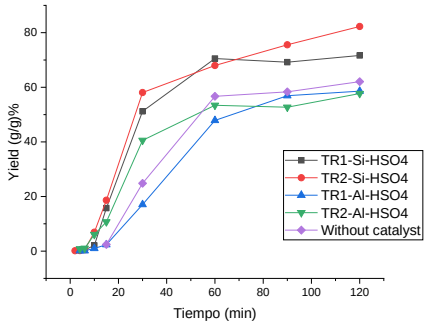

Figure 3. Reaction kinetic of 5-HMF, yield vs reaction time

As far as the triazolium ionic liquid is concerned, independently of the support, the second triazolium presented better results than its counterpart, probably due to the steric/electronic effect produced by the aromatic group attached directly to the triazolium ring, which could modify the physicochemical properties of the ionic liquid. This fact could favour the interaction between the anion and the HMF, via transfer of electron density from the O to OH groups, that is a crucial step to break the inter and intramolecular hydrogen bonding. However, these results were obtained considering just a few amounts of catalyst mass, so that the results could improve, and the yields may be higher than the non-catalyst case when the mass of catalyst increases.

4. Conclusions

The use of a new kind of ionic liquids based on triazolium salts anchored in different supports could represent a promising alternative supported catalyst for greener processes. Furthermore, these catalysts could be used to obtain high yield in the dehydration of fructose to produce 5-HMF.

**Corresponding author: idoia.hita@ehu.eus*

Highlights

- Zeolite supports enhance dehydration/condensation reactions
- The acidity features of the catalyst play a primary role in their performance
- The FeMoP/ZSM5 catalyst is the most selective towards aromatics

1. Introduction

In the recent years, bio-oil has been attracting great research attention given its potential as a sustainable source of fuels and platform chemicals [1]. When aiming for the production of chemicals (*i.e.*, aromatics, phenolics), hydrodeoxygenation (HDO) has proven to be a versatile approach for achieving an efficient conversion of the most refractory bio-oil components [2]. In this context, phosphided catalysts are known to provide high HDO activities [3]. However, no studies with raw bio-oil are reported to date.

2. Methods

The supported FeMoP catalysts (20 wt. %) were prepared by impregnation of three zeolites of different topology (*i.e.*, HZSM-5, Hβ and HY) with an aqueous citric acid solution in which were previously added Fe, Mo and P. A "bulk" FeMoP catalyst was also prepared as a reference. The catalysts were characterized by means of ICP-MS, N_2 adsorption-desorption, NH_3-TPD, and XRD. The bio-oil hydrodeoxygenation runs were carried out in a downflow fixed bed reactor described elsewhere [2] at 450 °C, 65 bar, space time, 0.15 g_{cat} h $g^{-1}_{bio\text{-}oil}$; 90 ml min^{-1} H_2; and time on stream, 0-8 h. Organic liquid products were assessed through two-dimensional Gas Chromatography coupled with Mass Spectrometry (GCxGC-MS).The water content in the aqueous product phase was quantified by Karl-Fischer titration.

3. Results and discussion

In contrast to the negligible specific surface of the bulk FeMoP, the FeMoP/ Hβ and FeMoP/HZSM-5 catalysts showed a specific surface of 356-366 m^2 g^{-1} (Table 1), with this value being significantly higher for the FeMoP/HY catalyst (750 m^2 g^{-1}) due to a much higher microporosity. The latter catalyst was also the most acidic (1.11 $mmol_{NH3}$ g^{-1}) and with a higher proportion of medium-

strong acidic sites (66 %). The FeMoP/ Hβ catalyst was the least acidic (0.27 $mmol_{NH3}$ g^{-1}) with a higher contribution of weak-medium acidic sites (35 %).

Table 1- Physico-chemical properties of the fresh catalysts

	FeMoP/Hβ	FeMoP/HZSM-5	FeMoP/HY	Bulk FeMoP
S_{BET} (m^2 g^{-1})	365.9	355.9	750.3	6.0
$V_{micropore}$ (cm^3 g^{-1})	0.084	0.082	0.207	0.002
Total acidity ($mmol_{NH3}$ g^{-1})	0.27	0.57	1.11	0.24
Weak-medium (%)	65	47	34	48
Medium-strong (%)	35	53	66	52

In Figure 1a, an increase was observed in carbon products upon incorporating the zeolite support (22.8-27.0 wt%) in contrast to the bulk FeMoP phase (16.5 wt%), due to the enhancement of dehydration/condensation reactions performed by the zeolites. The highest total acidity and stronger nature of the acidic sites of the FeMoP/HY zeolite enhanced HDO reactions (higher amount of water being formed), leading to lower carbon product yields. On the other hand, the highest carbon product yields were attained with the FeMoP/HZSM-5 catalyst, likely due to a compromise between total acidity and a moderate content of stronger acidic sites. Moreover, FeMoP/HZSM-5 catalyst is also the most selective towards phenol and phenolic compounds (Figure 1b, 12.6 wt% total phenolics), as well as aromatics (13.5 wt% total aromatics).

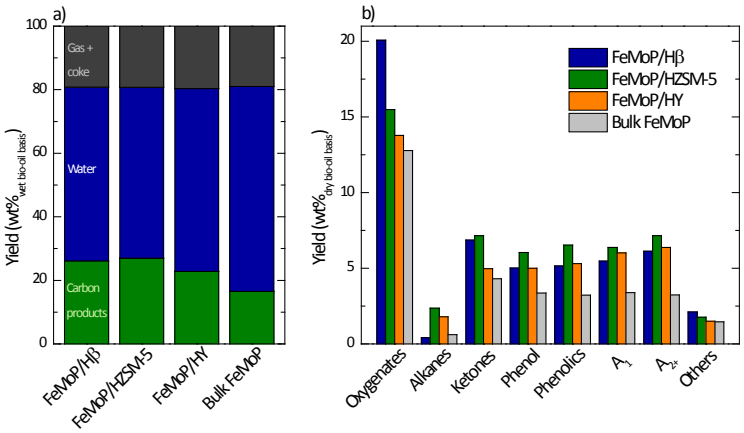

Figure 1. a) Total product yields (in a wet basis) and b) carbon product lump yields (in a dry basis) obtained with the different zeolite-supported catalysts and bulk FeMoP at TOS = 8 h.

4. Conclusions

The total acidity of the catalyst and an equilibrium between weak-medium and medium-strong acidic sites are the dominant catalyst property on the HDO of a raw bio-oil towards hydrocarbons, with shape selectivity playing a secondary role. The FeMoP/HZSM-5 catalyst was the most suitable, providing the highest yield of total carbon products, and also the most selective towards the formation of aromatics, phenol and phenolic components.

Highlights

- A kinetic model was developed for the one-step ethanol to butadiene process.
- The kinetic model includes the effect of co-feeding water.
- The experimental observations were explained through the model parameters.

1. Introduction

1,3-Butadiene is an important building block for the manufacture of synthetic rubber, resins, and elastomers. In the last years, the increasing use of ethane as steam cracking feedstock instead of heavier fractions has decreased the production of 1,3-butadiene, but its demand continues growing, so 1,3-butadiene short-term demand is not expected to be satisfied by the current capacity of oil refineries. In that context, the production of 1,3-butadiene from renewable sources, such as bioethanol, rises as an environmentally friendly alternative that may help solving demand issues.

In spite of the potential relevance of this process, very few studies have attempted to propose a kinetic model of the ethanol to 1,3-butadiene conversion, and none of these studies considered the most supported ethanol to 1,3-butadiene pathway, which includes ethanol dehydrogenation into acetaldehyde and its posterior aldo-condensation to crotonaldehyde, crotyl alcohol production from ethanol and crotonaldehyde MPVO reduction, and crotyl alcohol dehydration into 1,3-butadiene. That way, we aim to generate a formal kinetic model describing the main reaction pathway that can predict the catalyst performance in a range of operating conditions around the optimum. Besides, this kinetic model includes the effect of co-feeding water among with the ethanol feedstock, what has never been reported so far for this process.

2. Methods

The catalyst was prepared following the methodology reported in the work of De Baerdemaeker et al. [1]. Catalytic tests were carried out in a continuous flow fixed-bed reactor at 340-380 ºC, 1.12-9.8 h^{-1}, 0-15% w/w water in the feedstock, ethanol partial pressure of 0.21 bar and atmospheric pressure. The bed was divided into three sections. The top section was a SiC bed, the middle one comprised a bed of catalyst (0.3-0.5 mm) diluted in the necessary amount of SiC to

obtain a bed length of 13 cm, and the bottom section was also a SiC bed. All sections were separated by a glass wool plug. The ethanol was fed with an HPLC-pump and N_2 was used as carrier gas. The reactor output line was electrically traced and insulated to avoid product condensations before analysis by an Agilent 7890A on-line gas chromatograph (GC) equipped with two flame ionization detectors (FID) and a thermal conductivity detector (TCD).

3. Results and discussion

Making use of the tests carried out in the laboratory-scale reactor, a power-law model was developed, and the statistically significant variables in the rate expression for the generation of each product were found. The reaction scheme considered for the calculation of the balance is a simplification of the one proposed in our previous work [2]. The considered reaction rates are based on exponential rate equations or Langmuir-Hinshelwood kinetic.

The differential mole balance equations were solved obtaining an initial guess of the kinetic parameters assuming constant molar flow along the reactor and solving the algebraic system. These rough parameters were used as initial guess values for solving the differential mole balance along the reactor.

- Main reactions: $C_2H_5OH \rightarrow C_2H_4O + H_2$
  $C_2H_5OH + C_2H_4O \rightarrow C_4H_6 + 2H_2O$
- Ethanol dehydration: $2C_2H_5OH \rightarrow (C_2H_5)_2O + H_2O$
  $C_2H_5OH \rightarrow C_2H_4 + H_2O$
- Butanol formation: $2C_2H_5OH \rightarrow C_4H_9OH + H_2O$
- Butenes formation: $C_4H_9OH \rightarrow C_4H_8 + H_2O$
- Heavy compounds formation (diphenylketone) : $6.5\ C_2H_4O \rightarrow C_{13}H_{10}O + 5.5H_2O + 2.5H_2$

4. Conclusions

The formation of 1,3-butadiene over a Hf-Zn catalyst was evaluated. The main products observed were acetaldehyde, butadiene, ethene, diethyl ether, butanol, butenes and heavy compounds. A Langmuir−Hinshelwood type of kinetic model was developed for the equations involving acetaldehyde production and consumption. The model can be used to predict the rates of formation of the products and the predictions agree with the experimental data, as well as to design an industrial facility.

Photocatalytic decomposition of ethylene released from agricultural products

Fumihide Shiraishi*, Yuichi Akimoto, Toshiaki Koto, and Masashi Iwanaga

Section of Bio-process design, Department of Bioscience and Biotechnology, Graduate School of Bioresource and Bioenvironmental Sciences, Kyushu University, Motooka 744, Nishi-ku, Fukuoka 819-0395, Japan

Highlights

- The present reactor can reduce the ethylene concentration to below 40 ppb.
- Agricultural products releasing ethylene at a low speed can be kept fresh at least for 9 days.
- It is difficult to maintain the quality of fruit synthesizing ethylene quickly by only its decomposition.

1. Introduction

Ethylene released from fruits greatly lowers the quality of not only themselves but also agricultural products in their neighbourhood [1], which causes a serious problem when one stores the agricultural products or conveys them kept in containers by ship or truck. For solving the problem, it is necessary to keep the ethylene concentration in air at a low level. Although the extent of decrease in the ethylene concentration is different according to the kind of agricultural products, it should be fundamentally set as low as possible [2]. Unfortunately, there is no promising technique by which the ethylene concentration can be decreased to a very low concentration level.

Application of UV-excited titanium dioxide (TiO_2) to air purification has been actively investigated in the past two decades. One of the advantages of this application is that the VOC concentration can be reduced to almost zero (for example, below 40 ppb for toluene) if the reaction field on the TiO_2 surface is precisely controlled [3]. It is thus natural to apply the photocatalytic technique to the decomposition of ethylene released from agricultural products. It is known that this decomposition is strongly influenced by the moisture in the air. Therefore, this fact should be taken into consideration in applying photocatalytic technique.

In the present study, based on our accumulated knowledge and experience, we attempt to develop a photocatalytic reactor to rapidly decompose ethylene released from agricultural products. A photocatalytic reactor with three coiled glass tubes and six 6-W UV lamps was used to maintain the quality of agricultural products and the performance of the reactor was investigated.

2. Methods

An nanosized TiO_2 (Degussa P25)-coating solution containing H_2PtCl_6 was prepared by the same method as described elsewhere [4].This solution was poured into a coiled Pyrex glass tube and applied to its inside surface, which was then heated in an electric maffle furnace at 300 °C for 30 min. The same operation was repeated three times, so that a TiO_2 film was formed on the inside

surface. Three coiled glass tubes with TiO_2 were prepared in the same manner. A 6-W blacklight blue fluorescent lamp with a wavelength range of 300–400 nm was inserted into the center of each coiled glass tube. Three immobilized TiO_2 glass tubes thus prepared were vertically arrayed in a triangular framework. Furthermore, three UV lamps were put between the glass tubes to enhance UV irradiation. The photocatalytic reactor constructed was connected to an acrylic box (1.17×10^5 cm^3) via an air pump to circulate the air in the container. An apple, banana, persimmon, cucumber and cabos were put in the container. The UV lamps were switched on to start the decomposition. The experiment was performed over 9 days. A similar experiment was performed using an atemoya over 7days. For comparison, the experiment without treatment was carried out simultaneously. The temperature in the container was always kept at about 20 °C. The ethylene concentration was measured with a gas chromatograph equipped with a flame ionization detector. The detection limit of ethylene was 40 ppb for this analytical system.

3. Results and discussion

When the air was photocatalytically treated, ethylene released from agricultural products (mainly from the apple) was always kept at a very low level (below 40 ppb). Consequently, the qualities of all products were kept high at about 20 °C, at least, for 9 days. When no air was treated, on the other hand, the ethylene concentration constantly increased, attaining to 2.7ppm, which significantly lowered the qualities of persimmon and cucumber. Although the apple did not change apparently, it lost sweetness completely.

The atemoya was found to release ethylene five-times as fast as the apple did. The present reactor decreased the ethylene concentration to below 350 ppb, but the atemoya changed its surface color from green to brown after one week regardless of treatment. This result suggests that it is difficult to maintain the quality of fruit that synthesizes ethylene at a very high speed, by only decomposing ethylene.

4. Conclusions

The photocatalytic reactor with three coiled glass tubes is useful to reduce the concentration of ethylene released from agricultural products to a very low level, thereby making it possible to keep the qualities of agricultural products at a high speed over a long period of time. By contrast, for the agricultural products synthesizing ethylene quickly, the use of the present treatment technique is probably difficult to apply to even when the ethylene concentration is significantly reduced. In this case, we consider that the products should be kept refrigerated.

Highlights

- The definition of the pseudocomponents contributes to the uncertainty of the model.
- In principle, this effect can be separated from the other components of the model error.
- Therefore, the lumping scheme can be optimized within certain limits.

1. Introduction

Complex chemical processes are often modeled using lumped reaction networks [1]. Dealing with these models, however, involves some uncertainties. Firstly the overall predictive ability of the lumped kinetic model is limited (due to bias, variance, etc.). Secondly, the kinetic parameters can have broad confidence intervals, mainly because there are a number of alternative pathways in a lumped chemical reaction network that cannot be observed separately. Thirdly, there is an uncertainty in the lumping scheme, i.e. in how we define the pseudocomponents themselves.

In this work, we would like to deal with the latter. Given an experimental data set (of thermo-catalytic pyrolysis of real plastic waste) and number of pseudocomponents to follow (e.g. solids, at least two liquid fractions, gas) we measure the changes of model uncertainty as a function of how these pseudocomponents are actually defined.

The aim of our work is to measure and minimize the model error related to the lumping scheme in case of fixed structural complexity, i.e. for a certain number of lumps and reactions between them.

2. Methods

Pyrolysis of real plastic waste was carried out in a two-stage laboratory reactor system with 50 g shredded HDPE/LDPE/PP feedstock using various zeolite-based catalysts at different temperature levels (425/455/485 °C in the 1st stage and 380 °C in the 2nd stage). The gaseous product was driven through a water cooled heat exchanger. Condensate was collected and analyzed by gas chromatography at given time intervals, while the volume of the remaining gas was measured using a gas flow meter [2].

For the kinetic study, we propose a lumped chemical network in which the solid (polymer, coke), liquid (C_6-C_{30+}) and gaseous (C_0-C_5) products are distinguished. Here we would like to consider a

straightforward lumping scheme where we group the liquid components into a lighter and heavier fraction (L– and L+) and investigate how this classification affect the uncertainty of the model. It is a somewhat improved model derived from our previous work [3].

3. Results and discussion

After minimizing the uncertainty in connection with the identification process and the lumped chemical reaction network and then carrying out the identification procedure consecutively by changing the boundary between the two defined liquid lumps, we were able to relate the change in the squared error between the experimental and calculated data to the uncertainty in the model structure. Apparently, the definition of these pseudocomponents does have an impact on the error of the model, as you can see in Figure 1.

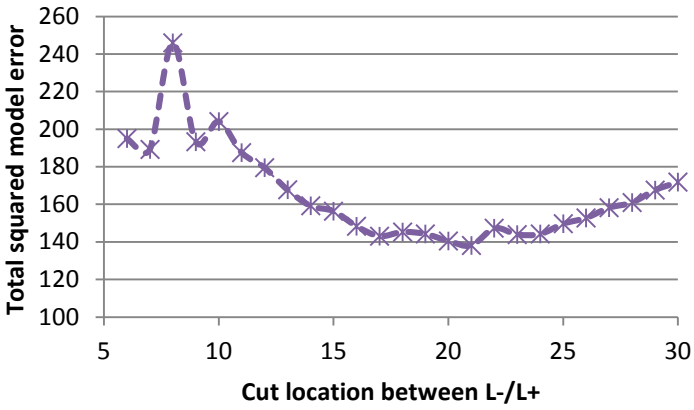

Figure 1. Development of total model error while moving the boundary between the two liquid pseudocomponents.

Undoubtedly, there is a limitation in how we define these two lumps, given that we would like to follow the concentrations of specific components, e.g. the boundary between gasoline and Diesel fuel is somewhere between C_{10}-C_{12}; nevertheless, this effect worth not to look over.

4. Conclusions

Our results already indicate that the uncertainty inherent to the model structure can be quantified. Nevertheless, there is much to be done. We would like to find the adequate measure of the complexity of the model. There are plenty of these in the literature and we have to find a select the most representative indicator. Moreover, the remaining uncertainty in the reaction network needs to be separated from the uncertainty of the lumping scheme. In any case, the proposed approach appears to be particularly promising and feasible to continue.

Experimental studies on ammonium heptamolybdate reaction with ammonium sulfide in turbulent micromixers

Michał Wojtalik, Wojciech Orciuch, Łukasz Makowski

Faculty of Chemical and Process Engineering, Warsaw University of Technology, Warsaw, Poland

** Michał Wojtalik: michal.wojtalik.dokt@pw.edu.pl*

Highlights

- Precipitation of molybdenum disulphide nanoparticles has been investigated in semi-batch and turbulent micromixers
- Particles size distribution has been evaluated in terms of precipitation kinetics

1. Introduction

One of the promising ways to obtain molybdenum disulfide for special purposes such as catalyst, lubricant additives [1] or semiconductors is wet chemical synthesis using ammonium heptamolybdate and ammonium sulfide [2]. In such a process, one can produce an amorphous product of molybdenum disulphide containing sulfa. Further recrystallization and purification by heat treatment can be used to improve product crystallographic properties. Obtained product due to its high surface area can be much more valuable than natural origin.

For advanced applications such as catalyst high quality and purity is crucial. Synthesis carried out in turbulent micromixers allows to control the process and make it continuously. In this work, authors focused on precipitation kinetics in turbulent micromixers and semi-batch system.

2. Methods

Synthesis of molybdenum disulphide nanoparticles was carried out in the turbulent micromixers with coaxial and tangential geometry and also in the semi-batch system shown in Fig. 1. Ammonium molybdate tetrahydrate $(NH_4)_6Mo_7O_{24}\cdot 4H_2O$ (HMA), citric acid $C_6H_8O_7$ (CA), and ammonium sulphide $(NH_4)_2S$ (AS) were used as substrates of the reaction [3]. Firstly, ammonium molybdate tetrahydrate and citric acid were dissolved at 90°C and mixed for at least 30 minutes with Mo:CA ratio of 1:2. This ratio was found best for the synthesis during previous tests in a batch procedure, due to the high selectivity of the reaction (up to 60% of MoS_2) and absence of sulphonic groups detected in obtained particles. Just before reaction, both prepared solutions were filtrated using 220 nm filters.

Produced particles were measured using LS Beckman&Coulter LS 13 320 analyzer, which uses PIDS – polarization intensity light scattering and LD – laser diffraction. Obtained particle size distribution was analyzed and used to calculate possible kinetics of the precipitation.

SEM imaging was also performed to determined particles agglomeration and morphology.

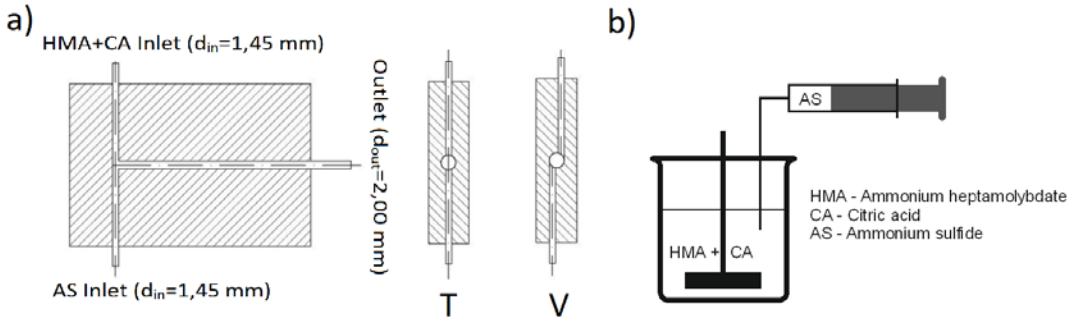

Figure 1. Turbulent micromixers (a) and semi-batch system (b) used in experiments

3. Results and discussion

The volume-weighted mean particle size D_{43} of obtained particles and an example of particle size distribution were shown in Fig. 2. Only the primary particles were taken into account. On Fig. 2. One can see that the average size is close to 200 nm regardless of flow and reactor type.

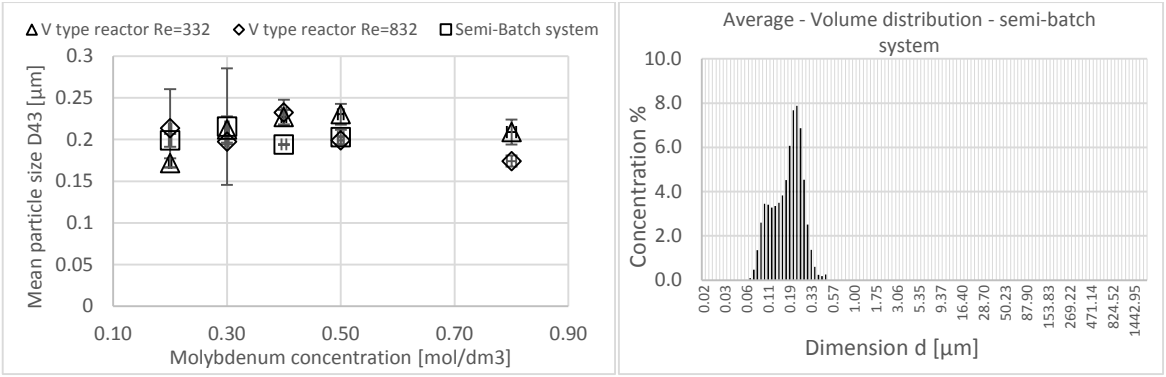

Figure 2. Mean particle sizes of particles (left). Example of particles size distribution obtained (right)

4. Conclusions

Molybdenum disulphide can be obtained by wet chemical synthesis in the turbulent micromixers. However, it is highly contaminated with sulpha and unreacted substrates. Due to contamination, it is not possible to use produced molybdenum disulphide directly after the reaction. Therefore, proper separation techniques have to be developed.

Mixing conditions appears to have a small impact on product size in the applications. The initial concentration and Reynolds number impact on precipitation process have not been observed.

Total Oxidation of VOC on Palladium Catalyst Supported on Activated Carbon from Cocoa Pod Husk

Karel Soukup[1], Pavel Topka[1], Vladimír Hejtmánek[1], Gerardo J.F. Cruz[2], Olga Šolcová[1]

1 Institute of Chemical Process Fundamentals of the CAS, v. v. i., Rozvojová 135, CZ–165 02 Prague 6, Czech Republic; 2 National University of Tumbes, Department of Forestry Engineering and Environmental Management, Av. Universitaria s/n, Campus Universitario, Pampa Grande – Tumbes, Peru

**Corresponding author: soukup@icpf.cas.cz*

Highlights

- Activated carbon was prepared from cocoa pod husk by chemical activation
- Palladium nanoparticles were supported on activated carbon
- Catalytic activity and selectivity in the oxidation of ethanol was studied
- At 99% ethanol conversion, the selectivity to CO_2 was higher than 95% for all catalysts

1. Introduction

Volatile organic compounds (VOCs) represent one of the most significant contributors to the air pollution [1]. Catalytic oxidation is recognized as an efficient, cost-effective and environmentally friendly way to treat VOC emissions [2]. Total catalytic oxidation of VOCs especially at low concentrations is a promising method to convert VOCs to water and carbon dioxide. Moreover, in contrast to thermal oxidation, dangerous reaction by-products such as NO_x are not formed [3].

2. Methods

For preparation of activated carbon samples, which will be further referred to as CPH–AC, cocoa pod husk was used. The cocoa beans, gathered in Tumbes Region (coastal region in north western Peru), were mixed with an activating agent ($ZnCl_2$) in a weight ratio of 1:1. Then, the mixture was directly carbonized under nitrogen atmosphere at 600 °C for 2 h with heating rate 10 C min^{-1}. After fast cooling with pressurized indirect air, the prepared samples were washed with 0.15 mol L^{-1} water solution of HCl and with hot and later cold distilled water. Prepared activated carbon was impregnated with the impregnation solution consisting of palladium(II) acetate (99.9% purity, Aldrich, USA) dissolved in the mixture of acetone and methanol (volumetric ratio 2:1) and 3.5 wt% of citric acid. The initial concentration of palladium acetate in the impregnation solution was the same in all cases (0.34 wt.%). The volume of the impregnation solution was adjusted to obtain 0.28 wt.% Pd, 0.61 wt.% and Pd, 2.64 wt.% Pd, for the 0.28Pd/CPH-AC, 0.61Pd/CPH-AC and 2.64Pd/CPH-AC catalysts, respectively.

3. Results and discussion

Conversion curves of ethanol oxidation are shown in Figure 1. The catalytic performance increased in the order of CPH-AC < 0.28Pd/CPH-AC < 0.61Pd/CPH-AC < 2.64Pd/CPH-AC (corresponding T_{50} was as follows: 249 °C, 206 °C, 158 °C, and 123 °C, respectively). The selectivity to CO_2 can be even

more important than catalyst activity due to the fact that some by-products of ethanol oxidation (e.g., acetaldehyde) can be even more detrimental for the environment and human health compared to ethanol itself. At 95% ethanol conversion, the selectivity to CO_2 decreased in the order of CPH-AC < 0.28Pd/CPH-AC < 2.64Pd/CPH-AC < 0.61Pd/CPH-AC (94%, 79%, 40%, and 33%, respectively). Ethylene, acetaldehyde, ethylacetate and traces of acetic acid were observed as the reaction by-products. However, it should be noted that at 99% ethanol conversion, the selectivity to CO_2 was higher than 95% for all catalysts.

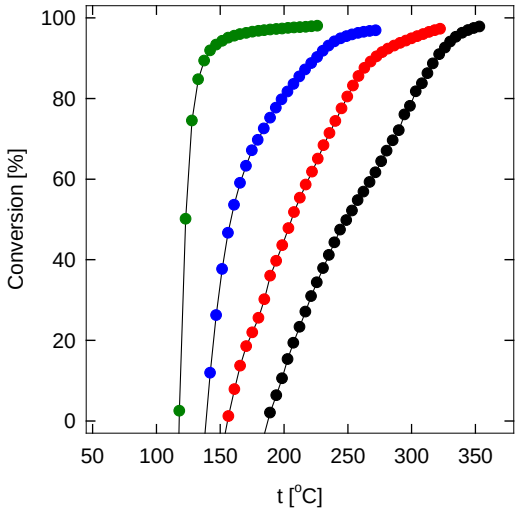

Figure 1. Conversion curves of ethanol during oxidation reaction over CPH-AC (●), 0.28Pd/CPH-AC (●), 0.61Pd/CPH-AC (●) and 2.64Pd/CPH-AC (●) catalysts

4. Conclusions

The activated carbon was prepared from cocoa pod husk using $ZnCl_2$ as an activating agent and employed as a catalyst support. Palladium nanoparticles were introduced by impregnation with palladium acetate in the presence of citric acid. In contrast to typical Pd/activated carbon catalysts, we were able to prepare catalysts with large palladium nanoparticles (~23 nm), which may be beneficial for oxidation catalysis. Moreover, these Pd nanoparticles were present on the external surface of the support and can be prepared even at low Pd loading (0.28 wt. %).

Screening of biomass degrading enzymes from *Aureobasidium pullulans*, using non-synthetic nitrogen sources

Matheus Maitan Vieira[1], Silvio Silvério da Silva[1], Felipe Antônio Fernantes Antunes[1], Anuj Kumar Chandel[1]

1 Department of Biotechnology, Engineering School of Lorena, University of São Paulo, postal code 12602-810, Lorena, SP, Brazil

Highlights

- *A.pullulans* can be a cellulolytic enzyme producer
- Enzymes can be produced by non-synthetic medium
- Submerged fermentation showed to be a good method to produce these enzymes
- Soybean represent the best non-synthetic nitrogen source in this process

1. Introduction

With the increasing demand for renewable fuels and bioproducts, with a view to sustainable development, lignocellulosic biomass has become an important compound to be applied in bioprocesses due to its low cost and high availability. Brazil generates foreseeable amount of lignocellulosic biomass primarily agro-residues such as sugarcane bagasse (SB), sugarcane straw (SS), corn stover (CS) and *Eucalyptus* residues round the year (LYND *et al.* 2002). These lignocellulosic residues are excellent feedstock for second-generation (2G) sugars production which could be utilized for liquid fuels and value-added products such as biopigments, biopolymers and several other biochemicals based on biorefinery concept. However, for the cost competitive production of these products, the most important concern is the economic production of 2G sugars, as these sugars act as building block in biorefineries (FERNANDES, 2006). For 2G sugars production, efficient cellulases production and their concerted action on lignocellulosic residues is vital. Commecial cellulases are available in the market but due to their high costs, limited supply and monopoly of certain industries, this is necessary to focus on in-house production of stable and complete cellulolytic enzyme cocktails. The objective of this work was to study the production of cellulolytic enzymes from the microorganism *Aureobasidium pullulans* using sugarcane bagasse residues and soybean meal, corn and rice as a source of nitrogen.

2. Methods

The investigations of the production of cellulase by the yeast *Aureobasidium pullulans* were carried out in order to evaluate sugarcane as carbon source using non-synthetic nitrogen source. Nonsynthetic nitrogen sources were soybean meal, corn bran and rice bran at 1.8 g/L, as well as for synthetic nitrogen sources in Mandel's medium, which obtained a total weight of 1.8 g/L total. For the fermentation 1mL of the isolate stock was transferred to a pre-inoculum in 50mL of Sabouroud dextrose broth in shaker 30ºC and 200 rpm for 48 hours. Subsequently, $1.6x10^6$ CFU were transferred to erlenmeyers containing 100 mL of the minimal Mandel medium with only one nitrogen source with 1% of the carbon source (sugarcane bagasse) and kept at 30°C for 96 h with shaking at 200 rpm. Samples were withdrawn every 24 hours with 5 minutes rest for decantation and 1mL of the supernatant was withdrawn for the reducing sugar test according to Ghose (1987).

3. Results and discussion

The maximum activity also occurred during 60 h, for CMCase soybean meal was 6.865 U/mL and for FPase 2,449 U/mL corn meal and rice meal with CMCase of 3.692 U/mL and FPase of 1.407 U/mL, and CMCase of 3.842 U/mL and FPase of 1.425 U/mL, respectively. The figure shows the enzymatic activity as a function of the bioprocessing time from the use of organic nitrogen sources as the only factor of nitrogen in the process of submerged fermentation for the production of enzymes of the cellulolytic complex. These nitrogen sources have different proportion of proteins and sugars (MARTINIANO *et al.*, 2017) and the results indicate that the protein source is important for the production of crude enzyme extract, however, not being the only factor, considering that these brans have very close amounts of protein (g/L). Ilmén *et al* (1997) questioned the action of nitrogen as an inducer in suggesting that the induction of nitrogen does not alter at the genetic level the production of enzymes, altering only the cell mass and, consequently, the production of enzymes. Non-synthetic nitrogen sources have been used in the literature to improve the cellulase synthesis conditions (AHAMED and VERMETTE, 2008), due to their low cost and to be, as well as sugarcane bagasse, a sub-agroindustrial product.

4. Conclusions

The submerged fermentation of non-synthetic sources (soybean, corn bran and rice bran) can be used to improve the productivity of a CMCase and Fpase by using *A. pullulans* as producer. This nitrogen sources have advantages as low cost, availability and efficiency on submerged fermentation for cellulase production. This study is a preliminary study for further proteomic approach.

Modified catalysts for a low-aromatic Dimethyl ether-To-Gasoline process

Benjamin Niethammer[1], Ulrich Arnold[1], Jörg Sauer[1]

[1]Karlsruhe Institute of Technology (KIT), Institute of Catalysis Research and Technology (IKFT)
Hermann-von-Helmholtz-Platz 1, 76344 Eggenstein-Leopoldshafen, Germany
*Corresponding author: benjamin.niethammer@kit.edu

Highlights

- Lab-scale investigation of miscellaneous acid zeolite catalysts.
- Catalysts with high selectivity to branched alkanes.
- Catalyst modification for an improved lifetime.

1. Introduction

The Dimethyl ether-To-Gasoline (DTG) process employs zeolite catalysts for the production of gasoline from dimethyl ether (DME). DME can be produced from renewable feedstocks, like biomass. This enables gasoline synthesis in a closed CO_2 cycle. Established DTG approaches generate a highly aromatic liquid product fraction. Due to their high octane numbers, aromatics can be used as anti-knock additives for gasoline, without increasing the oxygen content and lowering the heating value. On the other hand, aromatics are known to be precursors of soot formation in the engine combustion chamber. One approach to counteract this effect could be a change of the fuel composition to a reduced aromatics content in gasoline. Thereby, the reduction of greenhouse gases and the reduction of harmful particulate emissions in the transport sector could be addressed hand in hand. The intention of this work is to modify the DTG process to a low aromatic content and a large fraction of highly branched alkanes in the product spectrum [1].

2. Methods

Catalytic tests were performed in a continuously operated laboratory plant. DME, synthesis gas (H_2 and CO) and the inert gases N_2 and He can be fed as educt streams in a fixed bed reactor. The gaseous products of the catalytic conversion are transferred through a heated pipeline to a gas chromatographic (GC) online analysis. The GC (Agilent 7890) is equipped with a flame ionization detector (FID) and a thermal conductivity detector (TCD). Thereby, the educt conversion can be determined and an overview of the catalyst selectivity can be obtained. Subsequently, the gas stream is transferred into a cold trap, where the hydrocarbons in the range C_{5+} are liquefied. Analysis of the composition of the liquid samples is then carried out via gas chromatography according to the ASTM D6730-01 (2016) standard test method.

3. Results and discussion

Different acid zeolite morphologies were tested in the lab-scale plant. The catalysts were assessed and compared regarding their selectivity to non-aromatic C_{5+} components. The main focus was to

increase the content of highly branched alkanes, with high octane numbers, in the boiling range of gasoline. Promising zeolite types were identified, but these catalysts revealed only short lifetimes.

The conversion of DME to hydrocarbons is shown in equation 1, whereby -[CH_2]- represents the average composition of the product spectrum.

$$CH_3OCH_3 \rightarrow 2\ \text{-}[CH_2]\text{-} + H_2O \quad (1)$$

Consequently, the reaction comprises the formation of unsaturated components, which can as precursors of coke deposits that deactivate the catalyst. To improve the lifetime, modified zeolite catalysts were prepared and tested. The zeolites were loaded with hydrogen-active metals and H_2 was added to the educt feed. Thus, the formation of unsaturated hydrocarbons is reduced or prevented in the DTG chain-growth mechanism and alkanes (C_nH_{2n+2}) can be formed without organic byproducts, as shown in equation 2.

$$CH_3OCH_3 + H_2 \rightarrow C_nH_{2n+2} + H_2O \quad (2)$$

The lifetime of these catalysts clearly exceeded that of the unmodified catalysts, while maintaining or even improving the favorable product selectivity.

4. Conclusions

Modified zeolite catalysts that are able to incorporate co-fed H_2 into the chain-growth mechanism of the DTG process can improve the catalyst lifetime and the selectivity during the reaction with the intent to increase the content of branched alkanes in the product spectrum.

Kinetic model development of special hydrocracking of sunflower oil and petroleum mixture

Omar Péter Hamadi[1], Tamás Varga[1], Zoltán Till[1], Zoltán Eller[2], Jenő Hancsók[2]

1 Department of Process Engineering, University of Pannonia, Veszprém, Hungary; 2 Department of MOL Hydrocarbon and Coal Processing, University of Pannonia, Veszprém, Hungary

**Corresponding author: hamadio@fmt.uni-pannon.hu*

Highlights

- Sunflower oil and petroleum mixture special hydrocracking.
- 5-lump trickle bed reactor model development.
- Considering the change in hydrogen solubility along the reactor.

1. Introduction

Based on our previous work, a 5-lump kinetic and a simple reactor models were developed and validated against measurements in case of special hydrocracking of sunflower oil and petroleum mixture. In the model the effect of pressure has not considered and different parameter sets were determined for each pressure. The aim of that work was to characterize the catalyst fouling phenomena and its effect on the overall performance of the reactor. In this work the model is improved with the consideration of multiple phases and the mass transportation between these phases. Based on Korsten and Hoffmann reactor model [1]. Due to the reactions the composition of the reaction mixture changes along the reactor which has effect on the solubility of the hydrogen. The model of this effect is also built into the reactor model.

2. Methods

Experiments

A fixed-bed tubular reactor (diameter: 29 mm, length: 700 mm) was applied to perform the special hydrocracking reactions of the investigated oil mixture. The feedstock was the mixture of kerosene and sunflower oil in a mass ratio of 3:7. In the experimental system the temperature, the pressure and the LHSV can be controlled, so the hydrocracking experiments were performed at 533-613 K, 30-70 bar, 1.0-2.0 h^{-1} employing Pt/H-mordenite catalyst (Pt content: 0.45%, specific area, BET: 451 m^2/g, micropore volume: 0.18 ml/g, Si/Al ratio from XRF: 19 mol/mol, acid sites by ammonia TPD: 0.82 mmol/g, particle diameter: 1.4 mm). The measurements were performed after reaching a steady state condition.

Modeling

The pseudo (lumped) components in the developed kinetic model was determined by their boiling point range. Since the experimental data contains 5 pseudo components (triglycerides, diesel, kerosene, gasoline, and gas fractions), the kinetic model was developed using these lumps. For further improvement, the mass transportation of hydrogen was built in the model through

applying the Langmuir Hinshelwood mechanism and Henry's law. The unknown parameters of the proposed reactpr model were estimated based on measurement data with the application non-linear global optimization algorithm.

3. Results and discussion

In Figure 1 the validation of our previously described kinetic model for the mentioned material system can be seen. As the processes take place in the reactor are described in more details in the improved model we think that catalyst fouling effect can characterized much more precisely. The more we know about catalyst fouling the higher production efficiency can be achieved in the reactor.

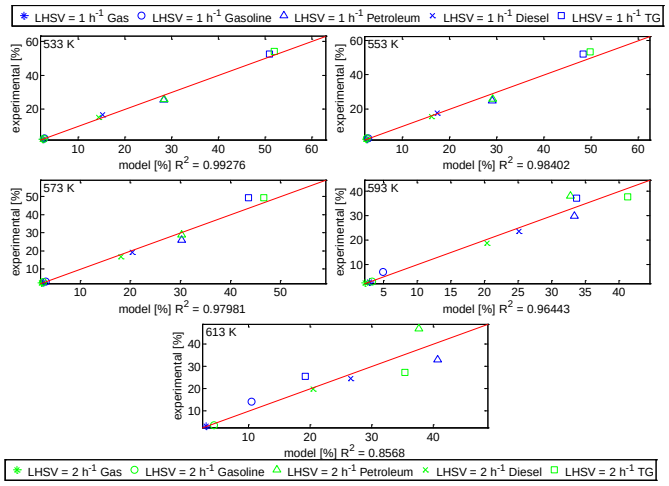

Figure 1. Parity plot for the previously described kinetic model at 30 bar

4. Conclusions

Our previous analysis of the investigated system revealed that there is a significant effect of catalyst fouling on the product composition. We consider the thermodynamic phases and the connections between each phase to improve the proposed reactor model. In the proposed model the effect of liquid composition on the hydrogen solubility was also considered. The performed model improvements support us to characterize the catalyst fouling phenomena.

Influence of fluid dynamic conditions on the course of precipitation reactions in a static mixer

Agata Małysiak[1], Przemysław Gidziela[1], Karolina Rurarz[1], Kamila Tomala[1], Piotr Synowiec[1]

1 Department of Chemical Engineering and Process Design, Silesian University of Technology, Strzody 7, 44-100 Gliwice, Poland

**Corresponding author: Agata.Malysiak@polsl.pl*

Highlights

- Three different salts were precipitated.
- Kenics static mixer was used as a multifunctional reactor.
- Influence of fluid dynamics on reaction kinetics and obtained crystals was investigated.

1. Introduction

In recent years there is a growing need to produce systems of small particle diameters with the desired and reproducible qualities and characteristics in an economical and easily scalable way. This is especially visible in the case of nanoparticles applications: the great desire is for pharmaceutics, cosmetics, medicinal imaging and diagnostics. Taking all that into account the natural choice would be precipitation. This reaction is simple, inexpensive and efficient thus the economy is favorable [1]. For the precipitation reaction the residence time is not of crucial importance, as the reaction is very fast. More significant will be high mixing efficiency and uniform unit power input in order to avoid an uncontrolled supersaturation regions [2]. For those reasons the precipitation could be successfully conducted in static mixers [3, 4]. In comparison to tank reactors they are much easier scalable and takes a lot less space, but their applicability is limited.

2. Methods

In this study precipitation of three compounds were considered: $CaSO_4$, CaC_2O_4 and $BaSO_4$. The production of those salts was conducted according to the equations:

$$Na_2SO_4 + CaCl_2 + 2H_20 \rightarrow CaSO_4{\cdot}2H2O\downarrow + 2NaCl$$

$$C_2O_4H_2 + CaCl_2 + H_2O \rightarrow CaC2O_4{\cdot}H_2O\downarrow + 2HCl$$

$$Na_2SO_4 + BaCl_2 \rightarrow BaSO_4\downarrow + 2NaCl$$

The substrates were aqueous solutions of Na_2SO_4, $CaCl_2$, $H_2C_2O_4$ and $BaCl_2$ respectively, introduced in stoichiometric proportions. Investigated salts are characterized by different solubility product and thus the relative supersaturation is maintained at the same level in order to investigate the influence of fluid dynamics on reaction kinetics and product characteristics.

The selected multifunctional reactor was Kenics static mixer with six inserts. Its total length was equal to 0.165 m and inner diameter was 0.0136 m. Change of fluid dynamic conditions was assured by investigating Reynolds numbers in the range of 500 to 2000.

The laboratory setup is presented in figure 1. It consisted of two tanks (1) in which solutions of two reagents were prepared and stored. Solutions were pumped to the reactor (3) using peristaltic pumps (2). The obtained suspension was collected in storage tank.

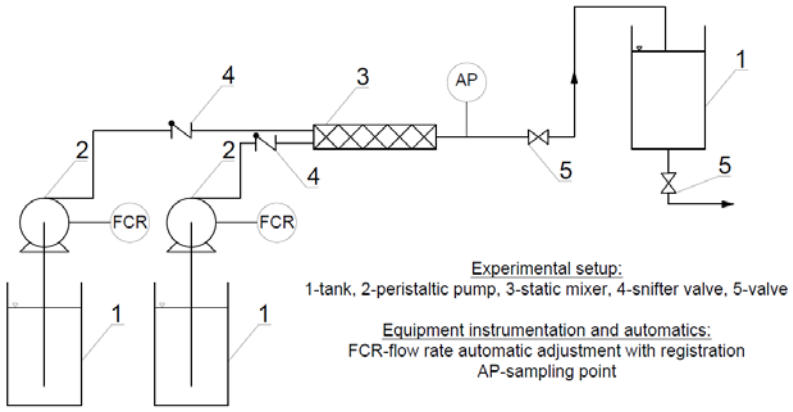

Figure 1. Experimental setup.

3. Results and discussion

The precipitation of three different insoluble salts was performed assuring the same fluid dynamic conditions in form of range selected range of Reynolds number and similar level of relative supersaturation. Each of investigated compounds was characterized by different solubility and product characteristics. The results show that there is a noticeable influence of fluid dynamic conditions on precipitation kinetics and product characteristics.

4. Conclusions

Different characteristics in terms of solubility of precipitated compounds results in very different kinetics of the reaction. The influence of fluid dynamic conditions on product characteristics is also undeniable.

Characterization of macrophyte *Eichhornia crassipes*: potentiality of wetlands pruning wastes in thermo-conversion processes.

Eliane Cristina Braga Martins Gonçalves[1], Francisco José Moura[1*], Marcos Alexandre Teixeira[2]

[1]Department of Chemical and Materials Engineering, Pontifical Catholic University of Rio de Janeiro (PUC-Rio), Rio de Janeiro, Brazil; [2]Department of Agricultural and Environmental Engineering, Fluminense Federal University (UFF), Niterói, Brazil.

**moura@puc-rio.br*

Highlights

- Evaluate of thermal conversion potential of *E. crassipes*.
- Physical-chemical characterization of the biomass.
- Determination of the biomass thermal properties.
- Potential use of the biomass for bioenergy production.

1. Introduction

In the search for a more sustainable and equitable energy for the future, the use of biomass residues from anthropic action arises as valuable source of raw material for bio or thermo-conversion, economically viable and ecologically sustainable. In this sense, aquatic macrophytes become interesting from the standpoint of their valorization as biomass source for energy production [1]. The objective of this paper was the fully characterization of the pruning wastes from macrophyte *Eichhornia crassipes* from secondary sewage treatment of wastewater treatment plant, in order to investigate the potential of the use of wetlands management control pruning residues for use as a renewable fuel.

2. Methods

The plant samples were analysed as a single whole fraction, including inflorescence, sheets, root and petioles. The characterization tests were based on the methodologies proposed by Soxhlet [2], Doc236 [3] and ASTM [4]. The thermogravimetric analyses were carried out in a simultaneous thermal analyser, model Netzsch STA449 - F3 Jupiter, according to following parameters: sample mass of approximately 10 mg, temperature programming (from 20°C to 900°C), inert gas (N_2), and heating rates of 10°C.min^{-1}, 15°C.min^{-1} and 20°C.min^{-1}.

3. Results and discussion

The bromatological and chemical analyses are essential for the evaluation of this source of biomass for thermal-conversion processes. The bromatological composition values obtained were: extractive content (4.06 wt%), lignin (9.99 wt%), cellulose (20.11 wt%) and hemicellulose (28.59 wt%). As expected for aquatic biomass, carbon (40.24 wt%) and oxygen (35.28 wt%) presented the highest content. Hydrogen and nitrogen average values obtained were 5.03 wt% e 5.71 wt%, respectively. The analysed macrophyte presented high moisture (95.19 wt%), as

expected. After forced drying, the moisture remained above 10 % (11.52 wt%) for the sample analysed. The high average value of ash content (16.07 wt%) can be attributed to the contribution of roots, which usually retain in their tissues high concentrations of insoluble materials such as silicates. *E. crassipes* samples also presented average values of 80.96 wt% for combustibility, 70.01 wt% for volatiles, 13.91 wt% for fixed carbon, with the ratio volatile/fixed carbon higher than 3.50. The higher heat value (HHV) is directly related to biofuels effectiveness. Biomasses with ash contents of less than 25% and HHV higher than 14.65 $MJ.kg^{-1}$ are considered energetically efficient [6]. The samples presented HHV average value of 15.89 $MJ.kg^{-1}$. According to thermogravimetric analysis of biomass (Figure 1), the TGA/DTG curves presented three distinct regions of mass loss relating to moisture reduction (I), hemicellulose and cellulose degradation (II) and lignin degradation (III). The region II presented the highest mass loss (39 - 44 %), due to the lower thermal stability of hemicellulose and cellulose. The increase of the heating rate changes the maximum mass loss of biomasses to higher temperatures.

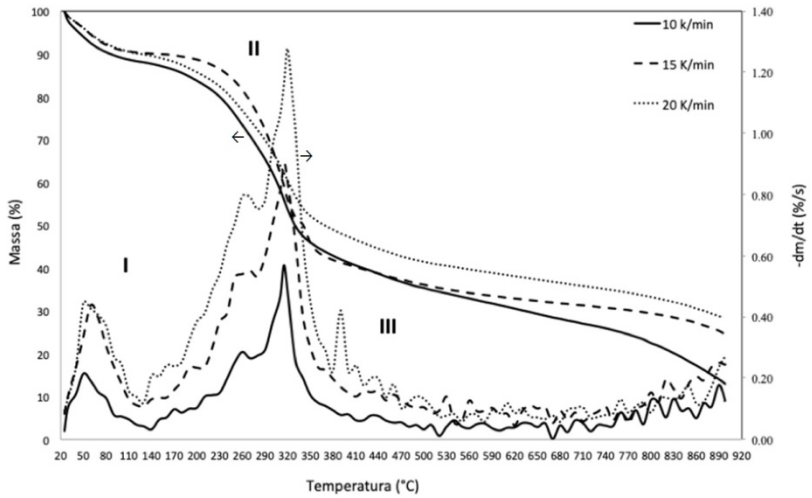

Figure 1. Influence of heating rates on TGA / DTG thermogravimetric curves.

4. Conclusions

The samples characterizations suggest that *Eichhornia crassipes* control pruning residues have potential for bioenergy production, especially biochar, associated with gasification rather than direct combustion process (due high ash content). High carbon and hydrogen contents affect positively the higher heat value of the biomass. High volatiles content (> 70%) increase the gas production. The biomass analysed presented HHV value of 15.89 $MJ.kg^{-1}$.

1. Introduction

The preoccupations about climate change and sustainability have driven the exploration of the production of alternative fuels. Bioethanol currently dominates the market and contributes 65% of the world's biofuel production [1, 2]. In this work, the feasibility of obtaining bioethanol from the lignocellulosic biomass in Guanajuato (Mexico) was studied, integrating SWOT tools and sustainability indicators of the reproduced processes into the study, that could be taken as a model in other cases of study at a national or international level under the same perspective.

2. Methods

The proposed methodology was divided into three stages: 1. Agricultural zones, 2. Reproducibility of the processes, 3. Analysis of the feasibility. **Agricultural zones (obtaining and quantification of raw material)**. The quantification of residual biomass from corn crops was carried out based on the model obtained by Bentsen [3], in which the waste index (WI) is exponentially proportional to the yield (Y) : $WI = a \cdot e^{bY}$, where a = 2656, b = -0.000103 ha· year · kg^{-1} and yield (Y) is given in units kg · ha^{-1} · $year^{-1}$. Waste produced (W) from the production of a certain crop is proportional to the volume produced (V) according to the relation $W = V \cdot WI$. Following the relation $W = P \cdot WI$, the expression to estimate the produced volume of waste in kg is: $W = V \cdot 2{,}656 \cdot e^{-0.000103\,Y}$.To measure the volume of waste from each municipality of the study area, the yield (Y) and production values recorded by the Secretariat of Agriculture, Livestock, Rural Development, Fisheries and Food (SAGARPA) [4]. **Reproducibility of the processes**. This was carried out based on the established methodology, figure 1 [5,6].

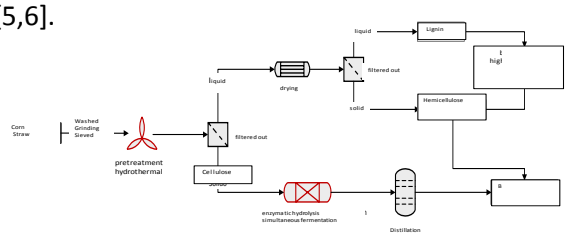

Figure 1. Scheme of the productive chains for the obtaining of bioethanol [6].

Analysis of the feasibility.

The indicators of sustainability were developed as indicated by the methodology of Indicators of Sustainable Development [7]. The SWOT matrix was developed by four types of strategies: strength-opportunity, weakness-opportunity, strength-threat, weakness-threat, that can be raised to convert weaknesses into strengths and threats into opportunities. The analysis of attractiveness was made based on the business template PNESINSO / strategy planning model, Innova Solutions

[8]. Based on the results obtained in the three stages, the feasibility of a sustainable biorefinery of the production for bioethanol was analyzed and discussed.

3. Results and discussion

The Guanajuato States was divided into geographical farming zones (Figure 2). The map shows the biomass potential within the state of Guanajuato in relation to corn residues ranging from 2,800 + 320 tons / year, representing a high energy potential of the production for biofuels and identifies the municipalities that contribute this biomass. The identification of these municipalities is the first step to evaluate the current availability of biomass and accurately estimate the bioenergy production capacity of waste derived from corn agricultural crops. The reproducibility of the pretreatment and delignification processes was performed to get a way cheaper to feasibility to the economy, that was analyzed base on the SWOT tools (Figure 3), and the sustainability indicators of from reproduced processes (Table 1).The results indicate that bioethanol production cost is 1.65±2.1 USD/gallon and potential production is 60.14 MM gallon/year using corn straw, which indicates that to reduce these costs should be optimized the processes.

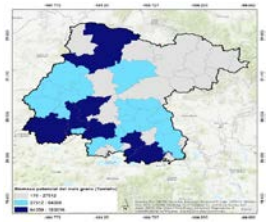

Figure 2. The residual corn biomass potential

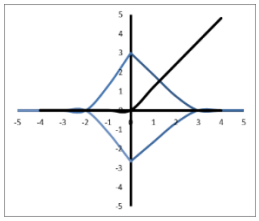

Figure 3. Graph resulting from the analysis of the Attractiveness [8].

Table 1. Indicators of sustainability

Policy in issue in NSDS	Indicator	Type of reference
Agriculture	Quantification of straw or residual biomass	SAGARPA, INIFAP, FINNOVATEG-CFINN0186 Project
Bioenergy	Index of projects related to Bioenergy	SICES CONACYT, SENER
Biorefinery	Cost analysis in productive chains	FINNOVATEG-CFINN0186 Project
Air quality	Air pollution from burning straw or residual biomass from agricultural crops	Pro Air of the State of Guanajuato Secretary of the Environment and Territorial Planning
GHG emissions	GHG and CO_2 emissions	FINNOVATEG-CFINN0186 Project, Pro Air of the State of Guanajuato Secretary of the Environment and Territorial Planning
Energy	Renewable energy use as a proportion of total	National Development Plans, State Innovation Agenda
Energy	Generation of biofuels	National Development Plans, State Innovation Agenda , SENER
Global responsibility	Environmental quality certification standards	ISO 14000

4. Conclusions

The pretreatment represented the stage of greatest cost in the conversion of biomass to ethanol, the investigations are focused on developing pretreatments of delignification, clean technologies and innovation methodologies. However, the cost of a liter of bioethanol is 48% below the current price of gasoline in Mexico. In parallel, the analysis with the tools SWOT and Sustainability Indicators, let us know the project has highly feasible to implement in Mexico, as an alternative to use the agricultural residues had been generated representing a high potential to obtaining new biofuels.

Experimental Investigations on Dynamic co-Methanation of CO/CO_2 mixtures using Ni/Al_2O_3 Catalysts

Dominik Meyer[1], Jannik Schumacher[1], Jens Friedland[1], Robert Güttel[1]

1 Institute of Chemical Engineering, Ulm University, Ulm, Germany

**Corresponding author: dominik.meyer@uni-ulm.de*

Highlights

- Transient turn-over frequency calculated for unsteady-state co-methanation.
- Dynamic regimes in reactor behavior identified based on frequency response.
- Critical switching frequency identified for pseudo-steady-state behavior.
- Criterion deduced for tolerant operation under transient conditions.

1. Introduction

The increasing utilization of regenerative resources in the chemical value chain induces new challenges in the operation strategy of chemical reactors. As an example, the chemical storage of regenerative energy via the power-to-X process (PtX) provides an option to store fluctuating electrical energy via water electrolysis and subsequent hydrogenation of carbon oxides. The formed methane can be stored and transported in the existing gas grid. However, this scenario implies a dynamic behavior of the process chain, depending on the installed storage capacity. As the storage of large quantities of electrical energy and hydrogen is not yet feasible, the necessity of an unsteady-state operation of the methanation reactor becomes likely.

An interesting carbon source for PtX are industrial exhaust gases, such as coke oven gas, which consist of a mixture of CO and CO_2 [1], which can be subject to strong fluctuations in composition. For the steady-state case the co-methanation mechanism is widely investigated [2]. However, for the unsteady-state case only little is known, even though a profound understanding of the dynamic methanation of CO/CO_2 mixtures is essential for the implementation of the co-methanation in a sustainable energy scenario based on renewables. The present contribution will discuss the strong interrelation between the unsteady-state behavior of the reactor and the frequency of feed composition alteration for methanation on a Ni/Al_2O_3 catalyst. Based on experimental results, conclusions on the effect of the frequency on the underlying transport mechanisms will be drawn.

2. Methods

The experiments are performed in an isothermal packed-bed reactor (length 20 mm, diameter 2 mm) using a self-prepared Ni/Al_2O_3 catalysts (Ni loading 5 wt%, particle size 800 µm, 200 mg). Two gas lines with different compositions (line 1: 0.8 H_2/0.1 CO_2/0.1 He; line 2: 0.8 H_2/0.1 CO/0.1 Ar) are switched by means of a 4-way valve with a frequency between 0.0083 and 0.25 s^{-1} and a split of 0.5. Both gas lines contain a different inert gas as internal standard for measuring the residence time behavior under reaction conditions. The effluent was analyzed by a mass spectrometer with sampling time of 0.5 s providing sufficient temporal resolution. Prior to dynamic experiments, the as-made catalyst was reduced and the catalytic behavior was studied under steady-state conditions

for various feed compositions and in a temperature range of 260 to 310 °C and 2 bar. The dynamic experiments were then performed under the same conditions.

3. Results and discussion

Figure 1 shows selected results in the phase plane. The fraction of either reactants or products at the reactor outlet are displayed as a function of the internal standard, according to our previous work [3]. The deviation of the profiles from a linear function between the steady-state conditions allow to conclude on the inherent transient system behavior. For example, the negative deviation of the CO fraction from the linear correlation in the increasing branch (Figure 1 a), lower red curve) indicates either a stronger adsorption of CO at the Ni surface or a more pronounced conversion into methane compared to CO_2. Since the mass balance is fulfilled and a limit cycle is reached for several consecutive periods, the data can be evaluated quantitatively. In this regard, Figure 1 b) indicates an increase in methane productivity upon periodic operation, as indicated be the upward shift of the limit cycle compared to the expected steady-state system.

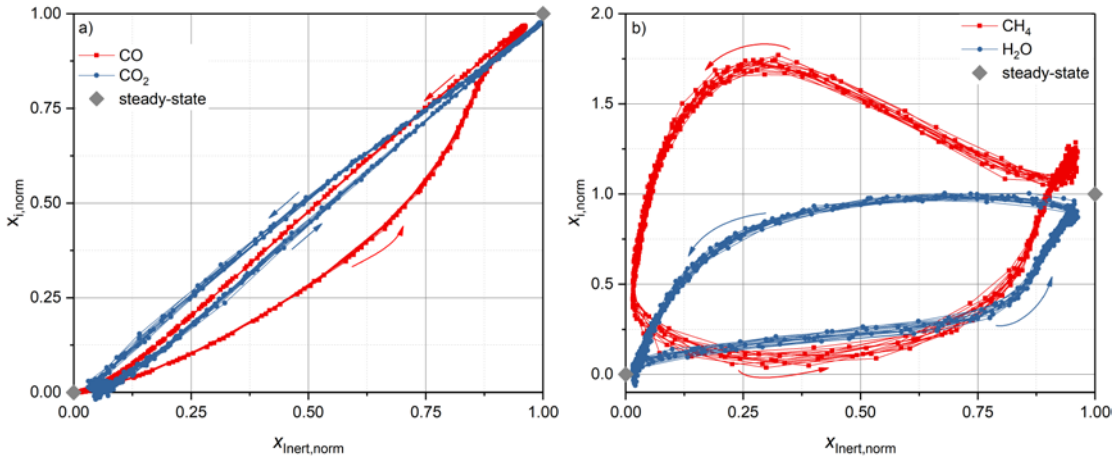

Figure 1. Limit cycle of the reactants (a) and products (b) in the phase-plane upon periodic exchange of CO with CO_2, period duration 30 s, T = 573 K, p = 2 bar, H_2/carbon source/inert = 8/1/1.

4. Conclusion

We present experimental results on the dynamics of the CO/CO_2 co-methanation on Ni-based catalysts. The different behavior of the reactive species indicates differences in interaction strength between those species and the active catalyst surface, which allows to deduce on the basic reaction mechanism. By quantitatively analyzing the dynamic change in the molar flow rate, we are able to determine a transient turn-over frequency (TOF) for methane formation and to compare it to the steady-state case value. Finally, we link the frequency response of each of the reactants to either the quasi steady-state, the full transient regime or the relaxed steady-state according to [4]. This provides to identify a tolerant operation window for fluctuating inlet compositions.

2 Budapest University of Technology and Economics (BME), Department of Chemical and Environmental Process Engineering, Budapest, Hungary;

3 Wroclaw University of Science and Technology, Faculty of Chemistry, Wroclaw, Poland.

**Corresponding author: ivanal888@yahoo.co.uk*

Highlights

- Cotton gauze was impregnated with *M. officinalis* extract using SFE-SSI process.
- Three different process modes were tested.
- FTIR analysis confirmed the presence of *M. officinalis* extract on cotton gauze.

1. Introduction

Lemon balm (*Melissa officinalis*) has long been used in herbal medicine due to its numerous biological activities including antioxidant, antimicrobial and antiviral [1].When there is a need to impregnate a solid material with a supercritical extract, merging of the supercritical fluid extraction (SFE) and supercritical solvent impregnation (SSI) into the one, integrated, SFE-SSI process enables energy savings as well as minimization of the extract losses [2-4]. The goal of this study was to obtain cotton gauze functionalized with *Melissa officinalis* extract for potential topical application by the integrated SFE-SSI process. The influence of different processing modes on the obtained impregnation yield was studied.

2. Methods

M. officinalis folium was milled in a blender and sieved prior the experiments. Integrated SFE-SSI process was performed on laboratory scale unit (High Pressure Extraction Adsorption (HPEA) 500, Eurotechnica, Germany), whereby both, extraction and impregnation, were performed at 10 MPa and 40 °C. Detailed equipment description and possible processing modes are presented elsewhere [3, 4].

3. Results and discussion

Three types of processing modes were performed in order to obtain maximal impregnation yield (I). **Mode I:** Batch mode - supercritical fluid was circulated through the system (extractor and adsorber) for 5 h. **Modes II and III:** Circulation of supercritical fluid through the system was performed in cycles (Table 1). Between the cycles, a continuous CO_2 flow (10 g/min) through the extractor and adsorber was maintained during 5 minutes.

Introduction of fresh CO_2 positively influenced the yield of impregnation (defined as the mass fraction of the extract in the functionalized material). Introduction of fresh CO_2 while maintaining the total process time approximately equal, enabled 6.5 times higher impregnation yield when

Mode III (2.24%) was applied compared to Mode I (0.34%). The introduction of fresh CO_2 positively affected the efficiency of extraction process, leading to the higher amount of the extract available for the SSI. Further increase in contact time led to the decrease of the impregnation yield.

Table 1. Impregnation yield of *M. officinalis* extract for different processing modes

	No of cycles	Cycle duration, h	Total contact time	I, %
Mode I	1	5	5 h	0.34±0.035
Mode II	3	2+2+1	5 h + 10 min flow	1.48±0.127
Mode III	5	1	5 h + 20 min flow	2.24±0.141

The FTIR spectra show the main differences between the impregnated and control cotton gauze in the range 3000–2800 cm^{-1} and around 1700 cm^{-1} attributed to C–H and C=O stretching vibrations, respectively, confirming that the balm extract was effectively impregnated into the gauze.

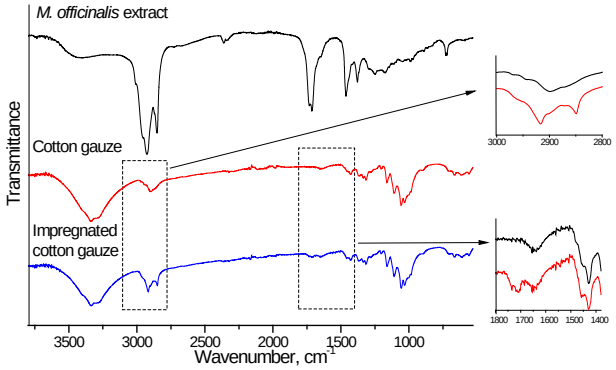

Figure 1. FTIR spectra of pure *M. officinalis* extract, control and impregnated cotton gauze.

4. Conclusions

Cotton gauze was successfully impregnated with *M. officinalis* extract using the integrated SFE-SSI process at 10 MPa and 40 °C. In order to optimize the process, three different processing modes were tested. The presence of extract on the surface of cotton gauze was confirmed by FTIR analysis.

Modelling and Simulation of Porous Catalyst Pellets for Unsteady-State co-Methanation of CO/CO_2 mixtures: Comparison of Diffusion Models

Jannik Schumacher[1], Dominik Meyer[1], Jens Friedland[1], Robert Güttel[1]

1 Institute of Chemical Engineering, Ulm University, Ulm, Germany

**Corresponding author: Jannik.schumacher@uni-ulm.de*

Highlights

- Unsteady-state methanation is modelled and simulated on the pellet scale.
- Different diffusion models are compared with respect to their dynamic effects.
- The exchange of CO_2 with CO is used as a model experiment of a dynamic process.

1. Introduction

The methanation process is a promising part of a sustainable energy supply and infrastructure via the power-to-gas (PtG) process. However, since the availability of renewable energy and carbon sources is fluctuating, the methanation has to work under unsteady-state conditions as well, depending on the upstream storage capacities [1]. One of the main challenges arising from this situation is the dynamic behavior of the porous catalyst pellets used for methanation, where heat and mass transfer occur simultaneously with the chemical reaction. Dynamically changing spatial profiles of temperature and concentrations develop, which are coupled non-linearly. Since the measurement of those profiles, especially under operando-conditions is very challenging [2], modelling and simulation provides a powerful tool for analyzing the occurring dynamic processes. Among methanation of pure CO_2 and CO a mixture of both carbon oxides is of interest especially when considering process gases, such as coke oven gas, as carbon source. However, when switching from CO_2 to CO-methanation or between various mixtures of both, the dynamic profiles change in an unpredictable way, which originates from the different reaction mechanism for CO and CO_2 hydrogenation. Thus, the present contribution analyses the dynamic behavior at particle scale based on modelling and simulation.

2. Methods

This work puts emphasis on the comparison of different diffusion models under isothermal and unsteady-state methanation conditions as a basis for reliable simulation results. The compared diffusion models comprise, but are not limited to, the models by Fick and Wilke-Bosanquet as well as the dusty-gas model [3]. The models are evaluated based on accuracy and numerical effort. Due to a lack of experimental data for validation the dusty-gas-model is assumed as the most accurate model, since it is the most complex one and thus probably considers all relevant effects on diffusion. Thus, the alternative (and simpler) models are compared to the results of the dusty-gas model as benchmark. The model equations for the unsteady-state reaction-diffusion problem are implemented to Aspen Custom Modeler for simulation. The diffusion models in accordance to Solsvik et al. [4] are used, while the reaction kinetics are taken from Xu and Froment [5]. For simulation typical

methanation conditions are chosen with respect to temperature, pressure and reactant composition. The catalyst pellet is assumed to be isothermal, in order to avoid super-imposed temperature influences. The effects at reactor scale are neglected, as well as external heat and mass transfer resistances, in order to isolate the diffusion effects. The dynamic profiles when exchanging CO_2 with CO are calculated with respect to the different diffusion models.

3. Results and discussion

As example Figure 1a shows the simulated steady-state profiles of the methane molar fraction in the CO_2-methanation process for different diffusion models. It is obvious that the choice of the diffusion model is a critical part in the modelling and simulation process. Although the concentration profiles calculated with the dusty gas model and the Wilke-Bosanquet are highly different, the surface methane fluxes and consequently the effective reaction rates are quite similar (Figure 1b). Based on the systematic evaluation of diffusion models under steady-state conditions, the dynamic behavior of the concentration profiles is analyzed by changing the switching frequency between H_2/CO and H_2/CO_2 as well as for different H_2/CO_x gas mixtures (not shown in abstract). From the obtained results the impact of mass transport on the behavior of the catalyst pellet is evaluated.

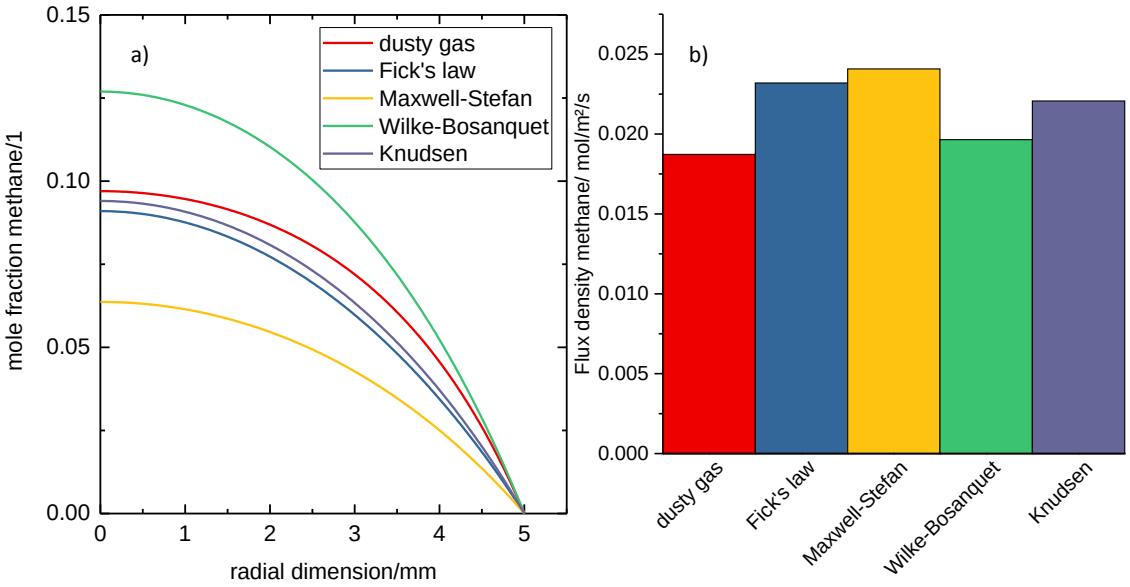

Figure 1. a) Steady-state methane concentration profiles for CO_2-methantion with different diffusion models, b) steady-state flux density of methane across the external surface of the catalyst pellet.

4. Conclusions

While the effective reaction rates in the CO_2-methantation process are quite similar for the studied diffusion models, the dynamic behavior of the profiles is expected to differ, since the concentrations are highly different.

Homogeneous, Continuous and Highly Selective mono-Bromination of 3-Methylanisole in a Microreactor System

Pei Xie[1], Kai Wang[2], Jian Deng[3], Guangsheng Luo[4]

The State Key Laboratory of Chemical Engineering, Department of Chemical Engineering, Tsinghua University, Beijing 100084, China

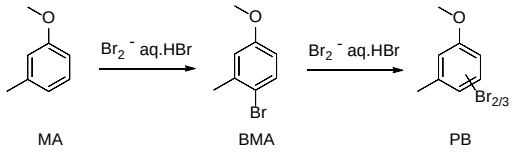
**Guangsheng Luo, gsluo@tsinghua.edu.cn*

Highlights

- Synthesize continuously 4-bromo-3-methylanisole in a microreactor system.
- Improve dramatically mono-brominated selectivity in a homogeneous reaction.
- Simplify greatly the purification process of crude 4-bromo-3-methylanisole.

1. Introduction

4-Bromo-3-methylanisole (BMA) is mainly used to synthesize ODB-2 which is the most important heat-sensitive dye in the manufacture of thermal paper. [1-2] In industry, BMA has been mass-produced by mono-bromination of MA with Br_2 - aq. HBr (Scheme 1). The crude BMA has to be distilled to remove high boiling point bis/tris-brominated byproducts (PB) because of the low mono-brominated selectivity in a heterogeneous reaction system. Therefore, the microreactor technology is expected to intensify the mixing and heat exchange of bromination reaction to reduce PB content in a homogenous reaction system and simplify the purification process of crude BMA.



Scheme 1. Heterogeneous Brominated Reaction

2. Methods

The homogeneous bromination of MA in $CHCl_3$ was performed in the microreactor system (Figure 1) whose core components are the micro-sieve dispersion reactor (Figure 2). Considering the corrosiveness of Br_2 and HBr, the tubes, M1 and M2 are made of PTFE. [3-4]

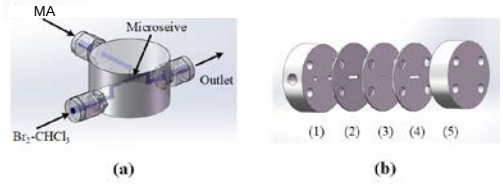


Figure 1. Structure of Micro-sieve Dispersion Reactor

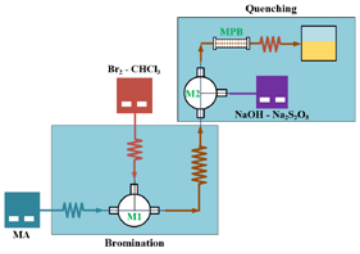

Figure 2. Microreactor System

3. Results and discussion

The mono-brominated selectivity (Figure 3) and BP content (Figure 4) were compared in the heterogeneous and homogeneous reaction system.

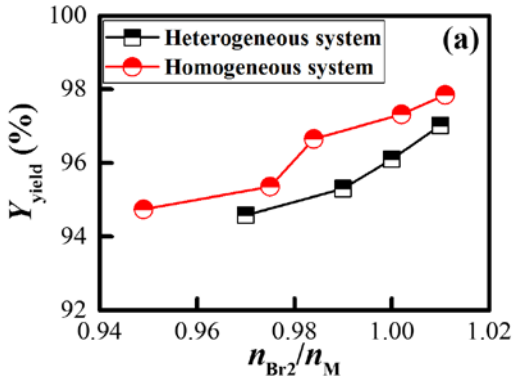

Figure 3. The Comparison of BMA Yield

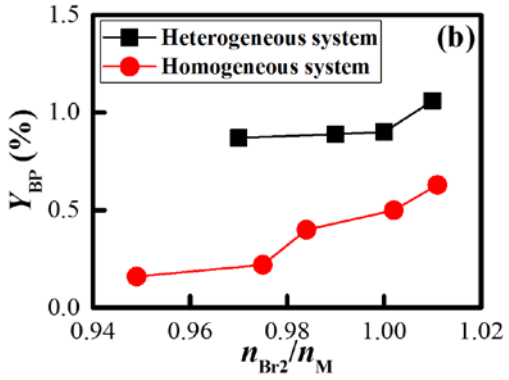

Figure 4. The Comparison of PB Content

4. Conclusions

BMA was synthesized continuously in a microreactor system under homogeneous conditions. The PB content can be controlled below 0.5% at a mild temperature (20-25 °C) in a minute residence time. Finally, the distillation purification of crude BMA is unnecessary as result of higher mono-brominated selectivity.

Analyses of a non-isothermal simulated moving bed reactor based on Multi-objective optimization

Jian Wang, Weifang Yu*, Jin Xu*

College of Chemistry and Material Engineering, Wenzhou University

**Corresponding author: ywf@wzu.edu.cn; xujin@wzu.edu.cn*

Highlights

- Non-isothermal operations of an SMBR for methyl acetate synthesis were evaluated by multi-objective optimization.
- In addition to unit throughput and product purity, solvent consumption was also considered.
- Effects of kinetic parameter and adsorption strength of reactant were investigated by sensitivity study.
- The feasibility of applying non-isothermal operations was systematically investigated.

1. Introduction

Simulated moving bed reactor (SMBR) couples in-situ adsorptive separation with chemical reaction. Conversion of a reversible reaction can be increased beyond the limit of thermodynamic equilibrium and, as the same time, pure product can be directly collected, simplifying the downstream purification processes [1]. SMBR consists of a series of columns packed with solid phase materials with both catalytic activity and adsorptive selectivity. Typically, inlet and ourlet ports divide the columns into four zones, each playing a specific functional role.

Efficiency of the onsite separation is crucial for the success an SMBR. VariCol and PowerFeed technologies that have been originally developed for SMB separation were proven to be effective for the improvement of SMBR performance [2,3]. Gradient operation by introducing different adsorptive strength into different zones according to their functions has been extensively used to reinforce SMB separation processes.

The ongoing work in this group and colleagues is aimed at examining the feasibility of applying temperature variance on an SMBR. For this purpose, synthesis of methyl acetate catalyzed by amberlyst 15 was used as the model reaction. It has been shown by both theoretical and experimental studies that complete conversion and separation can be achieved [4,5].

One of our previous study investigated the effects of temperature gradient under the frame of Triangle Theory [6]. Maximum unit throughput for complete conversion and separation was acquired by fixing conservative flowrates in zones I and IV and searching the two dimensional parametric plane consisting of flworates in zones of II and III. In this work, zones I and IV were also taken into consideration. Multi-objective optimizations were carried to evaluate SMBR performance in terms of unit throughput, product purity and solvent consumption as well.

2. Methods

Mathematical model and model parameters for the simulation of an SMBR reactor were established in previous publications [5,6]. A four zone SMBR has five independent operating parameters, namely, switching time and the four flowrate. The maximum flowrate that is limited by column pressure was assigned to zone I as a scaling factor. Simultaneous maximization of unit throughput and product purity was pursued by tuning the other four parameters that had been converted to dimensionless flowrate ratios. As in general, operating conditions have contradicting effects on these two objectives and the solutions form a pareto curve. Non-dominated sorting genetic algorithm (NSGA-II) was used to acquire the solutions.

3. Results and discussion

Pareto solutions of an SMBR operated under various modes are compared in Figure 1. Minimization of solvent consumption was then pursued by both parametric sensitivity analyses and 3-objective optimizations. Using the same procedure, effects of kinetic rate, adsorption strength of reactant and reaction heat on the SMBR performance were also investigated. More detailed results and discussions omitted here for conciseness will be presented in the conference.

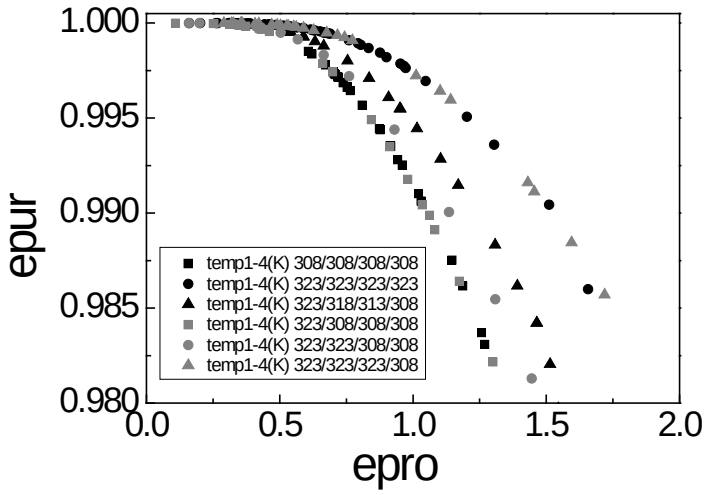

Figure 1. comparison of pareto solutions acquired for SMBR with several temperature distributions

4. Conclusions

Temperature may have both synergy and contradicting effects on reaction kinetics and separation in different zones. As a result, temperature gradient operation can be conditionally but not generally applied to improve SMBR performance.

The Differential Gibbs and Helmholtz Reactors for Ideal and Non-Ideal Gases and Selected Applications

Sindre Bakke Øyen[1], Tore Haug-Warberg[1], Hugo Atle Jakobsen[1], Jannike Solsvik[1]

1 Norwegian University of Science and Technology, Sem Sælands vei 4

Highlights

- Fluid mechanics combined with thermodynamics in continuity equations
- Rate expressions in classical reactors substituted out for minimizing Gibbs free energy
- A theoretical upper limit at all points throughout the reactor

1. Introduction

In chemical process design, equilibrium calculations are frequently carried out to explore whether the construction of a production plant is profitable or not. Simulation tools, such as Aspen HYSYS, provide the tools for this kind of calculation: the equilibrium reactor or the Gibbs reactor. Both obtain chemical reaction equilibrium by minimizing Gibbs free energy at the specified temperature and pressure, displaying the theoretical maximum production. However, this does not account for the real conditions in a reactor such as temperature, pressure and velocity gradients. This work is a continuation of the differential Gibbs and Helmholtz reactors presented by Solsvik et al. [1], where the idealized plug flow reactor, e.g. Fogler [2], with ideal gas conditions were used to illustrate a chemical reactor combined with the thermodynamic equilibrium condition, i.e. minimum Gibbs energy [3]. The reactor displays a maximized production at each point throughout the reactor, giving insight on both the deviation from optimality as well as how high/low the temperature can get at its extremes.

2. Methods

The idealized plug flow reactor model with Ergun's equation used by Solsvik et al. [1] is still used. The ideal gas model is used initially, and after successfully converging this problem, the model is extended to also consider equations of state for non-ideal gas behavior. This affects both the reactor models as well as the thermodynamic equilibrium calculation. The simulations are repeated for several chemical systems, numerical schemes and for both the differential Gibbs and Helmholtz reactors. The results are then compared to classical reactor models with rate expressions to see how the compositions differ throughout the reactor. The numerical scheme chosen will impact the complexity of the algorithm for solving the reactor model and, hence, the choice of energy surface to minimize, e.g. Gibbs or Helmholtz energy.

3. Results and discussion

Results presented here include the production of methanol from synthesis gas, a mixture of H_2, CO and CO_2. Results obtained with the differential Gibbs reactor are presented below. As seen, the immediate equilibrium next to the inlet yields a steep rise in temperature. The exothermic reaction also makes the density drop, which by continuity makes the velocity rise. The methanol production is however inhibited by the high temperature, and hence, the mole fraction of methanol is not at its maximum value. As the reactor is cooled, the mole fraction slowly rises, and at approximately 4 meters, the value stabilizes. The density rises to this point as well, causing the velocity to drop. After 4 meters, only the pressure drop from Ergun's equation affects the velocity and density to some degree. However, this has no significant impact on the equilibrium composition, since the pressure drop is relatively small.

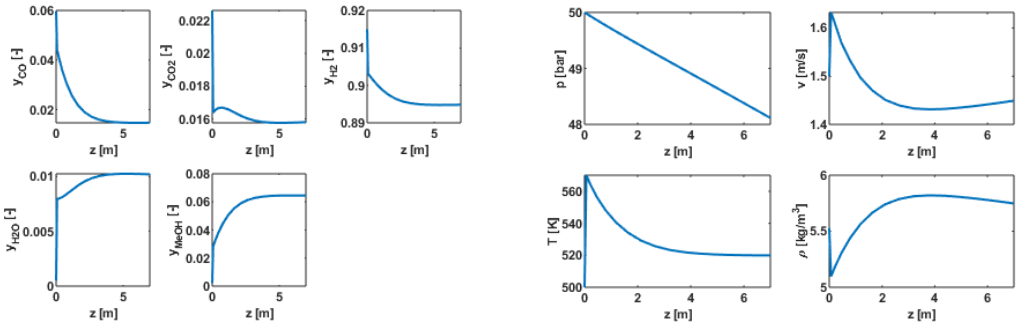
The apparent bump in carbon dioxide mole fraction is caused by the following reaction reversing:

$$CO_2 + 3H_2 = CH_3OH + H_2O$$

while the following reaction is shifted towards right:

$$CO + H_2 = CH_3OH$$

Therefore, only the mole fraction of H_2O and CO_2 is visually apparent.



4. Conclusions

The model considered suggests an approach for combining fluid flow with thermodynamic equilibrium. The thermodynamic part is a useful tool in the lack of reaction rate kinetics and in a process design feasibility study, while the fluid dynamic part retains the effects of fluid flow. The profiles from the fluid dynamic part can also be used to characterize worst-case scenarios, such as steep temperature rise, and therefore in risk assessment and online operation, making the model a proactive choice.

Influence of operating parameters on the single pass removal efficiency during the photocatalytic degradation of acrylonitrile.

Henrietta Essie Whyte[1], Cécile Raillard[1], Albert Subrenat[1], Valérie Héquet[1]

1 GEPEA UMR CNRS 6144, IMT Atlantique, DSEE, 4 rue Alfred Kastler CS 20722, 44307 Nantes, France

**Corresponding author: Valerie.hequet@imt-atlantique.fr*

Highlights

- Single-pass removal efficiencies can be improved according operating parameters
- A complete mineralization can be reached irrespective of initial pollutant concentration
- Conversion vs. mineralization rates show the probable formation of intermediates

1. Introduction

The hospital is a place where the air quality is very important as it plays an important role in the health of both patients and hospital staff. Microbial contamination in relation to nosocomial infections has been at the fore front of hospital air quality whilst chemical contamination is rarely studied [1]. One of the most demanding areas in terms of the air quality is the operating room (OR). Surgeons and operating theatre staff are routinely exposed to pollution from the surgical smoke. The chemicals present in greatest quantity in surgical smoke are hydrocarbons and nitrile compounds among which is acrylonitrile. Barret and Garber [2] reported acrylonitrile concentrations to be between 1 and 1.6 ppm. In ORs air quality is assured mostly by HVAC. However, this is not always enough thus additional treatment devices can be used to purify air. Stand-alone devices that use photocatalytic oxidation (PCO) are becoming increasingly popular to treat indoor air. The aim of this work is to assess if PCO is efficient for removing acrylonitrile and to study the influence of three operational parameters (air velocity, light intensity and initial concentration) on the photocatalytic removal efficiency of acrylonitrile.

2. Methods

A 420 L multi-pass dynamic photocatalytic reactor was used to carry out the PCO experiments. It has been described and modelled in a previous articles [3],[4]. The media used was supplied by Saint-Gobain Quartz (QUARTZEL®) and consisted of quartz fibers coated with TiO_2 deposited through a sol-gel method. The media was irradiated with two 18-W UVC fluorescent tubes (Phillips PL-L series). Acrylonitrile was supplied from a certified commercial gas cylinder produced by Air products. The cylinder contained 150 ppm of acrylonitrile balanced in nitrogen at a pressure of 150 bars. The selected average light intensities (I) ranged from 1 to 4.5 $mW.cm^{-2}$. The air velocities corresponding to the selected flow rates (73 - 216 $Nm^3.h^{-1}$) varied from 0.5 to 1.5 $m.s^{-1}$ and were determined as the ratio between the air flow rate and the cross-sectional area (0.04 m^2) of the photocatalytic module. Initial concentrations (C_0) chosen for the experiments ranged from 0.5 to 10 ppm which were representative of concentrations reported in the literature. The relative humidity (RH) was maintained at 50% at 20°C to be representative of average humidity levels found in operating rooms in European countries.

3. Results and discussion

First results showed that acrylonitrile is degraded within 1h based on the experimental conditions of C_0=2ppm, v=1 m.s^{-1} and I = 4.5mW.m^{-2} (Fig. 1). It was observed that the degradation followed a first order kinetic. The experimental points were then fitted to the model developed by Dumont and Héquet. The model describes the first order decay relationship of concentration vs. time and helps to determine the single pass removal efficiency. It is as follows:

$$\mathbf{C} = \boldsymbol{C_0}\,\mathbf{exp}\left\{-\frac{\boldsymbol{t}}{\boldsymbol{\tau_R}}\Big|[\mathbf{1}-\mathbf{exp}(-\boldsymbol{\alpha})]\right\} \qquad \textbf{(1)}$$

In Eqn. 1 the term α is the single pass removal efficiency and represents the fraction of the total flow treated during the time τ_R (residence time in the reactor). C is the pollutant concentration at time t and C_0 is the initial pollutant concentration. Numerical resolutions are carried out using Excel® Solver which is based on the least- square method.

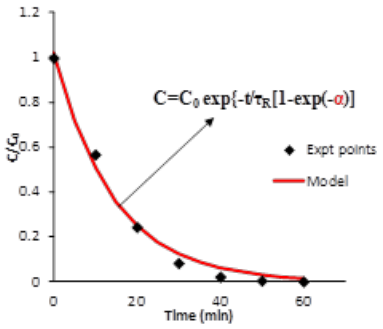

Figure 1. Experimental degradation curve of acrylonitrile fitted to model (C_0 = 2 ppm; v = 1 m.s^{-1}; I = 4.5 mW.cm^{-2}).

4. Conclusions

Conclusively, PCO is able to degrade acrylonitrile. The experimental points are well fitted to the model and enable the calculation of the one-pass removal efficiency. Since the global objective is to study the effect that the operating parameters have on the single pass removal efficiency, experiments are conducted at the selected air velocities, light intensities and initial concentrations to determine their influence.

Reductive amination in different solvent systems: reaction network analysis and kinetics

Sabine Kirschtowski[1], Christof Kadar[2], Andreas Seidel-Morgenstern[1,3], Christof Hamel[4]

1 Otto von Guericke University, Institute of Process Engineering, Magdeburg, Germany

Highlights

- Formulation of a reaction network for the reductive amination
- Good performance of the RA in homogeneous and thermomorphic solvent systems
- Kinetic description of the RA in two different solvents

1. Introduction

The Collaborative Research Center Transregio 63 of the German Research Foundation (DFG) develops methods and strategies to adapt established reactions to substrates from renewable raw materials. Focus of this project is the evaluation of the potential of complex homogeneously catalyzed tandem reactions using the example of the rhodium-catalysed hydroaminomethylation (HAM) of 1-decene. This reaction offers a direct and efficient synthesis of various pharmaceuticals, natural products, agrochemicals and fine chemicals [1]. To acquire detailed knowledge regarding the overall reaction the sub-network of the reductive amination (RA) step is analysed separately.
To recover the expensive Rh-catalysts from the homogeneous reaction solution thermomorphic solvent systems (TMS) are applied. In TMS the separation between products and catalysts is realized by using temperature dependent miscibility gaps in mixture of solvents of different polarity [2]. With regard to process development and optimization detailed knowledge of the reaction rates is necessary. We will report about a kinetic model to describe the reactions in homogeneous solvents and the transferability to TMS systems.

2. Methods

RA experiments were conducted in a high-pressure batch reactor system equipped with a gas supplying system and pressure and temperature controllers. The RA was investigated in three different solvent systems (2 homogeneous, 1 TMS) considering the reactants undecanal and diethylamine (DEA) ($c_{undecanal}$ = 0,18 mol/L, n_{DEA}:$n_{undecanal}$=4:1 and 1:1). The homogeneous solvent systems constituted of isopropyl or methanol (with 1 wt-% dodecane as internal standard respectively), whereas the TMS constituted of methanol and dodecane (w_{MeOH} : $w_{dodecane}$ = 50 : 50). The ligands triphenylphosphine (TPP) and Xantphos (XPH) were investigated, so that the catalyst is formed by Rh(acac)COD and the corresponding ligand (n_{Rh}:n_P:$n_{undecanal}$ = 1:2:1000). Kinetic experiments were carried out in the temperature and H_2 pressure ranges between 85°C…115°C and 10 bar…30 bar, respectively.

3. Results and discussion

Based on the experimental results a reaction network for the reductive amination is postulated considering four groups of compounds (Figure 1): the desired product n-amine, the intermediate n-enamine and the side products n-alcohole and aldole.

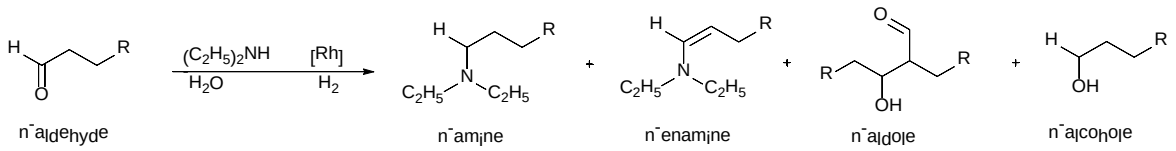

Figure 1. Main and side products of the rhodium-catalysed reductive amination of a linear aldehyde

Concerning the RA performed in methanol with the ligand XPH significant conversion X of the reactant and a high yield Y with respect to the n-amine were observed after 120 min ($X_{undecanale}$ = 100 %, Y_{amine} = 91 %, Figure 2a). The RA carried out in isopropyl revealed a different behavior. With the ligand TPP the reactant conversion is significantly lower ($X_{undecanal}$ = 90 %) and the yield is only Y_{amine} = 63 % (Figure 2b). In this case the hydrogenation of the enamine to the amine is clearly inhibited. The reductive amination carried out in the TMS methanol:dodecane = 50:50 showed similar conversions ($X_{undecanal}$ = 100 %) and yields (Y_{amine} = 85 %) as for the homogeneous solvent methanol.

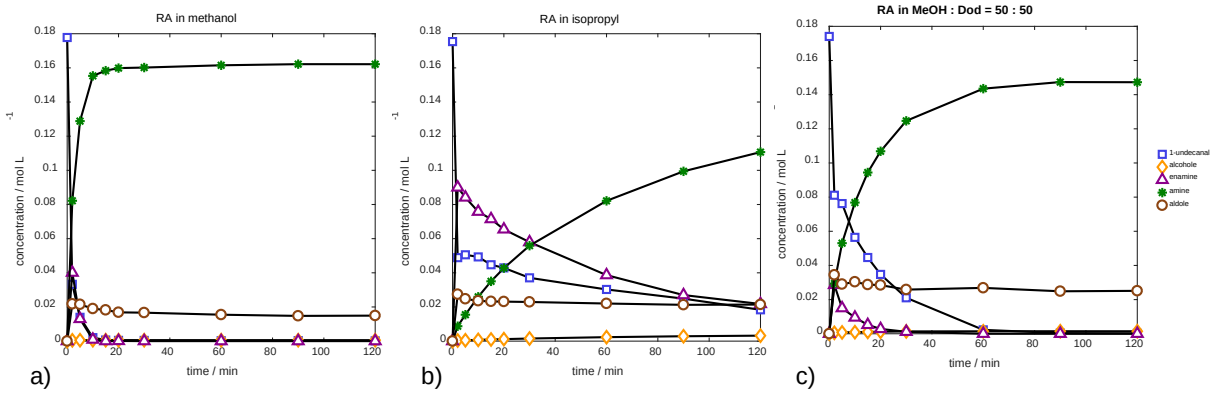

Figure 2. Reductive amination of 1-undecanale at T = 100 °C, p_{H2} = 20 bar. a) in methanol with XPH, DEA:Sub = 4 b) in isopropyl with TPP, DEA:Sub = 4 c) in TMS (MeOH:dodecane = 50 : 50) with XPH, DEA:Sub = 1

4. Conclusions

To describe the experimentally observed trends with a suitable kinetic model, the influence of the solvent composition needs to be considered. Currently the inhibition of the hydrogenation of the enamine to the amine is quantified in more detail in order to provide a quantitative kinetic model for the reaction carried out in the TMS.

Highlights

- Recovery of biomass components was studied.
- Extraction techniques for the isolation of valuable substances (antioxidants, carotenoids, waxes, fragrances) from plant sources was developed.
- Waste-less treatment is nowadays required for sustainable economy

1. Introduction

Bio-refining is a perspective branch that focuses on the development of separation methods for recovery of valuable substances from biomass or also for the processing of bio-waste from agriculture. The goal of the research was to propose a procedure for the waste-less treatment of plant material or the acquiring of health-beneficial substances suitable as e.g. dietary supplements.

2. Methods

Two ways of separating the monitored components from the solid matrix into a liquid solvent were tested. The first one was the extraction using Soxhlet´s apparatus, a highly efficient multistage process. The second more gentle process was a single-stage extraction in a stirred system at room temperature in an absence of light under inert atmosphere. From analytical methods mainly (U-)HPLC/MS was applied. The antioxidant activity of waste marc was determined using three methods: ABTS, DPPH and Folin-Ciocalteu.

3. Results

The aim of the study was the development of extraction technique for the isolation of carotenoids from medicinal plants (*Calendula officinalis, Tagetes sp.*), the separation of waxes from *Miscanthus sp.* stalks or the obtaining of fragrances from *Magnolia* × *pruhoniciana* blooms. From the waste biomass, the residual fresh marc after vine grapes pressing was processed to obtain resveratrol and other substances with antioxidant activity.

Raw processed biomass is shown on Figure 1.

Figure 1. Processed biomass. *Calendula* (a), *Tagetes* (b), *Miscanthus* (c), marc of white and red grapes (d), *Magnolia* × *pruhoniciana* blooms (e).

4. Conclusions

Carotenoids, especially lutein, contained in larger quantities in *Calendula* and *Tagetes*, are used as a component of poultry feed or as a dye in food supplements. It plays an important role in human nutrition as it has antioxidant effects in neutralizing free radicals causing degenerative changes in the retina.

Tall stems of *Miscanthus* contain a broad spectrum of various substances being potentially exploitable in cosmetics. Waste biomass has, after being pressed into the form of pellets, the potential for energetic utilization as “green fuel”.

Wine grape marc as an agricultural waste was tested on the antioxidant activity and resveratrol content. It is a rich source of polyphenolic substances with the influence on heart and blood vessel diseases.

Fragrant essences obtained by extracting fresh flowers of *Magnolia* × *pruhoniciana* have been tested as face creams and fragrant ingredients and they could be useful for other various cosmetic products.

All processes were designed to maximize the biomass utilization with a view to waste-less eco-recovery of valuable bio-material substances.

Hydrodeoxygenation of bio-oil model compounds over the nickel phosphide catalysts

Jundong Wang[1], Lokmane Abdelouahed[2], Luis Reyes[3], Bechara Taouk[4]

1-5-Normandie Univ, INSA Rouen Normandie, UNIROUEN, Laboratoire de Securité des Procédes Chimiques (LSPC EA 4704)

** bechara.taouk@insa-rouen.fr*

Highlights

- Detailed analysis of gas and liquid product of hydrodeoxygenation of model compounds
- Hydrodeoxygenation of model compounds
- Effect of temperature on hydrodeoxygenation of model compounds

1. Introduction

Multifarious efforts have been focused on the production of renewable and clean biofuels and chemicals to meet growing energy demand and environmental and sociopolitical concerns arising from a current heavy global dependence on fossil fuels. Biomass is considered as sustainable and abundant feedstock which can be effectively converted into liquid fuels via fast pyrolysis technologies. Unfortunately, although fast pyrolysis is a promising method to obtain bio-oil, the high content of oxygenated molecules (ketones, aldehydes, organic acids, furans, phenolic derivatives and lignin-derived oligomers) decrease its chemical and thermal instability [1]. It is unsuitable for direct use as a transportation fuel (or as a fuel additive) because of its low heating value and high corrosiveness caused by the presence of significant oxygenated compounds. These organic compounds are highly reactive, promoting the formation of ethers, acetals, hemiacetals and heavier organics through condensation reactions, resulting in some problem in bio-oil application, for example, coke formation. Therefore, it requires the investigators to improve the pyrolysis bio-oil to obtain an upgraded liquid fuel or some useful chemicals with proper properties which can be suitable for the global transport infrastructure.

In this paper, hydrodeoxygenation (HDO) experiments of the bio-oils model compounds upgrading reaction over the Ni_2P/HZSM-5 and Ni_2P/SiO_2 will be studied. Here presents an experimental study of influence of different reaction parameters, such as feedstock state, residence time, reaction temperature and reaction pressure (H_2 partial pressure) etc.

2. Methods

Supported nickel phosphide catalysts (Ni_2P/HZSM-5 and Ni_2P/SiO_2) were prepared by incipient wetness impregnation and a temperature programmed reduction (TPR). The XRD and elemental analyzer was used to characterize the catalysts. The model compounds feedstock (acetic acid, 4-Ethylguaiacol) vapor phase was introduced into a continuous fix-bed reactor under the high hydrogen pressure. The liquid phase feedstock had been conducted in a batch reactor. The gas

chromatography-mass spectrometer (GC-MS) and GC/FID will be used to analyzed the gas and liquid products to compare the results between different types of reaction.

3. Results and discussion

Figure 1 shows the main oxygenated compounds (CO, H_2O) content in the gas and liquid products of acetic acid HDO reaction. It indicated that the CO content in the gas products was decreased with the reaction pressure increasing. This can be explained by the promotion of the reaction CO and H_2 given that the H_2 partial pressure was increased. In addition, figure 1 also shows that the moisture content increase due to the increasing of reaction pressure. It means that more oxygen was removed by the hydrogenation reaction.

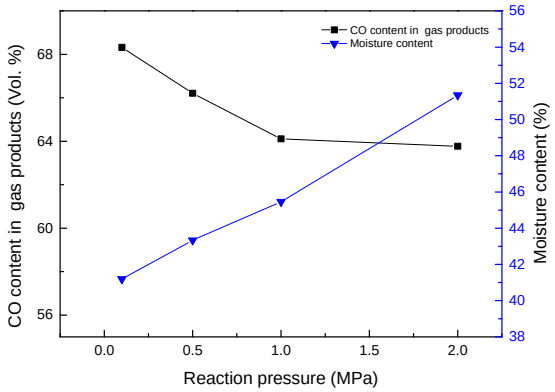

Figure 1. The CO content in gas products and moisture content in the liquid products under different reaction pressure.

4. Conclusions

In this work, the HDO reaction of different model compounds where studied in different experimental conditions (temperature, contact time and pressure) and catalysts. Results show that the pressure of hydrogen has a conspicuous influence on the HDO reaction. It had a promoted effect on the hydrogenation. The liquid products moisture was higher using the Ni_2P/HZSM-5 catalysts and relative lower using the Ni_2P/SiO_2 catalysts. It was possible that the conversion and products selectivity were higher when the HDO reaction took place in the continuous fix-bed reactor with the vapor phase hydrodeoxygenation of model compounds.

Highlights

- NIRS and Chemometrics applied to extraction process.
- Highly accurate prediction model. (R^2 = 0.967, SEP = 2.823 mg/L; ε = 5.04 %.
- The technical feasibility of the methodology was proved successfully.

1. Introduction

The applications and the importance of In-line real-time monitoring using Near-Infrared Spectroscopy (NIRS) and Chemometrics, as a Process Analytical Technology (PAT) in the Pharmaceutical and Food Industries, have increased through the years, due to their advantages and the results obtained (Scarff *et al*., 2006). Another interesting application for this technology is the chemical process of extraction. Liquid extraction using organic solvents is a very widespread technique for obtain molecules of industrial interest from biomass, *e.g.*, chlorophyll, that uses as colorant and additive. It is therefore interesting to search new sources of this molecule, one of this sources could be the pine needles, that left behind the forest exploitation, and have no apparent use. For this reason, the application of NIRS and Chemometrics for the real-time monitoring of chlorophyll extraction from pine needles is an alternative to improve the process and generate applicative knowledge.

2. Methods

Chlorophyll extraction process. Extractions were carried out according to the Lichtenthaler method (2001). Extraction conditions were optimizing with a Box-Behnken design, variables were: temperature (50 ºC), ethanol concentration (95 %) and time (240 min).
Reference method. Analyses were performed on an Agilent 1,100 liquid chromatographic system equipped with a diode-array UV/ vis detector. A 250 mm x 4.6 mm i.d., 5 µm particle size Inertsil ODS 2 column (Sugelabor) was used. Elution was performed at a flow rate of 1.0 mL/min at room temperature, using as the mobile phase a mixture (8:2 v/v) of methanol/water containing 0.025 % ammonium acetate and 0.05 % triethylamine as phase A and methanol/acetone (1:1 v/v) as phase B. Concentration is expressed in milligrams of chlorophyll by liter of extract.
NIRS measurements. Spectra were acquired with a Near-Infrared Spectrophotometer XDS Process Analytics (Foss- NIRSystems, Silver Spring, USA) using an in-situ fiber optic transflection probe, 3 mm pathlength. The samples were scanned in duplicate over the whole NIR range (800–2,200 nm)

every 20 min until the kinetic extraction was ended. The spectra were then averaged and derived (second derivative) in order to reduce the signal/noise ratio (Corro-Herrera *et al*., 2016).

Model development and validation. Linear models were constructed using Partial Least Squares Regression (PLSR 1). Ten extraction batches were used to collect the samples spectra. Development of all PLS models was carried out by Vision software (v 3.5, Foss-NIRSystems, Sylver Spring, USA). To avoid overfitting due to many factors or latent variables (LVs), the software predicts residual error sum of squares (PRESS) calculated from random subsets cross validation; a lower PRESS value indicates an adequate number of factors in the model. To assess the prediction capacity of the models, the coefficient of determination (R^2), standard error of calibration (SEC), standard error of prediction (SEP) and error (ε %) were used as quality parameters.

3. Results and discussion

Model quality parameters for calibration are R^2 = 0.974, SEC = 2.453 mg/L and for validation R^2 = 0.967, SEP = 2,823 mg/L; ε = 5.04 %. LVs = 4 (Figure 1a and 1b, respectively). Considering the SEC and SEP as first quality parameter, they are consistent according to the same magnitude order of the value. For R^2 of both, the values are close to the unit, showing the good correlation between the data and for validation.

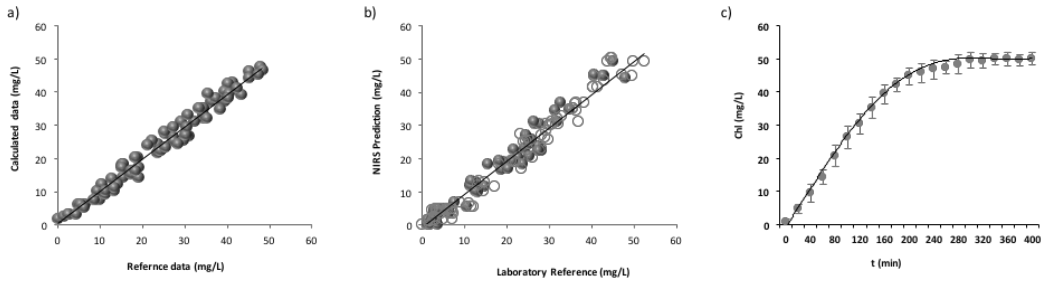

Figure 1. a) Calibration curve and b) Validation curve: (●) laboratory reference, (○) NIRS prediction. c) Real-time monitoring of chlorophyll concentration during the extraction, using the prediction model. (●) Experimental data, (—) prediction of the model.

Once the model was validated, it was now used to the real-time monitoring during the extraction process. 10 batches were carried out for collect the data shows in the Figure 1c. Fitting of the model is quite good with a R^2 =0.987. Chemometric model has the sufficient robustness to predict the concentration of chlorophyll throughout the process. Furthermore, this model fits to the variability of the process, and in addition to expresses the process kinetic behavior.

4. Conclusions

The technical feasibility of real-time monitoring through an immersion transflection probe, of chlorophyll extraction matrix, employing NIRS and Chemometrics, has been demonstrated. This assertion is based on the generation of a functional and robust prediction model for chlorophyll concentration, with R^2 values close to 1 and low SEC and SEP.

Highlights

- A fully integrated two-step flow process combining metal- and biocatalysis
- Use of deep eutectic solvent (DES) to overcome the problem of solvent compatibility
- Full conversion for both decarboxylation and subsequent Heck coupling
- The two-step process was successfully operated for more than 16 h

1. Introduction

Tandem-catalytic reactions are promising routes for the synthesis of high-value products in fine-chemical, agrochemical and pharmaceutical industry. Therefore, they have attracted the attention of researchers in the past decade. [1] Based on recent findings [2], in this work we present a fully integrated two-step flow setup consisting of an enzymatic decarboxylation followed by a Heck reaction coupling the decarboxylation product to an aryl halide as shown in Figure 1 to synthesize asymmetric stilbene derivatives. The most prominent derivatives of stilbenes are resveratrol and its analogues. Their conjugated double bond system gives the molecule anti-oxidant, anti-inflammatory, antidiabetic, antiaging and anticancer properties. [3]

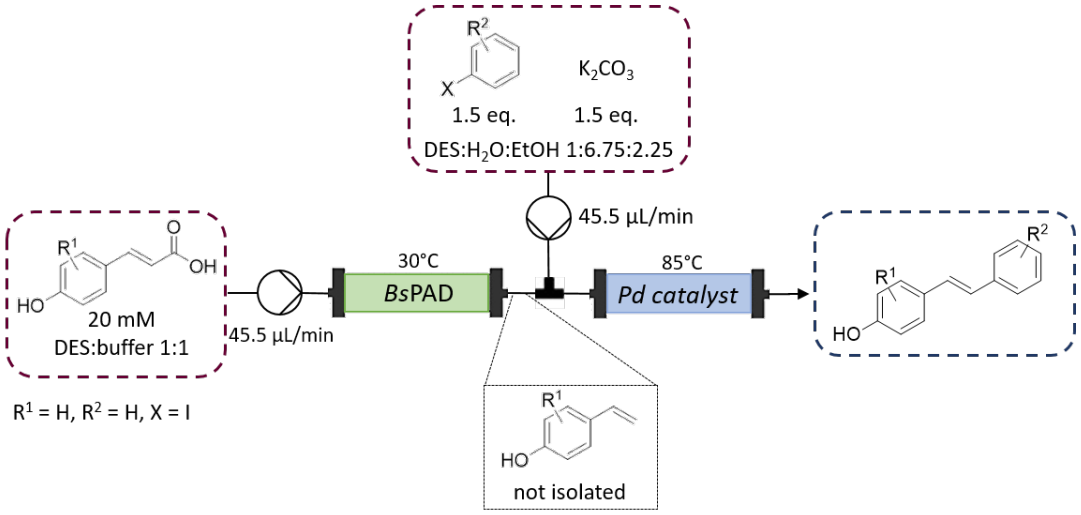

Figure 1. General reaction scheme for enzymatic decarboxylation with a phenolic acid decarboxylase from *Bacillus subtilis* (*Bs*PAD) yielding a 4-hydroxystyrene derivative, which serves as substrate for a Pd-catalyzed cross-coupling reaction with an aryl halide, resulting in a 4-hydroxystilbene product.

2. Methods

A cell-free extract (CFE) of phenolic acid decarboxylase from *Bacillus subtilis* (*Bs*PAD) was immobilized in 2 % alginate beads and employed in a 1:1 (v/v) mixture DES (Choline chloride:glycerol 1:2 (mol/mol)) with potassium phosphate buffer (50 mM, pH 6.0) to decarboxylate *para*-coumaric acid. [4] For the second step, the Heck coupling of the decarboxylation product to iodobenzene, an in-house developed heterogeneous Pd-catalyst (Pd-substituted cerium-tin-oxide with the composition $Sn_{0.79}Ce_{0.29}Pd_{0.01}O_{2-\delta)}$ was applied. [5] The reaction was conducted in a solvent mixture of DES (30 vol%), buffer (25 vol%), ethanol (34 vol%), and water (11 vol%) For the continuous mode, both catalysts were packed in stainless steel columns and heated to 30 °C (PAD) and 85 °C (Pd-catalyst) in a water bath, respectively.

3. Results and discussion

The residence time in the reactors was calculated to be 30 min for the decarboxylation and 45 minutes for the Heck coupling. The conversion of the first step could be followed visually as CO_2 bubbles left the reactor as soon a full conversion of the substrate was achieved. In continuous mode, full conversion was reached for both decarboxylation and Heck coupling. The two-step process was successfully operated for more than 16 h. While the continuous mode allowed to conduct both reaction at their optimal temperature, DES proved to be a solvent compatible with both reactions.

4. Conclusions

These results are important steps towards chemo-enzymatic reactions in continuous flow and should be further investigated in the near future. The results show the importance of DES to overcome obstacles like substrate solubility and solvent compatibility in chemo-enzymatic tandem reactions.

Highlights

- Xylitol production using yeast biomass as detoxification agent.
- Use of sugarcane bagasse and straw for biotechnological production of xylitol.
- Yeast biomass is a promisor raw material for detoxification procedures.

1. Introduction

New technologies which use the exploitation of lignocellulosic materials have been contributed for the development of bioprocesses in the context of biorefineries for example the sugar and alcohol sector. The production of biomolecules from its constituent fraction in this material such as hemicellulose have been studied for example xylitol [1, 2, 3]. Xylitol is a sugar-alcohol important in industry of food, pharmaceutical, cosmetic and odontological), which industrial production occurs by chemical route. Investigations have been done for development of technology of its biotechnological production and it was also stablished parameters such as pH, temperature, aeration. The detoxification before fermentation is required in function of toxic compounds resultant from plant cellular wall deconstruction usually done by diluted acid hydrolysis [4]. Usually detoxification is made with vegetal activated charcoal which contributes for the reduction of toxic content of the hydrolysate such as phenolic compounds [5]. Alternative for charcoal can be proposed as exploitation of residual cellular biomass from the production process of xylitol. The use of non-viable microbial cells in detoxification has as objective its utilization as adsorbent, which can occur the interactions between toxic compounds (adsorbate) and functional groups of the cell and/or its cellular wall (adsorbent) [6]. This research proposes the use of yeast cellular biomass of *Candida guilliermondii* FTI 20037 as detoxification agent of hemicellulosic hydrolysate from the mixture of sugarcane bagasse and straw for xylitol biotechnological production.

2. Methods

The hemicellulosic hydrolyzate from the mixture of sugarcane bagasse and straw (HHSBS) was obtained by diluted acid hydrolysis (1% w/v of H_2SO_4) [5] followed by vacuum concentration to increase its sugars content. For detoxification it was used residual dry biomass of *Candida guilliermondii* FTI 20037 from a previous xylitol production in HHSBS. The detoxification process occurs in HHSBS (adjusted pH for 2), 5% (w/v) dry biomass of *Candida guilliermondii*, temperature 30°C, in Erlenmeyer flasks at 100 rpm to 24 hours. The control with activated charcoal 1% (w/v), pH 2.5, 60°C for 30 minutes was also realized [5]. The fermentation occurred in detoxified hydrolysates,

with addition of nutrients (gL^{-1}): solution of rice bran extract (20), $(NH_4)_2SO_4$ (2), $CaCl_2 \cdot 2H_2O$ (0.1), for 46 hours. The determination of sugar concentration in hydrolysate was done by liquid chromatography, while phenolics by spectrophotometry [2].

3. Results and discussion

In the Table 1 are shown the results of fermentation of HHSBH with the use of dry biomass of *Candida guilliermondii* FTI 20037 as detoxifying agent as well the use of activated charcoal. The use of dry biomass of *Candida guilliermondii* residual of xylitol bioproduction indicates its potential as detoxification agent since removed 27% of phenolic compounds present in HHSBH compared with 40% when used activated charcoal. According the values shown in Table 1 the maximum value of yield and productivity was achieved in 46 hours, which were for yield ($g.g^{-1}$) 0.83 and 0.66; and productivity ($g.L^{-1}.h^{-1}$) of 0.46 and 0.63, for HHSBS detoxified with dry biomass and activated charcoal, respectively.

HHSBS detoxified with yeast biomass					
Time (h)	Biomass (gL^{-1})	Xylose consumption (%)	Xylitol (gL^{-1})	Y p/s (gg^{-1})	Qp ($gL^{-1}h^{-1}$)
22	7.15	14.85	6.97	0.19	0.42
46	9.95	48.69	21	0.83	0.46
70	13.37	81.74	29.45	0.69	0.42
HHSBS detoxified with activated charcoal					
Time (h)	Biomass (gL^{-1})	Xylose consumption (%)	Xylitol (gL^{-1})	Y p/s (gg^{-1})	Qp ($gL^{-1}h^{-1}$)
22	6.93	33.53	9.37	0.47	0.43
46	9.97	74.06	28.87	0.66	0.63
70	12.96	89.24	34.14	0.65	0.49

Table 1. Fermentative parameters from xylitol production by *Candida guilliermondii* FTI 20037 grown in HHSBS detoxified with dry cell biomass or activated charcoal.

4. Conclusions

The utilization of residual dry biomass from xylitol bioproduction in hemicellulosic hydrolysate of sugarcane bagasse and straw has potential to be used as detoxificant agent of this hydrolysate as economical strategy in relation to activated charcoal usually used in this bioprocess, besides the capacity of remove the toxics and promising fermentative parameters reached.

Kinetics and mass transfer for biomass reductive catalytic fractionation

Alexei Kramarenko, John van der Schaaf, *Fernanda Neira d'Angelo**

Eindhoven University of Technology

** M.F.Neira.dAngelo@tue.nl*

Highlights

- Biomass reductive catalytic fractionation is studied in a flowthrough reactor
- A kinetic model that successfully fits the experimental data is proposed
- The different reaction steps are studied step-wise by using both native lignocellulose as well as monomer model compounds

1. Introduction

Lignin is one of the main components of biomass, together with cellulose and hemicellulose. Despite its rich chemical structure and high aromatic content, it is the most underutilized fraction of biomass. This is due to the severe degradation of lignin during biomass fractionation. Innovative fractionation approaches such as reductive catalytic fractionation (RCF) enable the valorization of lignin by preserving the native structure of lignin. For optimal results during RCF (i.e., maximal yields of lignin-monomers), the RCF reactor should allow for a well-tuned balance between the following reaction steps: 1) lignin extraction from the biomass feedstock and depolymerization using liquid solvents (i.e., a solid-liquid process); and 2) immediate stabilization of lignin monomers using solid catalyst (i.e., a gas-liquid-solid process). Despite the promising results reported so far on RCF, understanding the dynamics of such complex multiphase system is very limited. By following a step-wise approach, we investigate the kinetics of the separate steps using lignocellulosic biomass and lignin-monomer model compounds. Integration of this kinetic information with multiphase transport rates, we propose a reactor model that can successfully predict product yield and product distribution as a function of various reaction parameters. Special emphasis is put on the effect of internal/external mass transfer under different operating conditions.

2. Methods

Experiments were carried out in a gas-liquid-solid fixed bed reactor containing a biomass bed and a metallic supported catalyst (Pd/C). The reactor was fed with cocurrent flows of hydrogen and liquid solvent. The studied experimental variables were: reaction temperature, catalyst weight, biomass particle size, residence time and gas/liquid flow ratio. The reaction samples were analyzed using HPLC, GC, GPC and NMR respectively. An heterogeneous 1-D steady state model of the reactor was built in MATLAB accounting for reaction kinetics and mass transfer between the different phases.

3. Results and discussion

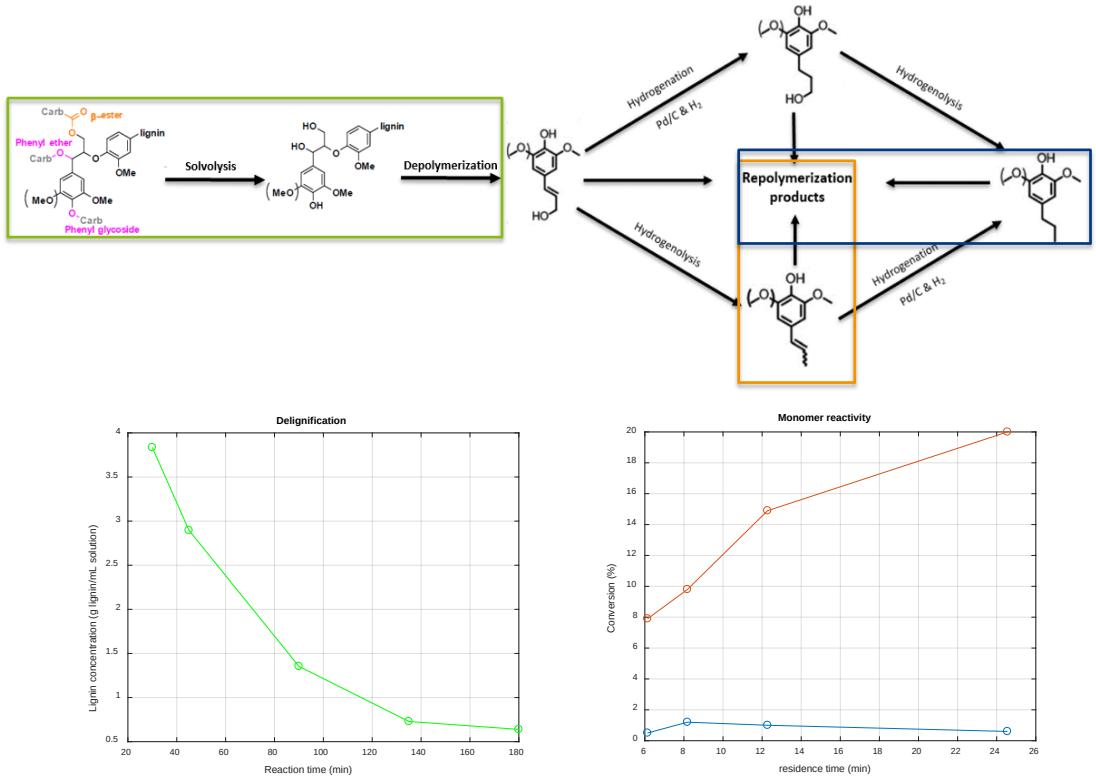

Figure 1: RCF reaction mechanism and experimental results corresponding to reactions (plot series colors match respective color boxes in the mechanism scheme)

4. Conclusions

This work provides a crucial understanding of the reaction mechanism. Kinetic parameters have been successfully extracted for the different steps of the complex reaction scheme, as well as relevant insights in the different mass transfer steps involved. The reactor model can successfully predict the experimental data, constituting a powerful tool for further process optimization

Highlights

- Solvent free Polymerization
- Devolatilization to 300 ppm
- Process Simulation

1. Introduction

The goal of most polymerization processes is to create a high molecular weight material with a specific structure. However, these polymerization processes are often highly exothermic and the final polymer is very viscous. The conventional production process for polymers requires large volumes of excess solvent and / or monomer to absorb the heat of reaction and to dilute the polymer to a low viscosity that can be processed. The LIST Kneader are able process extremely viscous materials, while adding or removing large amounts of heat, and this makes them an ideal alternative to the conventional processes.

A typical process using LIST Kneader consists of two stages. The first stage LIST Kneader is used to polymerize the monomers and catalyst in a highly concentrated, solvent-free phase. Conversion rates of 90% to 99% can be easily reached. In the second stage Kneader, the polymer is directly devolatilized to a residual monomer content of 1000 ppm or lower.
Especially in exothermic bulk (co)- polymerization processes, the large heat exchange surface of LIST Kneader in combination with evaporative cooling helps to precisely control the product temperature. The unique geometry of the mixing elements provides constant surface renewal which optimizes the heat transfer while minimizing product accumulation and dead zones. High quality polymer can be produced with low remaining monomer without solvent.

2. Methods

During the polymerization, conventional stirred-tank reactors require solvents to transfer heat and facilitate mixing of the viscous mass. After polymerization, solvents – whose concentrations can reach 90% – must be removed. Additionally, the conversion rate is limited [1].
The Kneader however, is designed to operate without or with little solvent, reaching a polymer concentration between 40 and 99%. In the case of polymerization without solvent, the conversion rate can exceed 99%. The polymer mass can then be directly devolatilized, to 100 – 500 ppm or lower.

3. Results and discussion

The technology is suitable for solvent-free living and free-radical polymerization with a polydispersity index less than 2. The unique design of the kneader provides constant surface renewal that improves heat transfer, allows excellent temperature control, and minimizes the diffusion and mass transfer limitations – particularly effective for exothermic bulk the polymerizations. The conversion rate in the polymerization step is up to 98,5% and monomer content in the final product after the devolatilization reaches 100 to 500 ppm. For the devolatilization a simulation program is used to scale the industrial process units.

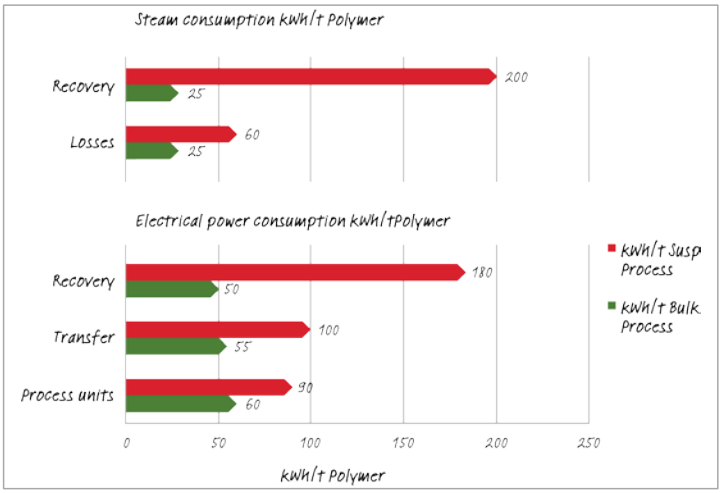

Figure 1. Energy consumption for the production of a meth acrylic polymer in bulk compared to suspension prcessing

The process intensification leads to savings in the entire process chain. Compared to the suspension polymerization, in bulk in total up to 65% of energy can be saved.

4. Conclusions

Due to this process intensification, process steps can be eliminated and the recovery step can be simplified. The result is a recreated or new process solution leading to the savings of raw material, operational costs, with improved product qualities and with a much smaller carbon footprint.

Evaluation of extraction of fermentable sugars from banana peels (*Musa cavendish*)

María Lara Triana[1], Edna Méndez Mondragón[1], Dionisio Malagón-Romero[2*], Mauricio Bernal Morales[3], Dolly Montoya Castaño[3]

1 Semillero Procesos Industriales, Universidad ECCI; 2 Universidad Santo Tomás-Universidad ECCI; 3 Instituto de Biotecnología, Universidad Nacional de Colombia

**Corresponding author: dionisiomalagon@usantotomas.edu.co*

Highlights

- The banana peel is a waste rich in fermentable sugar.
- The best sugar extraction is with water.
- The extraction is not the best method to use all banana peel.

1. Introduction

Due to the high volumes of banana production in Colombia, large amounts of waste have been generated (97.8 million boxes by the end of 2017, which represents approximately 29.3 million waste generated) [1]. The banana peel is a valuable source of bioactive compounds according to researchers[2] and constituting 30%-40% of a banana fruit[3], thus it is necessary to develop new alternatives to convert this waste generated into value-added products. Due to the high amount of soluble sugars, recent researches have been showing that banana peel is used as substrate to produce animal feed, organic acids, bio fertilizer, industrial enzymes, medicinal uses and energies clean by biological processes[4]. Through the development of this project, it is desired to use this waste for the extraction of fermentable sugars which can be a useful source of sugars.

2. Methods

Banana Peel was washed, dried, ground, sieved, and then was subjected to a granulometric analysis. It was collected about 20 kg of waste in different plantations near Bogotá (Colombia). Waste collected was characterized for determining humidity content and dry matter using the procedure described in the literature consulted[5]. The morphology and the content of carbon, nitrogen, and oxygen were determined from scanning electron microscopy with energy dispersive X-ray spectrometry (SEM-EDS) of samples of the banana peel to obtain an approximate data. Finally, the extractions of sugar in the pretreated material was carried out by the alkaline hydrolysis, acid hydrolysis and with water, evaluating the temperature and concentration parameters in a reflux system. The design of experiment was done for the alkaline hydrolysis with NaOH where two temperatures (40°C and 70°C) and two concentrations of the base (1% and 2%) were evaluated. The extraction with water was done at the same temperatures, finally, the extraction with acid hydrolysis was carried out with HCl at a concentration of 0,29M at 40°C. Additionally, all samples were exposed during 90 minutes in duplicate to evaluate the kinetics of the process taken samples every 30 minutes. Samples were centrifuged, the sugar extracted was determined by DNS according to the guide protocol[6].

3. Results and discussion

The average particle size was 0.9727 mm ± 0.115 for the Banana peel. The banana peel have a high percentage of moisture (86.84 % ± 1.56). This value is similar to reported by Dormond [7]. The nitrogen present in the peel is about 9.26-9.36%, the oxygen is about 64.78-69.54% and the carbon is approximately 6.89-6.99%. The picture 1.d) shows the morphology of the different particles that appear with an irregular size. For the alkaline hydrolysis the best results were obtained at a concentration of 1% and a temperature of 40 °C as shown in Figure 1.a). The acid hydrolysis is shown in Figure 1.b). Results obtained have shown a better extraction compared to the alkaline extraction at 40 °C. In both hydrolysis shows a decrease in the sugar concentration over time this could be due to the denaturing of carbohydrates due to the high concentration. Finally, the extraction with water showed the best results in the hole experiment, as it shows the figure 1.c). The best condition was obtained at 70°C. For this extraction, it was calculated that 0.2 grams of sugar are obtained for each gram of processed banana peel and the total sugars obtained was 6.1252 g/L which is the expected because is similar with reported by Kurto• lu and Yildiz[8]. Between the extraction protocols observed, there are no significant differences in fermentable sugars extracted because the approximation of the maximum value is 6 g / L for all of them. However, the high extraction of fermentable sugars begins at zero minutes with water.

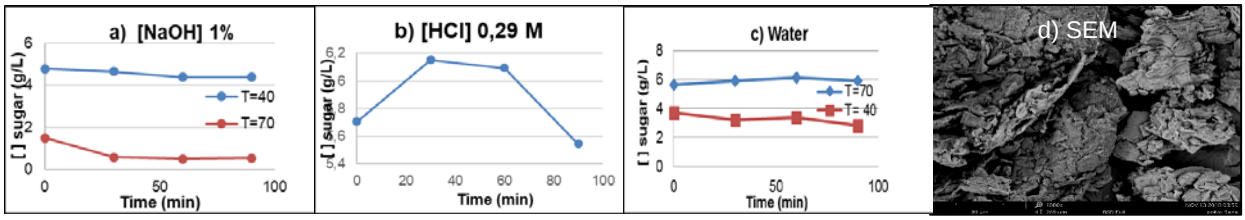

Figure 1. Kinetics of the different extractions.

4. Conclusions

It was observed that the amount of soluble sugars is higher with water compared with alkaline and acid treatment. Additionally, in alkaline conditions and water assays at initial time presents the higher extraction of fermentable sugars. These sugars could be used as substrate for fermentative process.

Catalytic Oxidation Kinetics of Arabinose on Supported Gold Nanoparticles.

Leolincoln Correia[1], Johan Wärnå[1], Henrik Grénman[1], Tapio Salmi[1], Dmitry Murzin[1*]

1 Laboratory of Industrial Chemistry and Reaction Engineering, Johan Gadolin Process Chemistry Centre (PCC), Åbo Akademi University, 20500 Turku, Finland

**Corresponding author: dmurzin@abo.fi*

Highlights

- A novel kinetic model for aqueous-phase arabinose oxidation on Au catalysts is proposed.
- Influence of oxygen flowrates, pH values and temperature was adequately described.
- The model shows adequate results for both D- and L-arabinose oxidation.

1. Introduction

In order to decrease the high dependency on fossil feedstock, lignocellulosic biomass has been considered as a renewable resource alternative. Representing 15-30% of the total lignocellulosic biomass, hemicelluloses are the second most abundant carbohydrate polymers [1-2]. Selective oxidation of sugars, such as arabinose, to their corresponding aldonic acids is one of the most important lignocellulosic biomass valorization processes. Several articles have demonstrated that supported gold nanoparticles as a sugar oxidation catalyst under alkaline conditions result in high selectivity towards aldonic acids [3,4,5,6]. In the previous work [3], kinetic data for oxidation of arabinose were generated and a kinetic model was developed. However, there were some systematic deviations in the description of the experimental data and the role of hydroxyl groups in the reaction kinetics was not explained and molecular adsorption of oxygen and contribution of different forms of sugar were not considered. The objective of this work is to revisit the data reported in ref. [3], evaluate the reaction kinetics and to propose a new kinetic model based on the plausible reaction mechanism for arabinose oxidation over gold supported on alumina.

2. Methods

All the experimental results, setup and catalyst characterization data concerning L-arabinose oxidation over supported gold catalyst used for modelling were obtained from the work of Kusema *et al*. [3,6]. In order to bring the reaction to a more practical level, an experiment in a standard batch reactor with D-arabinose was carried out. The novel model was developed taking into account the different forms of sugar in aqueous solutions, molecular adsorption of oxygen and production of H_2O_2. The set of differential equations representing concentrations of the reagents and products was solved numerically during the parameter estimation using the Levenberg-Marquardt or Simplex methods incorporated in the ModEst software [7].

3. Results and discussion

The fit of the proposed kinetic model to the experimental concentration profiles is presented in Figure 1, clearly illustrating a good correspondence between experimental and calculated data (R^2 = 99.35 %). There were no systematic deviations in the description of experimental data compared to the work of Kusema *et al.* (R^2 = 98.70 %). Moreover, simulation of D-arabinose oxidation in a conventional batch described very well the experimental data (Fig 2).

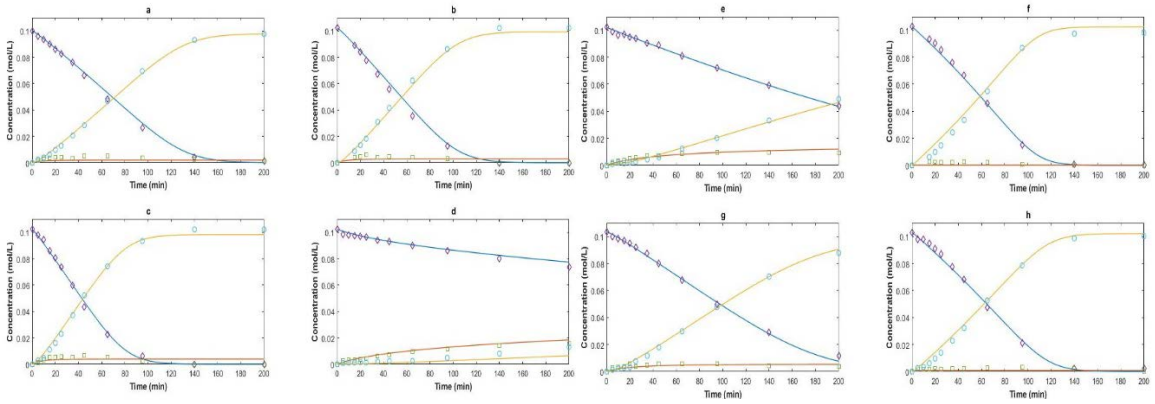

Figure 1. Experimental (dots) [3] and calculated (lines) concentrations profiles (◊→ L-arabinose, □ → arabinolactone, ○ → arabinonate) in arabinose oxidation over 1 wt% Au/Al_2O_3, m=0.25g. (a) 60°C, 2.5mL/min O_2, pH 8; (b) 60°C, 3.5mL/min O_2, pH 8; (c) 60°C, 5.0mL/min O_2, pH 8; (d) 60°C, 2.5mL/min O_2, pH 6; (e) 60°C, 2.5mL/min O_2, pH 7; (f) 60°C, 2.5mL/min O_2, pH 9; (g) 50°C, 2.5mL/min O_2, pH 8; (h) 70°C, 2.5mL/min O_2, pH 8.

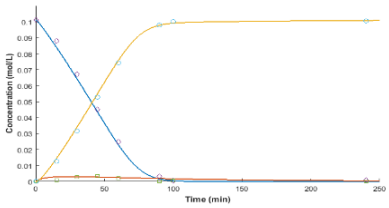

Figure 2. Experimental (dots) and calculated (lines) concentrations profiles (◊→ D-arabinose, □ → arabinolactone, ○ → arabinonate) in arabinose oxidation in a batch reactor over 2 wt% Au/Al_2O_3, m= 0.5g, T= 60°C, P_{O2} = 0.125 bar and pH=8.

4. Conclusions

A novel kinetic model for the aqueous-phase selective oxidation of L-arabinose over gold catalysts was proposed considering different forms of sugar in the solution. The parameter estimation was successfully carried out revealing that the calculated values are in good correspondence with the experimental behaviour. In general, oxidation kinetics for both D- and L-arabinose was successfully represented by the proposed elementary reaction mechanism.

Overall Reaction Rate of Oximation of Impurities in the Production Process of Caprolactam.

David Lorenzo*, Aurora Santos, Laura del Arco, Arturo Romero

Dpto. Ingeniería Química y de Materiales, Universidad Complutense de Madrid. Avda. Complutense S/N 28040 Madrid.

**Corresponding author: dlorenzo@ucm.es*

Highlights

- Impurities oximation using hydroxylamine sulfate as reagents.
- Reaction routes the main impurities formed in the caprolactam production process.
- Kinetic models of oximation reaction the main impurities in cyclohexanone.

1. Introduction

Caprolactam is used as a monomer in the nylon 6 production process. The most common caprolactam production process is promoted by oxidation of cyclohexane to obtain a reaction mixture known as KA-oil, which contains cyclohexanone, cyclohexanol and other impurities [1-3]. Cyclohexanone, after being purified, reacts with hydroxylamine, and subsequently epsilon-caprolactam is obtained by Beckmann rearrangement of cyclohexanone oxime [4]. The quality of the nylon 6 fibers is closed affected by type and amount of the impurities presented in ε-caprolactam. Leading companies in the production sector are currently examining the origin and the development of those impurities, to reduce their formation or to promote their elimination. The characterization of the quality of the ε-caprolactam, by means of the quantification and identification of its impurities is a complex task. Main difficulties in the determination of the impurities are their variety, low concentration and lack of information due to the confidenciality of the processes. Based on available information in literature the main impurities in cyclohexanone that could be transformed in the oximation step affecting the quality of ε-caprolactam have been selected. The scope of this work is the study of the transformation of these impurities found in the pure cyclohexanone in the oximation reaction step.

2. Methods

The impurities selected were n-heptanones (n=2,3), hexanal, n-methylcyclohexanones (n=2,3,4), 2-methylcyclopentanone, 2-cyclohexen-1-one. These ketones are in appreciable amounts in the purified cyclohexanone and have significant negative effects on the final nylon 6.

The oximes of these impurities were synthesized from their commercial ketone. They were identified by NMR and gas chromatography using a mass detector (GC/MSD) to obtain the stereoisomeric proportions that is produced in the oximation reaction. Oximation runs were carried out in an isothermal semicontinuous stirred reactor where NH_3 solution was continuously fed to neutralize the acid promoted to keep a constant pH. The reactions were carried out using hydroxyl ammonium sulfate as reactant (82 °C, atmospheric pressure and pH 5,5). In addition, it was studied the oximation reaction kinetics of those impurities that are in higher concentration in pure

cyclohexanone or have greater effect on the quality of ε-caprolactam. The experimental conditions used were closed to the industrial. The kinetic study of 2-heptanone, 2-cyclohexen-1-one and 2-methylcyclohexanone was carried out. Samples were taken at different reaction times to quantify the amount of reacted ketone.

3. Results and discussion.

A kinetic model was proposed to obtain an overall oximation rate, under the industrial operation conditions. The model was developed assuming the reaction takes place in the interphase of the organic and aqueous phases and it does not exist mass transfer limitations at each phase, because of the high agitation used. Good agreement between experimental and predicted values was found, which means to validate the model proposed and the model assumptions. The model proposed can be summarized as follows:

$$\frac{dX_{ONA}}{dt} = S \cdot k_{ap} \frac{(1-X_{ONA})}{V_{org}} \left(\frac{N_{SHA_0} - 1/2\,(N_{ONA_0}(1-X_{ONA}))}{V_{aq}} \right)^{1/2} \quad \therefore \quad k_{ap}{}' = \frac{S \cdot k_{ap}}{V_{org}} \qquad \text{Eq.(1)}$$

An apparent kinetic constant was proposed including the kinetic constant of the oximation rate of each respective impurity and the pH influence. In Table 1 the values of the apparent kinetic constant at 82 ºC and pH=5.5 are listed. It was found up that the oximation rate of 2-cyclohexen-1-one is the lowest one, followed by 2-heptanone, and finally, 2-methylcyclohexanone, whose apparent constant doubles the value of the 2-heptanone constant.

Table 1. Apparent constant values for the model proposed in Eq.1

Compund	$k_{ap}{}'$ ($kg_{aq}^{0,5} \cdot mmol^{-1,5} \cdot min^{-1}$)	SQR	% VE
2-heptanone	0.033± 0.002	0.098	96
2- methylcyclohexanone	0.066±0.006	0.078	97
2-cyclohexen-1-one	0.0057±0.0003	0.120	97

4. Conclusions

The importance the quality of caprolactam has been increased last few years due to development of new technologies. However, the information about the impurities which can affect the quality of the final product is limited. In this work, the main impurities present in the cyclohexanone used as intermedia in the caprolactam process were synthesized and identified by GC/MS and NMR. Besides a kinetic model of the most important impurities was proposed. Kinetics constants obtained provide helpful information useful for the analysis of the purification steps.

Highlights

- Sodium hydride and sodium borohydride are industrially important reducing agents
- Mathematical models for two complex multiphase processes were developed: synthesis of sodium hydride and sodium borohydride
- Experimental data obtained in laboratory scale were used in the modelling
- The advanced multiphase model is useful in process simulation and optimization

1. Introduction

Sodium hydride and sodium borohydride are strong reducing agents with widespread industrial applications. The synthesis of sodium hydride (NaH) and sodium borohydride ($NaBH_4$) are very demanding multiphase and multistep processes. Sodium hydride is produced industrially by letting melt sodium to react with gaseous hydrogen. In spite of many attempts to develop new processes for the industrial production of sodium borohydride, the procedure discovered by Schlesinger and Brown in 1940's and 1950's is still the dominant one. The process is based on the use of sodium hydride and trimethyl borate ($B(OCH_3)_3$) as raw materials. The reaction steps are carried out in dispersions of inert mineral oil at elevated temperatures. A typical reaction temperature for the preparation of NaH is 230-260°C, while temperatures 250-270°C are typical for the synthesis of $NaBH_4$. In spite that these processes are very classical, a vast majority of the published literature is of qualitative character only. Nowadays the understanding of complex multiphase processes has advanced very much and the modelling and computational tools enable a reaction engineering approach to these industrially important and technically demanding systems. Mathematical modelling of the reactions $4Na(l) + 2H_2(g) \rightarrow 4NaH(s)$ and $4NaH(s) + B(OCH_3)_3(l) \rightarrow NaBH_4(s) + 3NaOCH_3(s)$ is considered in the present work.

2. Methods

Both reactions are carried out in semibatch reactors. The processes were modelled based on plausible surface reaction mechanisms. The hypothesis for the formation of NaH was that it proceeds through a surface reaction between adsorbed hydrogen atoms on the droplets of finely dispersed Na in mineral oil. Solid NaH particles are formed and they react in the next step in a surface reaction with dissolved $B(OCH_3)_3$ in the oil phase forming $NaBH_4$ and $Na(OCH_3)$. A

partially hydrogenated intermediate (X1) is detected in the $NaBH_4$ formation step. Based on these mechanistic hypotheses, rate equations were derived and they were coupled to the mass balances of the components, taking into account the interfacial mass transfer effects.

The rate equation for the formation of NaH is, including two adjustable parameters (k' and K') only: $r=k' c_H^{1/2} /(1+K' c_H^{1/2})$

For the formation of $NaBH_4$, the rate equation is (B=$B(OCH_3)_3$) and X1=reaction intermediate)

$r=k'' c_{X1}/(1+ K_B c_B + K_{X1} c_{X1})$

The mass balances for the multiphase systems were described by taking into account the transfer of hydrogen from the gas phase to the mineral oil and from the mineral oil to the Na droplets. In the synthesis of $NaBH_4$, the mass transfer of $B(OCH_3)_3$ from mineral oil to the surfaces of the NaH particles was included. The correlations for Sherwood numbers were used to obtain expressions for the interfacial mass transfer coefficients. The behaviours of the Na droplets and the dispersed NaH particles were described with the generalized shrinking particle model developed by our group. The experimental data collected previously by us was used in the modelling.

3. Results and discussion

Examples of the modelling results of the NaH and $NaBH_4$ formation processes are provided in Figure 1. As revealed by the figure, the model describes well the behaviour of the system at a wide range of rotation speeds of the disperser. The yields of the main product (P=$NaBH_4$) and the reaction intermediate (X1) are very well predicted by the complex multiphase model.

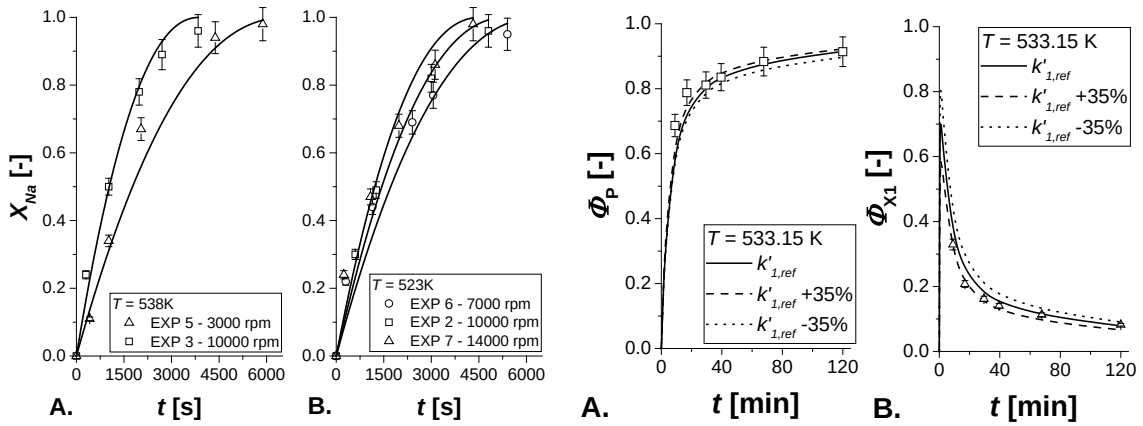

Figure 1. Effect of the stirring rate on the sodium conversion (X) to NaH and sensitivity analysis of the yields of $NaBH_4$ and X1 (Õ) Continuous lines represent model predictions.

4. Conclusions

New multiphase models were developed for the industrial synthesis of NaH and $NaBH_4$. The model parameters were determined from experimental data obtained from laboratory-scale semibatch reactors. The models can be used for process design and optimization.

Experimental Validation of the Production of PolyVinyl Acetate in a Pilot Reactor – A Case of Optimization

Andrés Augusto Herrera Morales, Bibiana Raba Mora, Iván Darío Gil Chaves, Gerardo Rodriguez Niño & Manuel Florez
[a] *Chemical and Biochemical Processes Group, Department of Chemical and Environmental Engineering, Universidad Nacional de Colombia, Bogota, Colombia.*
idgilc@unal.edu.co*

Highlights

- Validation of an emulsion polymerization.
- Polymer properties continuous determination during reaction time.
- Time reaction reduction up to 30% from a standard procedure.

1. Introduction

Polyvinyl acetate is obtained through an exothermic reaction in a process of free-radical emulsion polymerization. Polyvinyl acetate is widely used in the adhesives industry, and it is also largely implemented in the generation of sub products. For example, it is a film-forming ingredient in water-based (latex) paints; it is used in adhesives, varnishes and lacquer, paper coatings, fabric adhesives, resin bases, among others[1]. The demand for new latex products has rapidly increased, together with research efforts in modeling, optimization and control of the manufacturing process. In the past few years, multiphase models have been developed, reflecting factors like nonlinear behavior and the sensitivity to perturbations[2][3]. A pilot scale emulsion polymerization was developed on a 75L stirred tank reactor based on a model that describes emulsion polymerization phenomena such as initiation, propagation and termination stages. Temperature reactor, viscosity, solids content and particle size distribution were determined in order to validate the model.

2. Methods

At first, a dynamic model was proposed where by a control strategy to assess an optimal condition was defined. The purpose of this model is to minimize the reaction time by varying the heating/cooling flows fed through the reactor jacket. In turn, the model made it possible to estimate the effect of the initiator and the monomer dosage, as well as the influence of temperature on the reaction. Then, a description of the properties was made in order to follow up on the reaction and determine its quality in terms of the solids content, viscosity, distribution of size particle and residual monomer. Solids content and viscosity were determined based on a Colombian Technical Standard, temperature was measured and recorded in Siemens 1200 PLC and Particle size distribution was determined by a dynamic light scattering method with a Zetasizer Nano equipment. [4][5][6][2]

3. Results and discussion

A total of seven tests were conducted for the validation of the model: two under normal operation conditions and five reproducing the optimal profile. The profiles obtained through the

a: NTC 5003
b: NTC 2790

experimentation shows an approximation to the model values, allowing to conclude that the model studied is accurate to real heterogeneous phenomena.

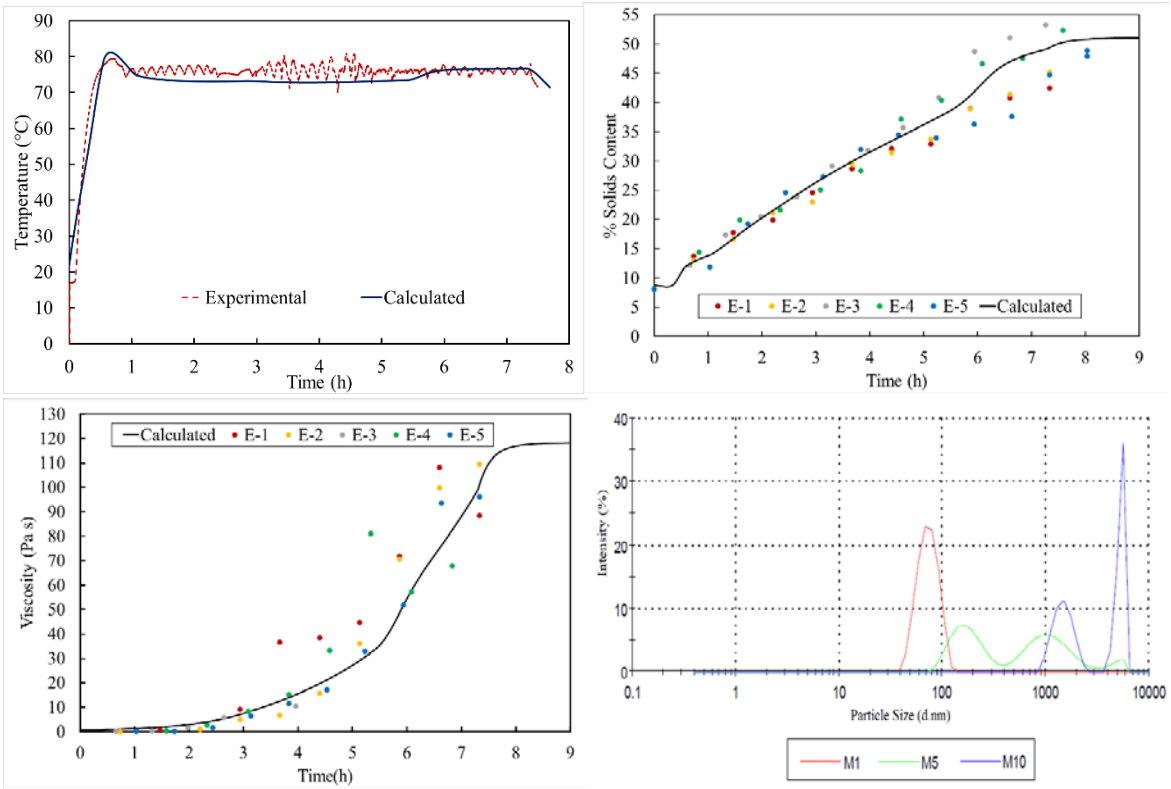

Figure 1. Temperature, solids content, viscosity and particle size distribution from an experimental data of an optimal time emulsion polymerization reaction.

4. Conclusions

From the data obtained from the temperature profile and the product's final properties it was possible to confirm that through the control strategies proposed for the temperature control optimization model it is possible to reduce the reaction time by 20%, taking as reference the reaction that is currently conducted in the industrial sector.

It was possible to implement strategies like the addition of the monomer and the initiator at different time intervals, as well as the variation of the heating/cooling flows feeding the reactor jacket in a pilot reactor (65 liters), where transport and mass transfer phenomena found in an industrial reactor, at a larger scale, were also present.

The results obtained for each one of the properties make it possible to ensure that the quality of the final polymer obtained through the optimized model is like the one obtained through the conventional process. The model used employed an optimal control, which is designed to track the temperature in the reaction system despite typical perturbations like initiator injections of the monomer.

Characterization of edible oil foams with a fast inline measurement using acoustic and ultrasound spectroscopy

Lorenzo Metilli[1], Mathew Francis, Megan Povey, Aris Lazidis, Stephanie Marty-Terrade, Elena Simone

[1] School of Food science and Nutrition, University of Leeds, UK; [2] Nestlè PTC York, UK

*Corresponding author: fslme@leeds.ac.uk, e.simone@leeds.ac.uk

Highlights

- Edible oil foams are used for reducing caloric density and modify food texture.
- The physical properties of foams affect rheology and stability of the final products.
- Acoustic techniques can be used to assess the physical properties of foams.

1. Introduction

Because of the dramatic rise of obesity in UK in the last three decades, several food companies have committed to design and manufacture healthier foods with reduced caloric content. An effective way of achieving this goal is by using edible oil-based foams (oleofoams) to prepare aerated confectionary food (e.g., mousses) [1].. The main constituents of edible oleofoams are a liquid oil phase, air bubbles and a further high-melting, crystalline fat phase, which stabilizes the bubbles via a Pickering effect. Such complex microstructure determines the macroscopic physical and nutritional properties of oleofoams [2]. Therefore, a correct characterization and continuous monitoring and control of oleofoams microstructure during process design and manufacturing is essential to ensure the quality of the final food product. Ultrasound spectroscopy is a fast and affordable monitoring technique, characterized by non-intrusiveness and non-destructive behaviour, which is particularly promising for inline, in situ characterization of oleofoams. The aims of this work are: (1) identify a methodology based on multiple offline techniques to characterize the microstructure of oleofoams and (2) find a robust correlation between the physical properties and microstructure of oleofoams and specific characteristic acoustic measurements.

2. Methodology

High oleic sunflower oil and cocoa butter were used to prepare the oleofoams. Melted cocoa butter was mixed to sunflower oil and recrystallized (oleogel phase) by cooling in a jacketed vessel equipped with temperature control. Aeration was performed using a Kitchen Aid whipping machine. The structures of oleogels and oleaofoams were characterized using several offline techniques including polarized and confocal microscopy, x-ray scattering and tomography as well as differential scanning calorimetry. Acoustic measurements were carried out using an airborne acoustic microscope, with two focused transducers at three variable frequencies.

3. Results and discussion

The experiments showed that both foamability and foam stability are dependent from cocoa butter content, with heavier (20-30%) oleogels reaching equilibrium air content later compared to lighter ones (10%). Confocal microscopy was proven successful to image surface layers of the foams, allowing an estimate of bubble size distribution. Figure 1 shows how air bubbles can be easily detected by this technique. Finally, samples were analyzed with the acoustic microscope and a positive correlation between the intensity of the reflected signal and the content of cocoa butter crystals in the samples was found.

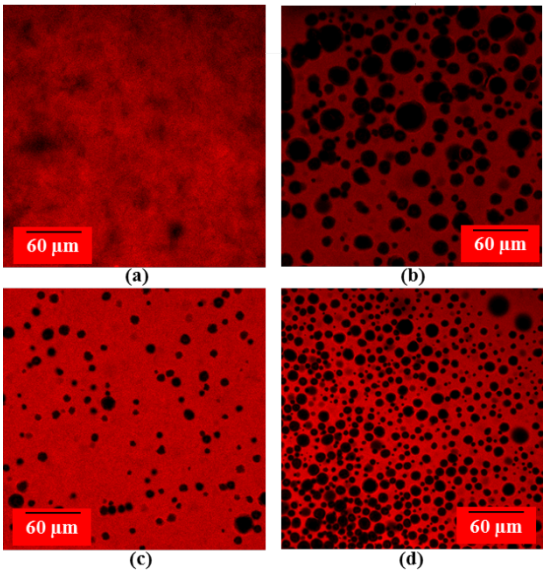

Figure 1. Confocal microscope images of four samples at (a) 0%, (b) 70% (c) 175% and (d) 200% overrun.

4. Conclusions

Oleogels and oleofoams were characterized with offline techniques as well as acoustic measurements. Initial finding showed the applicability of acoustic spectroscopy in detecting and quantifying fat crystals within oleofoams. In fact, acoustic reflectivity increased with increasing solid fat content in such foams.

In situ real-time rheological characterization of calcium alginate hydrogels

Ioanna Besiri[1], Thomas Goudoulas[1], Natalie Germann[1*]

1 Fluid Dynamics of Complexed Biosystems Group, Maximus-von-Imhof-Forum 2, School of Life Sciences Weihenstephan, Technical University of Munich, 85354 Freising, Germany

**Corresponding author: natalie.germann@tum.de*

Highlights

- Design of a custom-made geometry for the rheological study.
- *In situ* gelation kinetics of sodium alginate and calcium chloride.
- Understanding the initial phase of the reaction kinetics.

1. Introduction

Polysaccharides are among the fundamental components of biosystems, and they are responsible for a variety of functions. Alginate is an important polysaccharide and forms hydrogels. [1,2] As a linear negatively charged high-molecular-weight copolymer of two monosaccharides, it reacts with multivalent cations (e.g. Ca^{2+}, Ba^{2+}) in aqueous solutions and forms hydrogels through ionic crosslinking, also referred to as ´´egg-box`` structural formation. [3] The motivation was to develop an understanding of the fast gelation kinetics of this model system using a custom-made rheometric setup. In the future, this investigation can be extended to similar reactions and controlled drug delivery studies.

2. Methods

We studied the kinetics of the *in situ* gelation of alginate in the presence of Ca^{2+} ions during the initial gelation phase using a custom-made cone and plate geometry (Figure 1a). The lower plate has been altered, providing a cavity where the Ca^{2+} solution can exist. Only upwards flow to the surface can be achieved where the alginate solution is placed. The alginate solution covered the lower plate and the upper cone was adjusted at the corresponding gap. Using a volumetric syringe to supply the appropriate volume of the Ca^{2+} solution, instant gelation can be achieved and the rheological response can be recorded. In this study, $CaCl_2$ solutions were utilized with concentrations up to 200 mM and volumes between 0.1 to 0.25 mL. We performed small amplitude oscillatory shear time sweeps at alginate concentrations up to 4 wt.%, by applying 3% strain amplitude at 1 rad/s angular frequency. In all measurements, injection occurred after the initiation of the oscillatory time sweep.

3. Results and discussion

We found that with a sampling rate of 3 points per second, the rheometer can successfully record the fast gelation reaction during the initial ten seconds (Figure 1b, indicated area). For increased volumes of the injected Ca^{2+} solution, the elastic modulus G´ increases continuously in time while

the loss modulus G'' forms a plateau (Figure 1b). Moreover, the magnitudes of the dynamic moduli were significantly higher. When the injection volume was constant, the same effect was noticed for the Ca^{2+} concentration. For instance, by supplying twice the $CaCl_2$ concentration, the storage modulus of the hydrogel was doubled. At the end of the experiments, a macroscopic evaluation was performed and typical flowable soft gels were observed in all cases.

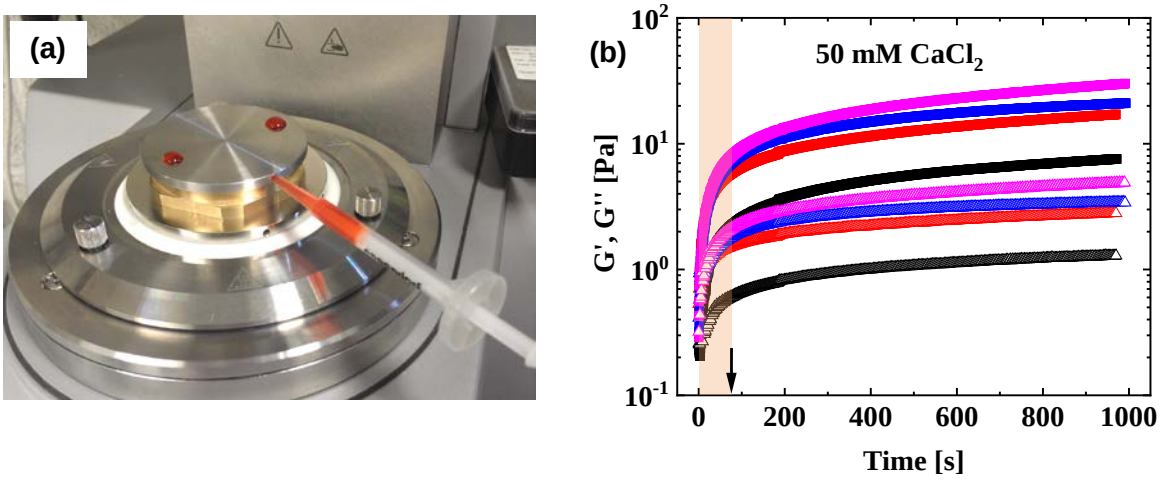

Figure 1. (a) Custom-made lower plate placed on rheometer. A volumetric syringe is used for supplying a tracing liquid through the internal cavity and the two micro-holes (approx. 250 µm) to the surface of the lower plate. (b) Storage modulus (G', filled square symbols) and loss modulus (G'', nonfilled triangle symbols) vs. time. The *in situ* conditions correspond to 1 wt.% sodium alginate and 50 mM calcium chloride for injected volumes of 0.10 mL (black), 0.15 mL (red), 0.20 mL (blue), and 0.25 mL (magenta).

4. Conclusions

In this work, we present a method for recording *in situ* real-time gelation kinetics, like fast changes of storage and loss moduli. By studying the Ca^{2+}/alginate system at various concentrations and volumes, we found that two distinct regions exist. The initial rapid region seems to be independent of the applied Ca^{2+} volume while the plateau region indicates a quasi-stable structure. The knowledge gained using this probing technique in this research can be applied in many engineering fields, such as food technology or tissue engineering.

Highlights

- Wood based compounds have the potential to be excellent stabilizers in food, pharmaceutics, and cosmetics
- Spruce GGM displayed exceptional capacity to inhibit lipid oxidation and act as a multifunctional stabilizer
- GGM was extracted with hot water using an additive, which is suitable for the alimentary and cosmetics industry
- The extraction rate was enhanced with the additive and amphiphilic water soluble lignin-hemicelluloses were formed

1. Introduction

The performance of hemicellulose-based compounds from lignocelluloses in the potential products is determined largely by the chemical composition and the structure of the molecules. The objective in the extraction processes has mostly been to obtain completely pure fractions of hemicellulose, lignin, and cellulose. However, a controlled mixed structure of the compounds can be an advantage in certain applications.

Recently researchers has shown, that galactoglucomannan (GGM) based compounds have the potential to replace the "golden standard" food stabilizer gum Arabic (GA) in food, pharmaceutics, and cosmetics. [1, 2] In these studies, GGM displayed exceptional capacity to inhibit lipid oxidation and act as a multifunctional stabilizer, enhancing both the physical and oxidative stability of emulsions. The higher content of phenolic residues in GGM compared to GA was concluded to contribute to GGM's excellent oxidation inhibition capacity. The exact mechanisms behind the beneficial influence of lignin residues in the GGM are unclear, as is the influence of the structure and composition of the lignin-hemicellulose complexes (LCC) on their performance. The basic phenomenon has been established, but many of the details are in the dark.

2. Methods

In our recent study, hemicellulose-lignin complexes from spruce were extracted with pressurized hot water (PHWE) in a batch reactor using a well separable additive, which is suitable for the alimentary and cosmetics industry. Detailed GC analysis and NMR were used in the characterization of the extracted compounds. The complexes were utilized for emulsion stabilization studies in

collaboration with specialists in alimentary research and emulsions. Different wood species combined with varying reaction conditions were tested and their performance as emulsion stabilizers and anti-oxidizing agents was evaluated.

3. Results and discussion

The results clearly demonstrated that the extraction rate was considerably enhanced with the additive (Fig. 1) and about 10-15% more lignin (Klason lignin in solid) was dissolved compared to normal PHWE. Moreover, the NMR results indicated that lignin stays covalently bound to the dissolved hemicelluloses forming amphiphilic water soluble LCC. The extraction method also influenced e.g. the molar mass of the obtained macromolecules as displayed in Figure 2. Clear differences in emulsification and antioxidant properties were observed between the samples. Revealing the detailed mechanisms of dissolution combined with understanding the mechanisms of emulsion stabilization are key factors for being able to tune the properties of the extracted compounds by varying the experimental conditions.

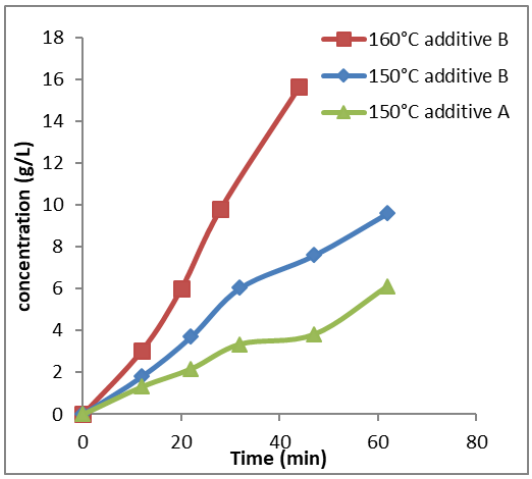

Figure 1. The enhancement of the extraction rate by selected additive.

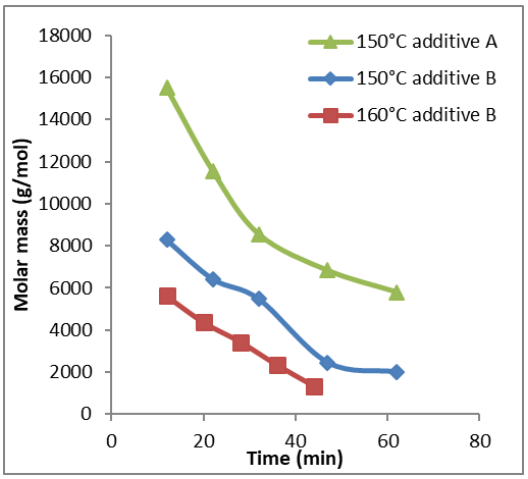

Figure 2. The influence of additive addition to the molar mass of the macromolecules.

4. Conclusions

The current interdisciplinary research focuses on building on a newly developed extraction method for enhancing hemicelluloses extraction, which enables tuning the lignin content and properties of the LCC. The work bridges the state of the art knowledge in the safely enhanced extraction of hemicelluloses-lignin compounds and the related reaction engineering (chemical engineering) and the utilization of the LCC for alimentary purposes (alimentary chemistry). Moreover, the potential utilization is by no means limited to the alimentary industry, but fields such as cosmetics and health products are highly viable.

Highlights

- Thermal reactions were followed in an inert cake model added with targeted precursors
- A wide range of markers were quantified fulfilling an observable reaction scheme
- Reactions were simulated by coupling stoechio-kinetics to heat and mass transfer models.

1. Introduction

In baked foods, process and formulation steps lead to the generation of a multitude of compounds responsible for quality: aroma, flavor, color and safety, through the activation of thermal reactions. However the link between composition, reactivity and quality determinants is not an easy task because of the interdependency of physical and chemical parameters and the complexity of real ingredients. Therefore, studying complex transformations in a food matrix under strictly controlled physical, structural and chemical conditions is of paramount help to verify the hypotheses formulated by many decades of results obtained in simple model systems (far from real foods) or in real products (with limited understanding on specific reaction pathways).

2. Methods

An inert model imitative of a sponge cake was developed in order to master the nature and the quantity of reaction precursors [1]. The cake model was added with targeted precursors to activate thermal reactions in a controlled way (caramelization in model G - glucose containing model; both caramelization and Maillard reactions in model G+L - glucose and leucine containing model). G and G+L models were submitted to controlled process conditions (140°C, 170°C or 200°C baking temperatures; high and low convection levels). Ten reaction markers (precursors, intermediates and products), were quantitatively analyzed during the course of baking (8 kinetic points) by a complementary sampling approach. Volatile markers (e.g. furanic compounds, pyrazines, Strecker's aldehydes, acids) were sampled from baking vapors by on-line sampling device and TD-GC-MS analysis while nonvolatile and water-soluble markers were extracted from the cake matrices and quantified as follows: reducing sugars by UHPLC-CAD, free amino groups by Sørensen formol titration, dicarbonyl intermediates by UHPLC-DAD/MS, furfural and 5-hydroxymethylfurfural by UHPLC-DAD. These markers were thus selected to fulfil the requirements for an observable reaction scheme and a stoechio-kinetic modeling.

Synchronous experimental data on heat and mass transfers and reactions were acquired under perfectly controlled conditions of thermal treatment (temperature and convective transfer coefficient) and used for the modelling of coupled transfers and reactions in the cake using Comsol™ and Matlab™.

3. Results and discussion

The only presence of glucose in the G model was sufficient to activate caramelization reaction with the production of high levels of furfural, 5-methylfurfural, 5-hydroxymethylfurfural, and acetic acid. These compounds showed a typical final product behaviour (exponential production) except from furfuryl alcohol (bell-shaped behaviour) and a dependency to baking temperatures and convection speed. These markers were also found in the G+L model where caramelisation and Maillard reaction could jointly occur. Interestingly, specific pathways were activated by the presence in the system of leucine and glucose: the quantification of 3-methylbutanal in high amounts showed the activation of the Strecker's degradation in model G+L. Moreover, when comparing the amounts of dicarbonyl intermediates, the higher generation rate of the 3-deoxyosone relatively 1-deoxyosone model suggested that the 1,2-enolisation pathway was favored compared to the 2,3-enolisation in the G+L model and showed that the higher the temperature and the convection level, the faster their degradation.

The stoechio-kinetic model was coupled with a mass and heat transfer model in order to predict markers content in the cake models during baking. Hence this joint approach provided an excellent opportunity to understand, model and control the kinetics of thermal reactions contributing to the generation of process-induced compounds in solid food.

4. Conclusions

An original methodology coupling chemical and physical on-line measurements was developed in order to follow a broad range of reaction markers and unravel Maillard and caramelization reactions under realistic but controlled processing conditions. Thanks to a solid food model (cake model) having a complex structure and technological history but only containing known amounts of one or two reactive precursors, two observable reaction schemes could be built and modelled into a stoechio-kinetic model, taking into account mass and heat transfer in the cake model. This model is helpful for capitalizing on knowledge about the impact of formulation and process on quality of baked products.

Highlights

- CGA adsorption on XAD 7 resin was described by pseudo-second-order and Langmuir model.
- Optimal capture conditions were the adsorption flow rate of 15 BV/ h and pH at 2.7 and desorption with ethanol 50% (v/v).
- CGA fraction from sunflower protein purification effluent had similar biological effects than commercial CGA

1. Introduction

The extraction/ purification of plant proteins for food applications yields a large volume of liquid effluent. Recently we developed a process for the production of sunflower proteins isolate. The purification step is made by ultrafiltration with a diafiltration step using NaCl solution. This effluent is composed of various organic micro-solutes (amino acids, organic acids, peptides, carbohydrates etc.). It also contains chlorogenic acid (CGA) which is the main sunflower polyphenol. Many reports show the great biological activities of this polyphenol (like anti-inflammatory properties [1, 2]). The capture of sunflower polyphenol and particularly CGA from ethanol or methanol extracts is well documented [3]. But the capture its capture from an aqueous media charged in hydro-soluble molecule and salts has never been performed to our knowledge.

This study presents the static adsorption/ desorption capacity of CGA in the effluent with macroporous resins. This allowed choosing the most appropriate resin for CGA capture. Then, we implemented a multi-objective optimization strategy to establish the best adsorption /desorption conditions for CGA capture in column. Finally, we studied the biological activity of the obtained fraction compared to commercial CGA.

2. Methods

Batch adsorption/ desorption of CGA was studied with five macroporous resins (XAD4, XAD7, XAD16, XAD1180 and HP20) by monitoring CGA in the liquid phase (SE-HPLC method). CGA in adsorbed on the solid phase was deduced by applying the mass balance. For the dynamic study (column), the effect of pH (2 – 5) and flow rate (5 – 15 BV/h) on dynamic binding capacity ($DBC_{10\%}$), productivity and recovery were modeled by nonlinear regression (Response Surface Methodology, RSM). For the desorption step, the effect of the ethanol concentration (30 - 90% v/v) on CGA purity

was also considered. The effects of these fractions on the viability of human THP-1 derived macrophages and wondered if they could moderate their LPS-induced inflammatory response.

3. Results and discussion

XAD 7, XAD 16 and HP 20 showed high CGA adsorption and desorption capacities at equilibrium. Four kinetic models are used to fit experimental CGA adsorption data. The pseudo-second-order model is the most suitable for describing the whole adsorption behavior. Four isotherm models were used to describe the adsorption properties of CGA on resins. The Langmuir model was the most favorable for describing the adsorption at equilibrium (Fig. 1A). For the dynamic study, XAD7 has been selected resin due to showing high specific surface adsorption capacity. The effect of the pH and charge step flow rate on $DBC_{10\%}$, CGA recovery and process productivity by DoE (Fig. 1B). R^2 obtained for the 3 criteria was higher than 0.9 meaning that the regression models appropriately fitted experimental data well. The multicriteria optimization strategy showed that the best conditions were a flow rate of 15 BV/ h and a pH of pH 2.7 and the most appropriate ethanol concentration was 50% (v/v). Fig. 1C demonstrates that CGA fraction (F1) and CGA standard did not affect cell viability on human THP-1 derived macrophages at dose 50-100 mM. Results revealed that TNF-α was inhibited approximately of 15-20% when we treated samples with LPS before and after 1 hr, similar to that obtained with CGA standard. These results suggested a newly discovered anti-inflammatory feature of CGA from by-products of protein extraction.

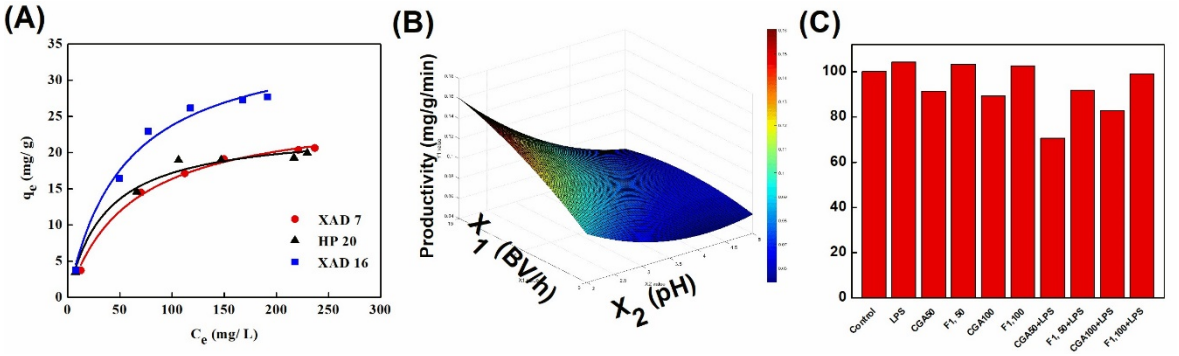

Figure 1. Illustrated results**.** A. Langmuir model; B. Response surface of productivity; C. Cytotoxicity on THP-1 cells line.

4. Conclusions

In the static study, the adsorption of CGA had a monolayer adsorption behavior. The pH of the starting effluent significantly affected the adsorption and desorption capacities. Based on RSM, the optimal conditions for purification of chlorogenic acid was defined. The obtained fractions and standard did not affect cell viability. This natural product may then be proposed as an alternative product that helps in preventing and treating inflammatory disorders. Studies are currently ongoing to evaluate the capacity of these fractions to reduce THP-1-derived macrophages inflammatory response.

Rheological and Tribological Characterization of Different Commercial Hazelnut Based Spreads

*Laura Principato[1], Gulliermo Duserm Garrido[1], Roberta Dordoni[1], Spigno Giorgia**

1 DiSTAS – Department for Sustainable Food Process, Università Cattolica del Sacro Cuore, Piacenza (Italy)

* *giorgia.spigno@unicatt.it*

Highlights

- 5 hazelnut-cocoa base spreads characterized for rheological properties
- Influence of used geometry on the obtained flow-curves
- Substantial differences in tribological behavior with both recipe and temperature

1. Introduction

The principal aim of this work was the knowledge development in the research area of rheological characterisation of food semi-solid systems as hazelnut-cocoa based spreads. Five commercial cocoa spreads with different hazelnut/fat compositions were selected and rheological and tribological tests were carried out. Bulk and lubrication properties were estimated to investigate the occurring of microstructural changes from handling and storage step to oral consumption, respectively.

2. Methods

Both rheological and tribological tests were carried out with a laboratory rheometer (Anton Paar MCR 302). Spread flow curves were obtained at different temperatures with different geometries. Oscillatory mode test was conducted to determine linear viscoelastic region (LVR) , storage and loss modulus (G' and G''), complex viscosity (η) and tan(δ). Three-run flow cycle was applied to estimate the variation of thixotropic properties with temperature. Finally, tribological Stribeck curves were evaluated.

3. Results and discussion

Rheological analysis highlighted a pseudo-plastic behaviour in all spreads with the elastic component prevalent on the viscous one (G'>G''). Rotational analysis showed the strictly dependency of flow curve from temperature in all cases. Moreover, geometry changing determined only flow index (n) value modification. Curves obtained with parallel plates showed n value lower than cup and bob device. Furthermore, in the same way as viscosity, consistency index (K)

decreased with temperature in all samples. The effect of temperature on K may be modelled by Arrhenius equation obtaining a linear correlation between ln(K) and 1/T. A stronger dependency of consistency index (K) on temperature may be related to higher sensitivity of microstructural change to thermal stress. Spread with greater K variation demonstrated a higher tendency of G' and G'' curves to cross-over at higher temperature. The occurring of cross-over point expressed the shift from solid-like to liquid-like behaviour due to melting of solid lipid fraction. In addition, a greater decrease of friction factor and more significant shape modification of the Stribeck curves highlight thermal structural changes. Three-run flow cycle showed that palm oil based spread exhibit higher thixotropic behaviour meanwhile the sample with the highest hazelnut percentage (45%) displays the narrowest hysteresis area. Finally by Casson regression, it was found plastic viscosity (η_{CA}) increase by decreasing the fat/sugar ratio. This latter result may be related to lower lubrication and emulsifying properties of fat layer around solid particle with consequently higher friction.

4. Conclusions

The principal aim of this work was the knowledge development in the research area of rheological characterization of food semi-solid systems as hazelnut-cocoa based spreads. Rheological analysis highlighted a pseudo-plastic behavior in all spreads with the elastic component prevalent on the viscous one (G'>G''). Rotational analysis showed the strictly dependency of flow curve from temperature in all cases. Moreover, geometry changing determined only flow index (n) value modification. Spread with greater K variation demonstrated a higher tendency of G' and G'' curves to cross-over at higher temperature. In addition, a greater decrease of friction factor and more significant shape modification of the Stribeck curves highlight thermal structural changes. Palm oil based spread exhibited higher thixotropic behaviour meanwhile the sample with the highest hazelnut percentage (45%) displayed the narrowest hysteresis area.

The influence of water addition in Pre-Treatment of Sugarcane Straw Using Three Different Ionic Liquids

Felipe Ferrari[1*], Ariel Hijo[1], Jorge Pereira[2], Marcus Forte[1*]

1 Faculty of Food Engineering, University of Campinas (UNICAMP), Campinas 13083-862, SP, Brazil; 2 School of Pharmaceutical Sciences, São Paulo State University (UNESP), Rodovia Araraquara-Jaú/Km 01, Campos Ville, 14800-903 Araraquara, SP, Brazil

Highlights

- Acetate based ILs had better performance on dry straw pre-treatment.
- [Emin][Ac] showed the best aptitude to pre-treat the dry straw.
- [Emin][Ac] was the most impacted by water addition.
- [Mea][Hex] was the only IL positively affected by water addition, regarding enzymatic digestibility.

1. Introduction

The replacement of fossil fuels by renewable alternatives has been studied in order to mitigate the environmental impact of energy production. However, the use of lignocellulosic (LC) residues, such as sugar cane straw (SW) to the synthesis of biofuels, demands pre-treatment, due to its complexity. The recent use of ionic liquids (ILs) in this process emerges as a strategy to overcome the problems faced, such as high-energy demand and inhibitory compounds production [1]. The ILs´ aptitude to efficient pre-treat SW in presence of water is crucial since LC materials are highly hydrophilic, and water addition is one strategy to overcome the hurdle of IL cost.

2. Methods

Brazilian Bioethanol Science and Technology Laboratory (CTBE) provided the grinded straw. Sieves (between 16 and 24 mesh) were used as feedstock for pre-treatments. Chemical composition was assessed before and after each experiment using NREL31 methodology adapted from CTBE. 1-ethyl-3-methylimidazolium acetate ([Emim][Ac], 98 % pure) was purchased from Iolitec (Germany) and used as received. 2-hydroxyethylammonium acetate ([Mea][Ac]) and 2-hydroxyethylammonium hexanoate ([Mea][Hex]) were synthetized in Schott flasks through acid-basic neutralization. All other chemicals and standards were purchased from Sigma Aldrich (Germany) and used as received. Enzymatic hydrolysis was performed in 1.5 mL plastic tubes using Cellic CTec2 (Novozymes), at 5% (w/w) of solid loading and 10 FPU of enzyme per gram of biomass. Hydrolysis was carried out in pH 4.8, citrate buffer, for 48h. The enzymatic digestibility of cellulose and hemicellulose was calculated according the relationship between initial solid mass and sugars concentration from supernatant (adapted from NREL's LAP TP-510-4363031,32). Pre-treatment assays were done in triplicate. 0.6 g of dry SW was mixed with pure IL, and with IL 70 %(w/w) in H2O solution at 6% (w/w) solid loading, and then placed, in a convection oven at 90 °C for 12h. After the pre-treatment 10 g of water were added to each sample.

3. Results and discussion

The process using [Emin][Ac] had the best performance among the tested pure IL, entailing in 100 % of glucose realize after enzymatic digestion, followed by [Mea][Ac] and [Mea][Hex] 69 % and 46 %, respectively, without water addition. Both $[Ac]^-$ based IL had similar performance on hemicellulose digestibility, 54 % for [Mea][Ac] and 55 % for [Emin][Ac]. Although acetate based ILs are described as good enhancers on biomass pre-treatment [2], it is evident that changes of cations also play an important role on IL aptitude to pre-treat LC, mainly on cellulosic portion.

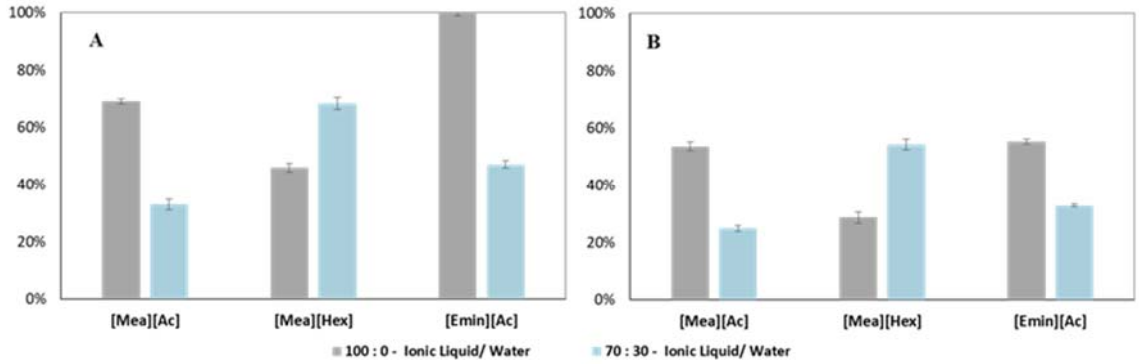

Figure 1. Enzymatic digestibility of cellulose (A) and hemicellulose (B) prevenient from residual solids after pre-treatment.

Nevertheless, in presence of water, [Mea][Hex] had the best performance among the tested IL, showing an opposite effect in this circumstance. Instead of the negative effect as observed in [Mea][Ac] and [Emin][Ac] process, water addition enhanced cellulose and hemicellulose digestibility in 49 % and 89 %, respectively. Acetate based ILs are good hydrogen bound acceptor, reason why IL species with this anion have good performance on LC pre-treatment [3], which also lead to higher interaction with water through hydrogen bound. Moreover, water tends to interact closely to the charged areas of IL (hydrophilic moiety) [4], the longer chain length of hexanoate anion my difficult the solvation of the molecule, thus allowing it to interact more efficiently with LC matrix than acetate in presence of water.

4. Conclusions

Considering enzymatic digestibility as criteria, [Mea][Hex] showed the best performance regarding water addition (the same values of cellulose and hemicellulose digestibility comparing with the pure [Mea][Ac]). The acetate based ILs were negatively impacted by water presence. Moreover, [Emin][Ac] had the worst stability regarding water addition, in the tested conditions, despite its good performance without water addition.

Development of capillary suspension by green tea powder and coconut oil to produce novel sol-gel characteristic functional food.

Hiroki Sato† and Masanao Imai*

Course of Bioresource Utilization Sciences, Graduate School of Bioresource Sciences, Nihon University, 1866 Kameino, Fujisawa, Kanagawa-pref. 252-0880, Japan
† present address: Iwai Pharma Tech Co.Ltd., 3-17-10 Higashi-Kojiya, Ota-ku,Tokyo 144-0033, Japan
**corresponding author: XLT05104@nifty.com*

Highlights

- Capillary suspension by green tea powder and coconut oil appears novel rheological food.
- When the volumetric fraction of additive water was 0.032, the fluid dynamics was changed.
- Apparent viscosity and shear stress were increased by small amount of additive fluid.

1. Introduction

Solid-liquid suspension was commonly appeared in foods, cosmetics and pharmaceutical supplements. Fluid dynamic character of conventional solid-liquid suspension was drastically changed by small amount of additive fluid[1]. That has been called as a capillary suspension illustrated by Fig.1. Networks of liquid bridges of additive fluid were looks like as a "capillary mesh"[2]. Some additive small amount of fluid was introduced into a conventional solid particles in oil suspension, fluid dynamics was drastically changed at the desired amount of additive fluid. It showed typical rheological character not Newtonian fluid. The aim of this study was to investigate change of fluid dynamic character of food based solid in oil suspension and capillary suspension[3]. It was promise for forthcoming novel rheological characteristic fluid applied for tubular packaged foods, cosmetics and pharmaceutical supplements[4].

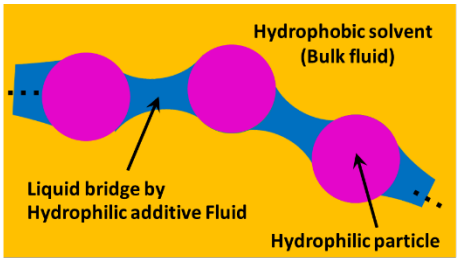

Figure 1. Network structure of capillary suspension.

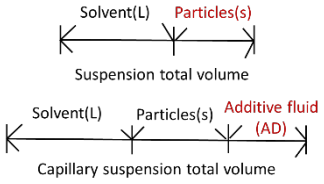
Table 1. Definition of volume fractions.

$$\phi_{S/T2} = \frac{\text{Volume of particle}}{\text{Total volume}}$$

$$\phi_{L/T2} = \frac{\text{Volume of solvent}}{\text{Total volume}}$$

$$\phi_{AD/T3} = \frac{\text{Volume of Additive fluid}}{\text{Total volume}}$$



2. Methods

In this study, green tea powder and coconut oil was employed to make a conventional solid in oil suspension. Water was used as an additive fluid to make a capillary suspension. Green tea powder was purchased from Tsujiri Ltd. (Kyoto, Japan). Spherical assumed mean diameter was measured as 4.07 µm. Density of green tea powder in dried state was measured 1.12 [g·cm^{-3}]. Coconut oil

was purchased from Nissin Oillio Co. Ltd. (Tokyo, Japan). Density of coconut oil was measured 0.926 [g･cm^{-3}]. Coconut oil appeared liquid state at room temperature. Rheological character of suspension and capillary suspension was measured by ARES Rheometer, TA Instruments. Disc diameter was 8 mm. Gap was set at 0.5 mm, and the shear rate in measuring was ranged within 0.1 s^{-1} – 100 s^{-1}. Temperature was conveniently set at room temperature 298±1 K.

3. Results and discussion

Definition of volumetric fraction of green tea powder particle in coconut oil shows as $\Phi_{S/T2}$, where S indicates “solid” , L indicates liquid, and T2 means “2 components system”. Volumetric fraction of additive water shows as $\Phi_{AD/T3}$,where AD indicates “additive water”, and T3 means “3 components system”. Table 1 summarized these definitions.

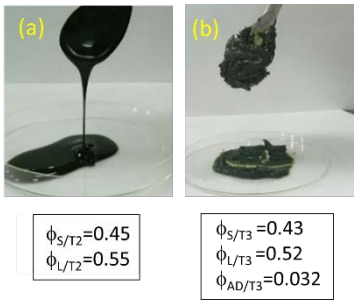


Figure 2. Preparation of capillary suspension

(a)Normal suspension (b) Capillary suspension.

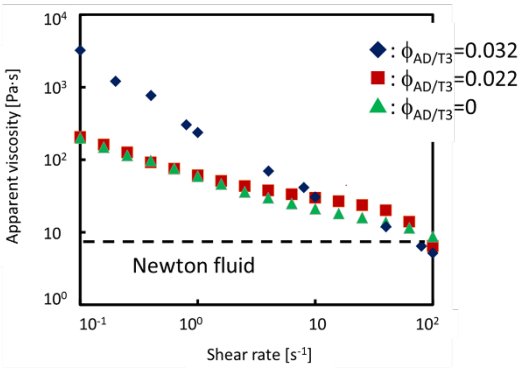

Figure 3. Apparent viscosity vs. Shear rate

When the volumetric fraction of additive pure water more than 0.032, the fluid dynamics of suspension was drastically changed to gel-like capillary suspension (Fig.2).

The rheological properties of the capillary suspension were measured by a strain-controlled rheometer. Apparent viscosity and shear stress were increased by adding a small amount of additive fluid (Fig.3). This indicated that capillary suspension has characteristic to keep the form.

4. Conclusions

Capillary suspension composed by green tea powder and coconut oil was successfully prepared. Apparent viscosity and shear stress were increased by small amount of additive fluid. When the volumetric fraction of additive water $\Phi_{AD/T3}$ was 0.032, the fluid dynamics was changed to gel like character. Novel rheological characteristic fluid was applied for tubular packaged foods, cosmetics and pharmaceutical supplements. They were promised as easy handling for chidden, older people and handicapped persons.

*deivissr2000@hotmail.com

Nowadays, the importance of pollen is given by its great source of protein, colorants among other functional compounds that are incorporated into the human and animal diet; beyond pollination (fertilization process between similar plants) to improve them, make them resistant to pesticides, to dehydration or increase crop production. It's like that in this research we sought to determine the best type of extraction using the Soxhlet method with and without pretreatment through the use of an ultrasonic bath. Additionally, the influence of the type of solvent based on its polarity was analyzed, using acetone and ethanol. For this purpose, apicultural pollen collected from the municipalities of Tenjo and Zipaquirá was used, botanical origin, taken mainly from flowers *Taraxacum officinale* (L.) Weber and Eucalyptus sp. of native forest in the area. On the other hand, the second pollen was extracted from the municipality of Fundación, Magdalena, with a botanical origin especially from *Citrus* sp., *Theobroma* and *Coffea*. For both pollen processes, the preexperimental variables were % humidity, % dry mass, pH and ° Brix, where these gave similar values, while the obtained yields showed that the combination between ethanol and ultrasonic bath is the most suitable for extraction with values higher than 20 % yield. In this context, it was established that, with the use of the ultrasonic bath for the extraction of apicultural pollen dyes and depending on the botanical origin, the solvent used and the extraction method to be used will perform a marked action on the yields of the extracts that will be obtained.

Highlights

- Physical and chemical properties of sucrose and sugar solutions
- The growth kinetics of sugar crystals in pure and impure sugar solutions
- Simulation and mathematical modeling of new processes and technologies
- Experimental work for industry and cooperation with industrial partners

This paper represents a summary of most important research activities in sucrose crystallization, in which the Department of Carbohydrates and Cereals, part of the University of Chemistry and Technology (UCT) Prague, have been focused over the last 25 years. A wide range of these projects has been carried out in cooperation with many research institutes, universities and industrial partners.
These activities can be divided into four main research areas that are interconnected and support each other.

1st area: Physical and chemical properties of sucrose and sugar solutions

The main condition for a successful control of the crystallization process is knowledge of physical properties of sucrose, other sugars and their impure solutions. At the beginning, it was necessary to obtain and verify these data experimentally. The most important properties to measure were: *(a)* density of sugar solutions (cooperation with Prof. Dandar, STU Bratislava); *(b)* solubility of sugars in technical sugar solutions (cooperation with Dr. Parkin, the British Sugar Research Centre in Norwich); *(c)* the effect of impurities on a shape of sugar crystals (cooperation with prof. Mantovani and Prof. Vaccari, University of Ferrara); and *(d)* the increase of boiling point of sugar solutions (Dr. Sarka, UCT Prague). This work involved a modification and/or design of new experimental devices. The most important data and results have been published in professional and scientific papers; included in the SUGAR TECHNOLOGY MANUAL (authors: Bubnik, Bruhns, Kadlec, Urban); and presented in congresses, such as CITS, ESST and AvH.

2nd area: The growth kinetics of sugar crystals in pure and impure sugar solutions

This area included work on gathering kinetic data that describe the growth of sugar crystals under conditions simulating the industrial environment. Equations describing the crystallization process have been suggested and verified using the data obtained from the 1st research area. Newly designed and built experimental equipment have been also used in laboratory and pilot plant trials.

Ultrasonic techniques for measurement of properties of sugar solutions and suspensions as well as US methods for determination of the metastable zone width have been developed and applied for sucrose crystallization control.
In cooperation with Prof. Mathlouthi from the Universite de Reims Champagne-Ardenne, a new image analysis method has been developed for control of the crystal formation and evaluation of crystal size distribution in crystallization processes.

3rd area: Simulation and mathematical modeling of new processes and technologies

Physical data about sugar solution properties and kinetic equations became an indispensable condition for further work on creation of new technological diagrams; simulation and modeling of processes; and not least, design of new manufacturing process diagrams for industrial partners. These activities were carried out under the European project Copernicus SUCLEAN that has been focused on raw juice crystallization and design and modeling of new sugar processing diagram. Partners in this project were: University of Ferrara, UMIST Manchester (Dr. Klemes), UCT Prague and Politechnika Warszawska Fillie Plock (Prof. Urbaniec). An essential part of the research was a study of application of membrane filtration (MF and NF) for purification of sugar solutions before crystallization carried out in cooperation with LSU Baton Rouge, USA.

4th area: Experimental work for industry and cooperation with industrial partners

The fourth part of our activities involves application of experimental data in measurement and modeling of processes in real sugar manufactures. Significant cooperating partners were VUC Prague (continuous crystallizer, Dr. Gebler), sugar factory TTD Dobrovice and other Czech sugar plants, ZVU Hradec Kralove, Czech Technical University Prague, and the Mikropur Company Hradec Kralove (Dr. Pridal).

Understanding freeze drying of sucrose solutions

Mercedeh Sadat Hosseinalipour, Luca Bosetti, Viktoria Wiedmeyer, Marco Mazzotti*

Institute of Process Engineering, ETH Zurich, 8092 Zurich, Switzerland

mhossein@ipe.mavt.ethz.ch

Highlights

- Freeze drying, a pharmaceutical unit operation to ensure prolonged product stability during storage
- Model study of sucrose, as one of the main excipients used in pharmaceuticals
- Importance of ice nucleation for freeze drying and final product structure

1. Introduction

Freeze-drying is a process, where a solvent, e.g. water, is removed from a frozen product under vacuum. Such a process, also called lyophilisation, is widely used in pharmaceutical industry to improve stability and long term storage of labile drugs [1]. Freezing and drying are the main two steps of the process, among which the latter can be further divided into primary and secondary drying. Controlling ice nucleation temperature during the freezing step is one of the most challenging aspects of the development of a lyophilisation cycle and it affects drying time, product morphology, protein preservation, intra-vial and vial-to-vial heterogeneity and process performance [2]. In order to overcome this challenge, understanding thermodynamics and kinetics of the product is of great importance.

In addition to being bulking agents, disaccharides, like sucrose, have proven to be most effective in stabilizing products such as liposomes and proteins during lyophilisation [3]. Since in many pharmaceutical preparations the bioactive content amounts to no more than a few percent, the freeze-drying characteristics of such formulations are often governed mainly by the physical and thermomechanical behaviour of the excipient mixture [4]. In the present work, sucrose-water solution has been chosen as a model solution to be freeze-dried regarding its wide usage in pharmaceutical formulations.

2. Methods

The basis to investigate thermodynamics and kinetics is the state diagram of sucrose-water solution with experimentally driven equations of solubility, solidification and glass transition temperature [5], which is shown in Figure 1.

Experiments were performed to investigate the effects of different thermal treatments, drying conditions and solution volume on the final freeze-dried product. XRD and TGA were used to study crystallinity and water content of different experiments.

3. Observations and discussion

Freeze-dried sucrose of all experiments were amorphous, as expected [5]. Samples with the same freezing treatment but different drying conditions resulted in very different specifications of the final product related to cake appearance, colour and stickiness. Regarding their characteristics, some of the products were classified as totally or partially collapsed cakes. These observations further clarified that sucrose, as an important component in pharmaceutical formulations, can present various states.

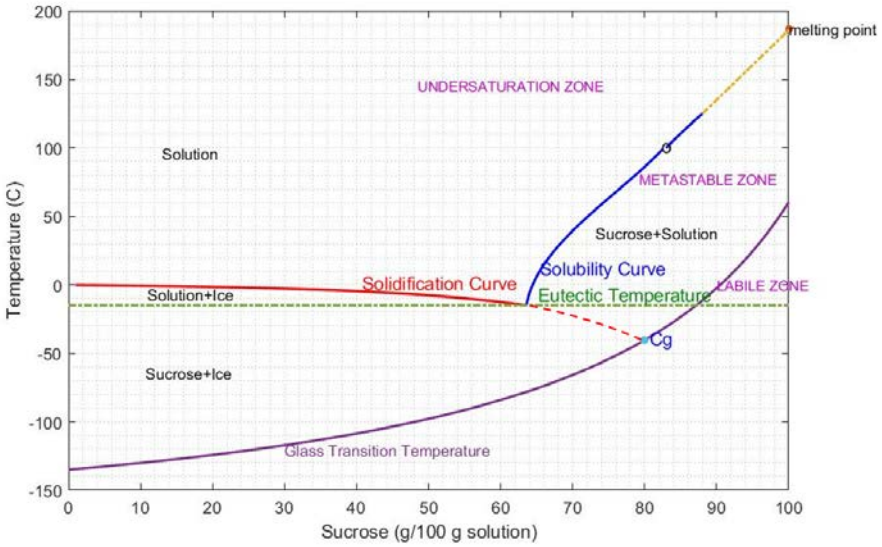

Figure 1. State diagram of sucrose-water [5]

4. Conclusions

In this work, it has been discussed how better understanding of the state diagram for a formulation to be freeze-dried can lead to a successful process. The importance of thermodynamics and kinetics is crucial to improve the design of a lyophilisation cycle of a formulation in a more predictable way.

Highlights

- Citrus peel is a by-product, which represent a potential source of valuable components.
- A three layer FFBP-ANN was investigated for hesperidin prediction in orange peel extract.
- The ANN model was found to be a useful tool for hesperidin yield prediction.

1. Introduction

During industrial citrus processing, large quantities of waste material is produced mainly as citrus peels [1]. These food industry by-products represent a potential source of valuable components being important raw materials in the food, chemical and pharmaceutical industries. Hence, the utilization of these citrus residues rich in bioactive and functional components has become a study of interest. In recent years, artificial neural networks (ANNs) are receiving more attention from researchers as an effective predictive tool. It has also been reported that ANN models can be used to predict extraction yields [2]. So in this study, the prediction of hesperidin content as the main bioflavonoid in orange peel extracts was studied by ANN.

2. Methods

In this work, an ultrasound-assisted extraction (UAE) was performed from reused orange peel (after SC-CO_2 extraction) in order to obtain the extracts rich in hesperidin - bioflavonoid with wide range of pharmacological properties. A three-layer feed-forward backpropagation artificial neural network (FFBP-ANN) was proposed to investigate the influence of four operating parameters: extraction temperature (30, 50, 70 °C), time (15, 30, 45 min), ethanol/water ratio (20%, 50%, 80% v/v) and solvent-solid ratio (10, 30 and 50 mL/g) on the extraction yield of hesperidin in UAE extracts. The performance of the developed ANN predictive models was evaluated based on the obtained mean square error (MSE) and coefficient of determination (R^2) parameters. The experimental hesperidin yield was determined by reversed-phase high performance liquid chromatography (HPLC) and its content was in the range from 3.3 to 23.0 µg/mg.

3. Results and discussion

Comparing developed models based on the AAD (Average Absolute Deviation), MSE (Mean Square Error), and R^2 coefficient (Coefficient of determination), the best performing ANN model was determined. These statistical parameters are useful in assessing model performance. The obtained

AAD of 5.24 %, R^2 value of 0.9769 and 0.9837 and minimum MSE of 0.0108 and 0.00796 during training and testing stage indicated that developed 4-5-1 FFBP-ANN model is the best performing model in predicting the hesperidin yield for studied dataset.

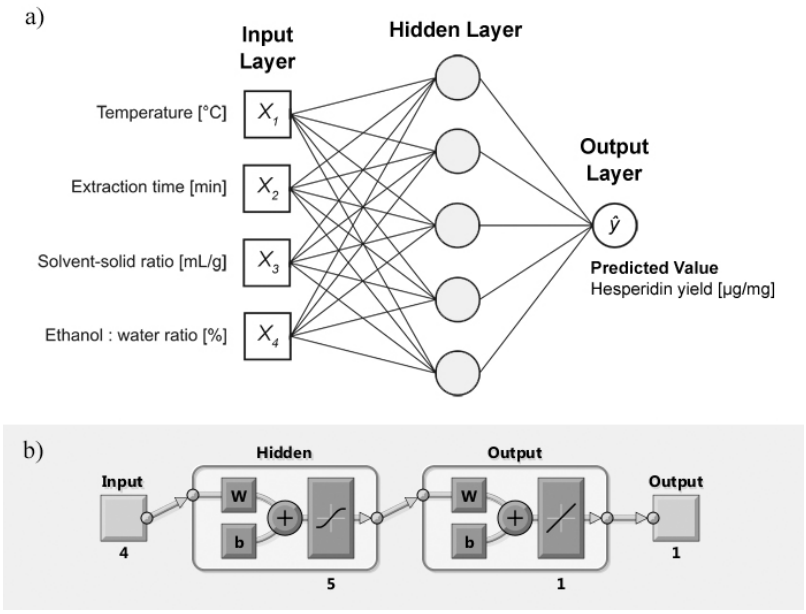

Figure 1. Configuration of the developed ANN [4-5-1], a) schematic representation and b) diagram automatically generated by MATLAB software.

4. Conclusions

Yield prediction of target components is of great importance and the first step for defining the optimal operating conditions, but also necessary for a successful regulation of extraction processes. It is well-known that citrus peel is a rich source of bioactive natural compounds, therefore it is essential to find an appropriate technique for optimization of extraction process. The ANN predictive model was found to be a suitable performing model for extraction hesperidin yield prediction from orange peel extract, as indicated by the statistical analysis.

Risk & Decision Making in Research Environment.

Anastasia Kalugina, Thierry Meyer

Ecole Polytechnique Fédérale de Lausanne

Institute of Chemical Sciences and Engineering; EPFL SB ISIC GSCP, CH-1015 Lausanne Switzerland

**Corresponding author: Thierry.meyer@epfl.ch*

Highlights

- Laboratory Risk profile is not limited by the number of Hazards.
- Underestimation of the Human Factor might lead to severe consequences.
- Real Risk Reduction Potential of the Measures is influenced by the Feasibility of them.

1. Introduction

During the last decades, many studies have been carried out on topics related to risk and decision-making (DM) in different sectors of economics. With an improvement in quality of life, as well as the introduction of Corporate Social Responsibility principles, more and more companies' resources are spent on safety enhancement. Generally, risk management (RM) and DM tools are only developed in the business environment. However, when talking about Academia, one has to consider this environment as safe. In order to keep such brand image, universities have to implement an effective system of risk management. An essential part of the RM process are the risk assessment and the DM steps. Due to the complexity of the Academia environment (different cultural background of the employees and students, high turnover, explicit professional features of the individuals and the important role of their creativity), the decision-making process becomes more complicated. Thus it requires a tool which takes into account the entire specific features of the environment and allocates resources according to the objectives, reducing the risk to an acceptable level. The objective of this project is to develop such a methodology which will allow making optimal decisions according to the settled objectives.

2. Methods

A combination of various qualitative and quantitative research methods has been used: unstructured interviews of safety experts, surveys, participant observations, case studies and simulations. Some of the qualitative data obtained have been transformed using semi-qualitative research methods such as FAHP (Fuzzy Analytical Hierarchy Process) and TOPSIS (Technique for Order of Preference by Similarity to Ideal Solution).

3. Results and discussion

In order to build a useful decision-making tool, it is important to have reliable outputs from the Risk Assessment step. The model is built in such a way that it considers the Risk as a 3-component phenomenon (fig. 1). The legal component of the risk [1] allows decision makers to choose among binding and optional measures. The introduction of the Human Factor [2] allows decision makers to choose among different corrective measures, those which are more suitable in the specific working environment. Furthermore, the Human Factor serves as a signal to act on the

improvement of the Safety Climate. Hazard indexes are evaluated based on the model proposed in the Laboratory Assessment Risk Analysis (LARA) method [3]. According to this method, the risk is calculated in relation to each particular Hazard and represents a combination of several parameters, which cumulatively give the value of the Laboratory Criticality Index (LCI).

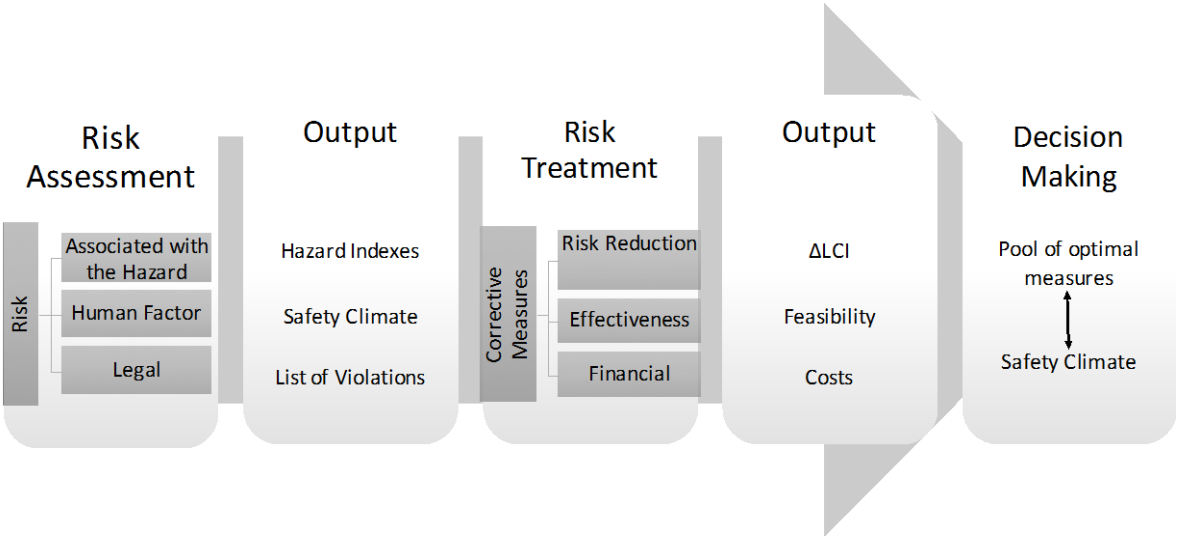

Figure 1. Decision-Making tool.

The next step of the RM process is the evaluation of the chosen corrective measures. It is important to consider their effectiveness from the risk reduction perspective, but also take into account how suitable they are in the specific working environment and in relation to the processes analyzed. Six parameters influencing the decision-making process have been identified based on the observations of the audits conducted by the OHS group at EPFL and following discussions with safety engineers or safety specialists. Two parameters describe characteristics of the measures which are affected by the Human Factor, three parameters address the technical effectiveness of the measures and one parameter is an indicator of cost-effectiveness. The six parameters are combined together in one parameter – Feasibility. Based on the results of the Risk Assessment and Evaluation of the measures, Fuzzy-TOPSIS is then used for a Resource Allocation optimization.

4. Conclusions

The model described here for Decision-Making in a research environment is a flexible tool that can be applied to different laboratories, where different safety climates, risk profiles and financial situations are present. This method allows decision makers to obtain optimal safety decisions depending on the settled objectives. It is multi-objective and can be used not only by experts but also by inexperienced users for interpretation.

How hurricane Harvey affected the Chemical and Process Industry.

Valeria Casson Moreno[1], Noor Quddus[2], Alessio Misuri[1], Valerio Cozzani[1*]

1 University of Bologna, Department of Civil, Chemical, Environmental and Materials Engineering, Italy;
2 Texas A&M University, Mary Kay O'Connor Process Safety Center, College Station, United States
**Corresponding author: valerio.cozzani@unibo.it*

Highlights

- The effect of hurricane Harvey on Chemical and Process Industry was investigated
- The focus was on the release of chemicals from industrial installations
- Vulnerable equipment were identified
- A lack of effectiveness of physical safety barriers was revealed

1. Introduction

The number of climate related natural catastrophes is growing in last years (Hopper, 2016), arising the concern of stakeholders such as civil society, industry and insurance companies. Indeed, in the recent past, the impact of natural phenomena on industrial facilities has proved to be able of severe consequences and escalating scenarios (Krausmann and Cruz, 2016). For this reason, understanding NAtural events triggering a TECHnological scenario (NaTech) is becoming a crucial topic.
In this study, the effects of hurricane Harvey on Chemical and Process Industry were analyzed. Harvey was one of the most severe and costliest hurricane hitting the United States ever. It heavily affected the economy of the region: during Harvey, the estimated loss on U.S. refining capacity was of approximately 20 %.
The analysis is focused on the releases of hazardous substances during the hurricane. The aim was to identify the equipment and conditions involved. The key issues highlighted in the present research provide a valuable insight for better informed decision making during risk assessment and management of NaTech events.

2. Methods

The analysis of the events is based on the data available from the United States Coast Guard National Response Center (NRC) Database (http://nrc.uscg.mil/). The Database is aimed at the collection of information on oil spills and chemical releases. Among all the dataset available, the records included in the present analysis were those related to industrial facilities only and explicitly ascribable to hurricane Harvey.

3. Results and discussion

The total number of record selected from the NRC Database was 80. The majority of the records (91 %) are related to on-shore facilities and, in particular, the claimed loss of containment was from: (i) equipment (85 %) and (ii) pipelines (4%). In 2 cases, the release of chemicals took place from mobile trailers: one of the cases is the well-known Arkema incident (Chemical Safety Board, 2018). The remaining 9% of the cases described are related to off-shore facilities.

The analysis of the equipment involved in the loss of containment revealed that tanks are the most vulnerable equipment (see Figure 1). Nevertheless, it has to be noted that a similar share of events involved emergency gas flares: the release of chemical was not "accidental" but took place because of emergency shut-down (and following start-up) procedures as a consequence of the hurricane.
The majority of the releases recorded was to air (41 %, see Figure 2), followed by water (35 %) and soil (5 %). Unfortunately, in 6 cases only (8 %), the release was contained (e.g. in dikes or containment ponds), revealing a lack of effectiveness of physical safety barriers.

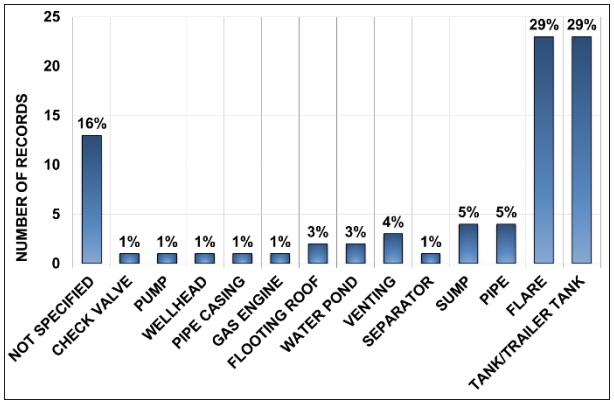

Figure 1. Analysis of the equipment involved in the release of chemicals during hurricane Harvey based on NRC data.

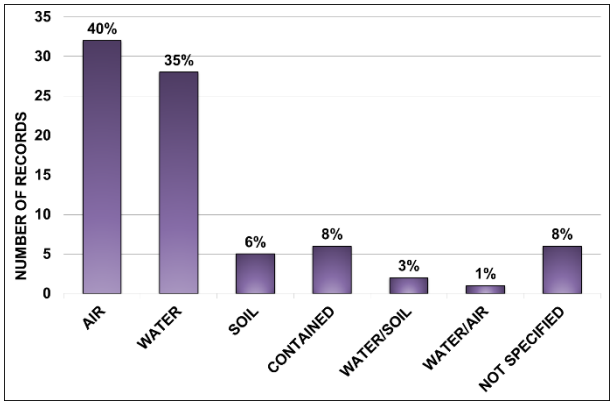

Figure 2. Analysis of the release to air, soil, and water environments during hurricane Harvey based on NRC data.

4. Conclusions

The analysis of data on the releases of chemicals during Harvey highlighted that tanks were the most vulnerable equipment during the hurricane. Of particular note was the role of flares during emergency shut-down and start-up operations. In general, a lack of effectiveness of physical safety barriers was observed.

Fire and Explosion risk indexing methods analysis and application to chemical plants

Enrico Danzi[1], Luca Fiorentini[2], Giovanni Pinetti[2], Marta Farinella[2], Luca Marmo[1]

1 Applied Science and Technology Dept. Politecnico di Torino, Cso Duca degli Abruzzi 24, 10129, Turin (Italy); 2 TECSA SRL, Via Figino 101, Pero MI, (Italy)

Highlights

- Fire and explosion risk assessment
- Chemical process plants
- Indexing methodologies

1. Introduction

Risk assessment in industrial workplaces is mandatory by a number of national and over national laws, directives and technical standards and it must consider the totality of potential hazards related to processes and manufacturing activities. Among them, fire and explosion hazards, and related risks, are present in most industries, particularly in chemical and process industry due to the hazardous properties of the substances handled as well as, often, the process conditions. Most common and simplified methods for oil & gas industry have been developed by Dow Chemical Company and Imperial Chemical Industries, namely Fire and Explosion Index (F&EI) [1] and the Mond Index [2]. Lately, Khan et al. have developed the SW&HI method (Safety Weighted & Hazards Index, [3])which could also apply to fire and explosion risk evaluation in chemical industrial realities. Both the methods allow a fast approach to fire & explosion risks given a number of indexes.

In the proposed work, aforementioned methods have been applied to a process plant to verify their similarities, discrepancies, and accuracy. The case study was a “chemical process” department of a chemical plant, where the main products are fine chemicals and powdered products. “Moderate” risk level have been obtained similarly by the different methods, the Mond Index being the highest among them. The most critical process for F&E risk in the facility, according to all the methods, has been identified in the the combustible powder packing operation.

A modification of the SW&HI index is proposed by the authors to overcome identified and discussed limits for a more versatile tool, to be used as a preliminary screening tool in the risk assessment workflow suitable. The new index method incorporates hazards related to solid substances having oxidizing, explosive and combustible properties. A critical and comparative analysis of the different incomes and application strategies of the three methods is given and a normalized risk index (NRI), is also proposed.

2. Methods

Plants not ruled by Seveso EU Directive, could although imply a high F&E risk, if any prevention/protection strategies are implemented. As to evaluate numerically this risk, indexing methods, devoted to risk evaluation screening procedure, could be applied. The SW&HI (Safety Weighted Hazard Index) method [3] has been developed as a quick and user-friendly tool for identifying hazards and assessing fire and explosion risk in the process industry. It represents an evolution of previous oil & gas based method, being more comprehensive and less time-consuming in the evaluation process.

3. Results and discussion

The chemical plant examined in this work is a North-western Italy company, the methods have been applied in the risk assessment of Department defined as “Chemical Product 1”, in which main products are plastic additives,

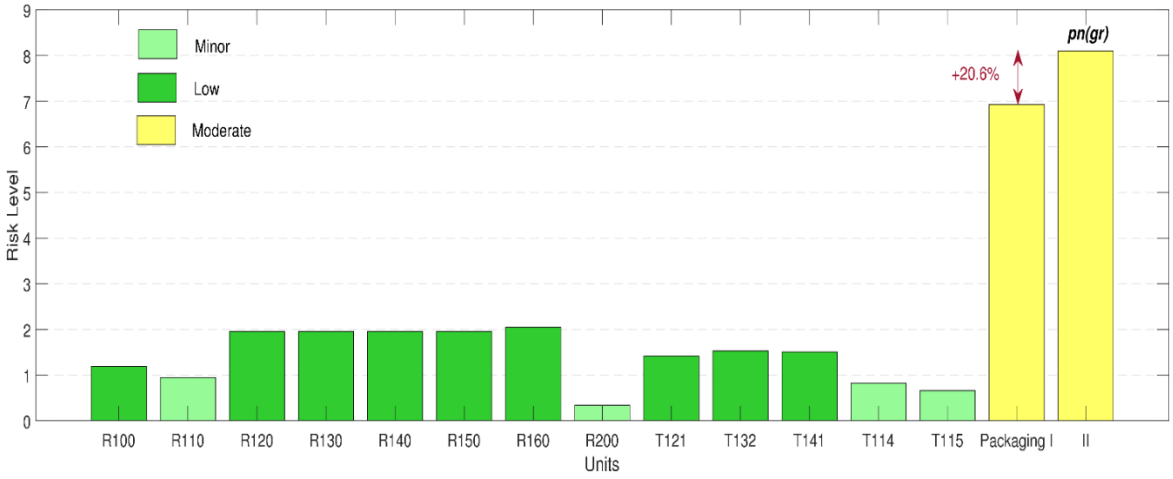

Figure 1. SW&HI results for case study, where packaging department is evaluated twice, before and after the algorithm modification imposed in this work (as to consider combustible powders).

Application of the Mond Index to the chemical department CP1 seemed to be most appropriate technique, due to its general approach in the identification of the substance (directly through physic-chemical characteristics, like ΔH_c) and the process hazards. F&EI application underlined how effectively different risk scenario could be mitigated: the measures adopted by the company manager demonstrate to be adequate with respect to actual potential hazards

4. Conclusions

A normalized risk index, defined here as NRI is introduced (Eq. 1), as to compare methods outputs: this value has to be considered as a preliminary risk level indication, or to be used in comparison with other department or chemical plants, while most hazardous areas (with a higher risk than NRI) has to be considered carefully and a detailed assessment is due to adopt the adequate protection measures. The algorithm modification of SW&HI evaluation implies an increase of about 20% of the risk level (as in Figure 1), which has not been accounted in the original method and gives the analysis a broader range of application and a more conservative approach.

$$NRI = \frac{\frac{Average\ SW\&HI}{Max\ SW\&HI} + \frac{Average\ F\&EI}{\mathrm{Max}\ F\&EI} + \frac{\ln Average\ Mond}{\ln Max\ Mond}}{4} \quad (1)$$

Highlights

- Development of improved relief scenarios for fully integrated Aromatics complex
- Simulation of vapor flow rates from columns with fired heater reboilers
- Mitigated relief loads resulting in considerably smaller flare header

1. Introduction

The design of Aromatic complexes has become increasingly more integrated over the years. The first process integration was achieved by removal of intermediate storage followed by feed-effluent heat integration. In recent years, a large degree of heat exchange between units has been applied. Together with the use of co-produced desorbent and a large amount of dividing wall columns, these developments have resulted in fully integrated aromatics complexes.

When developing relief scenarios for such an integrated complex, one should therefore look beyond the single-equipment envelop. In this paper, an example will be provided how power-failure scenarios were established and optimized for an integrated Aromatics plant.

2. Methods

The design of a 60” flare header resulting from large vapor flow rates in the Aromatics plant under relieving conditions triggered Fluor to establish a baseline relief load. Estimates from a simple black-box assessment, coupling the plant inventory to the residual heat, provided significantly lower relief loads for the governing relief scenarios. Therefore, Fluor assessed these scenarios in the various units of the complex heat-integrated Aromatics plant and established the basis for the combined relief load by development of a fully integrated plant scenario. The design data from the distillation columns, fired heaters and hydraulic circuits were used to simulate the vapor flow rates contributing to the combined relief load. By applying high integrity pressure protection systems (HIPPS) on the fired heater reboiled columns, an improved general power failure scenario provided the governing relief load and a new basis for the hydraulic calculations to perform flare header sizing.

3. Results and discussion

The basis for the general power failure scenario is a typical steady-state total unmitigated relief load resulting from the residual heat input of the fired heater reboilers into the isolated process at normal operating conditions with full loss of cooling capacity (**Figure 1**). Therefore, the relief

loads are result of the duty of the fired heaters and the available column inventory. As sizing of the individual relief valves serves the primary purpose of column protection, interaction between columns in the heat-integrated plant is not taken into account. This approach results in an overly conservative and often, cost prohibitive design of the flare header. Considering that there is a fixed amount of residual fired heater duty, the proper identification of heat integration and application of HIPPS provides an improved relief scenario and mitigated relief loads. The overall result is a more balanced design and a considerably smaller flare header of 32".

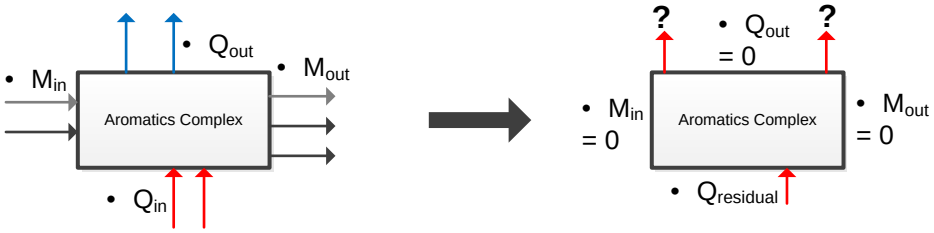

Figure 1. Sketch of the relief load resulting from the residual fired heater duty into the isolated process.

4. Conclusions

Column overpressure safety systems for completely heat-integrated plants should be carefully designed by looking beyond the single-equipment envelope. Only with a fully integrated plant scenario a proper assessment can be made for both column safety and the impact on the combined relief load for the governing relief scenario. In addition, mitigation of the combined relief load will lead to a substantial cost benefit in the design.

Air quality assessment of smart-sustainable cities and innovative sensors system

Angela Poletti[1], Irina Tumini[2]

1 Politecnico di Milano Piazza Leonardo da Vinci, 32 Milan (Italy); 2 Indipendent researcher (Spain)

**Corresponding author: angela.poletti@polimi.it*

Highlights

- Novelty in environmental monitoring sensors.
- Bio- and chemo-sensoristic contribution to smart environment.
- Assessing smart-sustainable project of pollution reduction.
- Integration between Air Quality Monitoring (AQM) stations and crowdsourcing.

1. Introduction

Many studies describe different types of sensors and methods used for air quality monitoring, impact and exposure of an individual to air pollution, interpolation, and calibration techniques on collected data [1]. Pollution monitoring is of huge importance to environmental protection and in health effects estimates. The Air Quality Monitoring (AQM) stations network has limited ability to account for spatial variability of pollution levels in heterogeneous regions such as urban areas, which in return, renders exposure assessment a very difficult task [2]. The interest in widespread environmental monitoring is limited in the implementation of smart and sustainable city projects despite the great importance given to climate change. While monitoring technology is proliferating, thanks to the decrease in sensor costs and the diffusion of different types of technological devices, research to inform the translation of air sensor data into information that might guide an individual's decisions about daily activities remains limited [3]. At the same time, the demand for rapid detecting biosensor will increase in the near future [4].
Starting from the recent literature on bio-sensoristic and chemo-sensoristic devices for detection of environmental contaminants, the paper tries to highlight how without a quality monitoring and diagnostic system identifying chemical and biochemical substances in the environmental matrix the goal of a smart city will be missed. With this purpose, we examine a series of smart city projects focusing on the theme of environmental pollution and applied sensor technologies.

2. Methods

After selecting ten case studies in the Italian context, following the criteria of demographic dimension of the city and the presence in the first positions of the international rankings related to smart cities, we assess the smart environment (based on the Giffinger components of Smart City [5]). The assessment focuses on sensors technology and its applications in the case studies, and on the ability to make the city evolve towards greater environmental sustainability and quality of life of its inhabitants. The assessment approach is based on the multi-criteria decision aid theory, specifically using the Multi-Criteria Decision Aid Constructive Approach (MCDA-C).

3. Results and discussion

According to the literature, application of low cost sensors/monitors have already changed the paradigm of air pollution monitoring, and application of these technologies is set to grow. In real case study, the full potential of existing projects is not achieved. However, only by analysing what has been done and its impacts is it possible to identify existing problems and ensure that the integration of intelligent innovation helps users and service providers to make better decisions and take decision in real time. In this sense, the integration between monitoring networks and data collected by citizens is still in an ancillary phase, also due to the need for an expert intelligence that re-elaborates and provides suitable indicators to influence individual behaviour without creating alarmism.

4. Conclusions

The paper described an analysis of smart city projects for the sole component of environmental pollution and focused on the use of innovative sensors and sensor networks in Italy and on a sample of 10 cities selected according to the size demographic criterion and presence in national and international rankings on smart cities. The assessment of the projects was based on adherence to the achievement of sustainability and the quality of life of citizens. We have applied Multi-Criteria Decision Aid Constructive Approach (MCDA-C). The results showed a fair distance between the capacity of existing technologies and described in literature and reality.

Nanocellulose explosions: influence of the agglomeration and turbulence on the combustion rate-limiting step and flame propagation

Audrey Santandrea[1], Marine Gavard[1], Stéphanie Pacault[1], Alexis Vignes[2], Laurent Perrin[1], Olivier Dufaud[1]*

1 Laboratoire Réactions et Génie des Procédés, Université de Lorraine, CNRS, LRGP, F-54000 Nancy, France
2 INERIS, Parc Technologique ALATA, BP 2, F-60550, Verneuil-en-Halatte, France

**Corresponding author: olivier.dufaud@univ-lorraine.fr*

Highlights

- Great influence of agglomeration on the rate-limiting step of the combustion
- Consideration of the whole reactive surface area when evaluating explosivity
- Estimation of an unstretched burning velocity for nanocellulose

1. Introduction

Dust explosion risk assessment is relatively well established for micron-sized particles and requires the determination of key safety parameters representing the ignition sensitivity and explosion severity of the dust. When considering nanoparticles, the particle size distribution (PSD) is more likely to vary during the injection process, due to both the agglomeration phenomenon inherent to strong interactions and the fragmentation phenomenon due to flow shear stresses. As a consequence, safety parameters and their determination methods can differ significantly from micro to nanopowders. A peculiar attention has then to be given to the cloud characteristics (PSD, turbulence), more precisely at the exact moment of ignition. This work focuses on nanocellulose and aims at evaluating the influence of the agglomeration phenomenon and flow turbulence on the dust combustion. Flame propagation tests were performed to evaluate the unstretched burning velocity and explosions tests were carried out to estimate the combustion mechanisms involved.

2. Methods

A nanocellulose powder (NCC - CelluForce), with a specific surface area of 400 $m^2.g^{-1}$ and primary fiber dimensions of 3 nm width and an average length of 70 nm, was chosen for this study. The powder was mechanically pressed and then coarsely ground to form agglomerates. In addition to the pure nanocellulose, two ranges of agglomerate diameters were chosen in order to highlight the influence of particle agglomeration on dust explosion: 30-180 µm and 180-450 µm. Explosion tests were performed in a standard 20L sphere according to EN 14034-1 & -2 [1] and the combustion gases were collected and analysed by gas chromatography. The burning velocity was estimated by filming the flame propagation within a semi-opened tube and the flame stretching was analysed. In both the tube and the 20L sphere, the PSD was measured during the dispersion using in situ laser particle size measurement and the turbulence level was obtained using Particle Image Velocimetry.

3. Results and discussion

Dispersion and explosion tests were performed for the three samples to estimate the evolution of the PSD during the injection and its influence on the explosion severity. It appears that the maximum rate of pressure rise significantly decreases when the agglomerate size increases, whereas the maximum explosion pressure is less sensitive to the variation of PSD. Indeed, the particle size has a direct influence on the rate-limiting step, as the combustion can be controlled by surface reaction (small particles) or by the diffusion to the surface (agglomerates). By controlling the agglomerate size, it is then possible to highlight both limitations and their effects. Chromatographic analyzes performed on the gases collected after the combustion of nanocellulose (mainly CO_2, CO, H_2, CH_4, C_2H_4, N_2 and O_2) show that, when increasing the dust concentration, the remaining oxygen content decreases slower for a diffusion-controlled reaction than for a surface-controlled one. It also appears that if the representation of the explosion severity is very commonly done as a function of the mass concentration, considering the whole reactive surface area of the dust cloud leads to agreement when the explosion kinetics is controlled by a surface reaction.

Among their specific properties, nanoparticles exhibit low sedimentation rates. This particularity allows tests at a low turbulence and can lead to an estimation of the unstretched burning velocity, which is an intrinsic parameter of the mixture. By varying the ignition delay time t_v during the tests, the turbulence is modified and thus the flame stretching. Figure 1 shows the flame 20 ms after ignition for different ignition delay times. By increasing the latter, the turbulence decreases and the flame becomes smoother and similar to gases explosion (parabolic profile – Fig 1c). The spatial flame velocity was determined considering the flame kernel growth before the interactions with the walls, and an unstretched burning velocity of around 12 $cm.s^{-1}$ was determined for nanocellulose using the linear relation between the burning velocity and the Karlovitz factor [2].

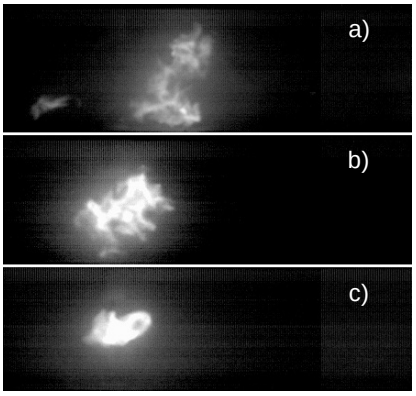

Figure 1. Flame propagation images 20 ms after inflammation for a) tv = 135 ms, b) 220 ms, c) 340 ms

4. Conclusions

Nanopowders tends to be naturally agglomerated. The size of their agglomerate depends on the turbulence of the dust cloud and plays a role on their combustion kinetics and thus on their explosion severity. Controlling these parameters and choosing the right parameter to represent the PSD helps to ensure a reliable explosion risk assessment. Finally, tests are currently performed to highlight the influence of dust agglomeration on the unstretched burning velocity of nanocellulose.

Visualization of aluminum dust flame propagation in two different lengths prototypes: some experimental considerations

Clement Chanut[1*], Frederic Heymes[1], Pierre Lauret[1], Elena Asquini[1], Pierre Slangen[1]

1 LGEI, IMT Mines Ales, Univ Montpellier, Ales, France]

**Corresponding author: clement.chanut@mines-ales.fr*

Highlights

- Aluminum dust flame propagation in two different lengths tubes: 70 cm and 218 cm
- Comparison of visualization and physical measurements (pressure): pulsating behavior
- Influence of rupture disk on flame propagation (pulsating behavior)
- Influence of optical properties of the walls (radiative thermal losses)

1. Introduction

Dust explosion is a major hazard for all industries dealing with powders, as all fine flammable dusts can cause an explosion when dispersed. These industries have to predict the consequences of potential explosions in given scenarios. To predict dust explosion consequences, models commonly used for gas explosions can be adapted. Although these models can be adaptable for organic dust explosions they are not accurate enough in case of metallic dusts [1]. Experimental studies are necessary to understand flame propagation mechanisms for these metallic dusts. Aluminum dust flame propagation is studied inside two prototypes of different lengths.

2. Methods

The first prototype is a vertical tube of 700 mm height and 150x150 mm square cross section. Walls are made of glass to visualize the dust dispersion and the flame propagation. The dust is dispersed by the discharge of two 1-liter compressed air vessels inside four vertical dust injection tubes, located in the corners of the tube. A fully characterized spark between two electrodes ignites the dust cloud. The energy of the spark is measured for each test. For the tests presented here, this energy is about 13 J. A rupture disc is located at the top of the prototype to limit the overpressure inside the prototype and also to keep control on the dust concentration. Details of this experimental setup can be found in [2].

The longest prototype is adapted from this first one. It consists of three parts of the previous prototype. Dust is injected on the two first stages. The rupture disc is located between the second and the third floor. No dust is initially present in the third floor, which is used to visualize the flame propagation after the rupture disc. Details of the second setup can be found in [3].

Aluminum powder with a mean diameter of 6.5 µm is studied. Flame propagation is analyzed thanks to fast camera and pressure sensors.

3. Results and discussion

Aluminum dust flame propagation is recorded in both prototypes. Pulsating behavior of light intensity is observed during the propagation of the flame. These light intensity pulsations correspond with the pulsations obtained with the different pressure sensors. Other authors also observed light pulsating behavior during aluminum dust flame propagation [4].

Complementary experiments are realized with the smallest prototype. First the influence of the rupture disc on flame propagation is investigated. This rupture disc has a weak rupture resistance (rupture around 35 mbar) to limit the influence of its rupture on the flame. Experiments are realized with and without the presence of this rupture disk. Diminution of the pulsating behavior of the flame is observed for the tests realized without the rupture disc.

In each prototype, the main pressure peak is recorded after the flame leaves the prototype, while the flame front is inside the exhaust duct. Change of optical properties of the walls is supposed to explain this main pressure peak. Inside the prototype, the walls are made of glass. The flame is supposed to present in this case important radiative thermal losses at the walls. On the contrary, the exhaust duct is made of galvanized steel. Inside this duct, the flame is supposed to present less radiative thermal losses leading to an acceleration of this flame. For this purpose, experiments are realized in the smallest prototype. Some walls of glass are covered of aluminum paper. With two opposite walls covered of aluminum paper, a more important pressure peak inside the prototype and a faster flame propagation are observed confirming the hypothesis of the influence of optical properties of the walls on aluminum dust flame propagation.

4. Conclusions

Aluminum dust flame propagation has been studied inside two different lengths prototypes. A pulsating behavior has been observed especially inside the longest porotype. Observations made inside this prototype conducted to realize complementary experiments inside the smallest one. This pulsating behavior decreases when the rupture disc is not present inside the prototype.

An important pressure peak has been recorded as the flame reached the exhaust duct with each prototype. This effect is probably linked to optical properties of the walls. The walls of the prototype are made of glass, presenting a potential thermal loss by thermal radiation for the flame. Inside the galvanized steel exhaust duct the flame is accelerated by decreasing the thermal losses of the flame. This observation emphasizes the importance of the properties of the walls for experimental investigation but also for comparison with numerical results. For safety purpose, this result underlines the importance of the material used for exhaust ducts inside industrial plant and its influence in case of accident.

Highlights

- Copper is the main element in PCB scrap.
- Ammonium salt solutions can selectively recover the copper.
- Influence of reagent concentration and liquid/solid ratio were studied.
- Copper recovery of 100% and a selectivity of 77% were achieved.

1. Introduction

End-of-life electrical and electronic equipment such as printed circuit boards (PCB) are becoming a major environmental problem due to their composition, which comprises toxic metals, polymers and ceramics. From an environmental and economic point of view, the amount of metals present, especially copper, makes this residue an interesting secondary source of metals.

The recovery of metals from electronic scrap using hydrometallurgical methods has attracted considerable attention in the literature for being effective and less harmful to the environment [1]. This process uses acid or basic solvents to extract the metals, which are then separated and purified using processes such as precipitation, solvent extraction, adsorption or ion-exchange.

In this context, this work aims at processing the metal containing fraction of PCB using hydrometallurgical processes. A solution of ammonia and hydrogen peroxide was used as oxidizing agent, in order to combine high levels of extraction efficiency as well as a low environmental impact.

2. Methods

The analyzed PCB scrap sample was provided by an E-waste Recycling Portuguese company, and was constituted by 4 kg of computer motherboards, RAM memories, mobile phones and processors. First, a mechanical/physical processing was performed, consisting in the dismantling and fragmentation of components using a guillotine and a sheet mill. Afterwards, a blade mill was used to reduce the PCI particle size, which was then separated into two fractions – oversize (>0.0707 mm) and undersize (<0.707 mm).

The chemical characterization was performed by x-ray fluorescence (XRF) model Rigaku Nex CG. Previously, acid digestions were performed in open systems by heating the waste with aqua regia reinforced with hydrogen peroxide. The Cu recovery tests were carried out in a closed cylindrical reactor, with a condenser attached, a termocouple and a mechanical stirrer. Two relevant operation conditions, namely liquid/solid (L/S) ratio and reagent concentration were studied using a 3 level full factorial design of experiments.

3. Results and discussion

The chemical characterization of the raw material is shown in Figure 1.

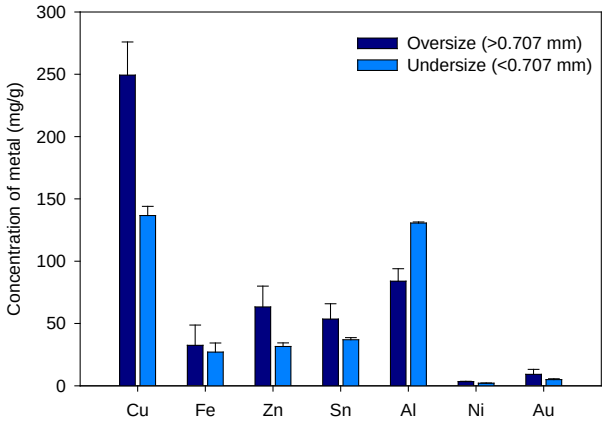

Figure 1. Chemical composition of the PCB components analyzed.

The results show that copper is the most abundant metal in PCB and is mostly found in the oversize fraction, with a maximum concentration of about 244 mg/g of waste. Precious metals such as gold are also present in promising quantities, which can also be recovered.

The influence of reagent concentration and L/S ratio on the recovery of Cu is reported in Table 1.

Table 1. Leaching yield and selectivity of the Cu recovery.

Run	L/S	C % (vol. %)	Yield (wt. %)	Selectivity (wt. %)
1	3	23.2	64.3	75.9
2	5	23.2	63.9	75.5
3	7	23.2	86.4	74.9
4	3	42.7	68.0	86.2
5	5	42.7	69.3	75.9
6	7	42.7	64.4	73.9
7	3	72.4	74.1	76.9
8	5	72.4	100	77.0
9	7	72.4	78.0	72.0

A yield of 100% and a selectivity of 77% was obtained for the copper extraction using a reagent concentration of 72.4% and a L/S ratio = 5. It can be concluded that the concentration and L/S ratio have a positive effect on the extraction efficiency. The higher the concentration and the smaller the amount of residue, the easier the dissolution of the metals with the reagents.

4. Conclusions

Copper is the main basic metal present in PCB scrap. The best yield for copper extraction was obtained at a maximal reagent concentration (about 72.4%) and a L / S ratio = 5. Recovery of almost 100 % of copper was achieved.

Phase-Change Solvents For CO_2 Capture: Sustainability Aspects.

Gulnara Shavalieva[1], Stavros Papadokonstantakis[1]

[1] Chalmers University of Technology, SE-412 96 Gothenburg, Sweden

*Corresponding author: gulnara.shavalieva@chalmers.se

Highlights

- Sustainability assessment should be considered already during solvent selection
- Assumptions will significantly influence the results of the assessment
- Extra equipment might be required to guarantee safety of the workers

1. Introduction

2°C warming scenario requires widespread adoption of efficient carbon capture and storage technologies. Post-combustion CO_2 capture by chemical absorption is the most mature of existing ones. However, high energy requirement and associated costs of the capture process hinder the technology's diffusion and large-scale employment. Phase-change solvents is a novel solution to an energy penalty problem of post-combustion CO_2 capture. At certain temperatures the solvents generate two phases and one of them is recycled back to the absorber reducing the input to the energy-intensive stripping process.

While the improved performance processes using phase-change solvents are proven by various studies [1], [2] there is limited research done on the environmental and health aspects of such processes. Many of the phase-change solvents are new molecules with no or very limited occupational safety and health information that makes it challenging to perform a sustainability assessment. Potential hazards linked to the process use of the harmful molecules affect the cost and design of the process and need to be considered already during the selection of solvent.

2. Methods

The analysis was done with the help of literature study and a holistic method combining life cycle (LCA) and environmental, health and safety assessments (EHS). During the literature study problems associated with process use of CO_2 capture solvents were gathered and evaluated in terms of applicability to phase-change solvents. Additional challenges were also thought through. Since there is no data on industrial use of phase-change solvents, different scenarios and assumptions were generated to anticipate the different behavior of the system in terms of solvents loss and process specific hazards such as products of solvent degradation and volatile emissions.

3. Results and discussion

Two phase-change solvents were used for the study: MCA (N-methylcyclohexanamine), and a novel solvent S1N. The molecules are structurally similar chemicals, however MCA is a more volatile and S1N- more soluble in water. LCA impact of solvent manufacturing is lower for S1N solvent. EHS values for the chemicals are close, but MCA has worse S (safety) and H(health) values due to higher mobility of the chemical, whereas S1N performs worse in E (Environment) category. Losses of the

solvent during the capture process due to degradation, aerosol formation and vaporization and energy consumption of the process are the main contributors to the LCA impact in such categories as global warming potential, cumulative energy demand and ReCiPe endpoint indicator at the process level. The overall impact is highly influenced by the assumptions discussed below.

Due to low vapor pressure and high solubility in water S1N is expected to have the lowest loss of the solvent during the process operation [2]. It is more difficult to estimate loss of the solvent due to aerosol formation. It has been reported that aerosol formation can increase the emissions by 1-2 orders of magnitude if left uncontrolled [3]. Study performed by [4] states that substantial amine loss via aerosols can occur even for low volatility solvents, thus to recover and remove the significant part of the MCA and S1N solvents from the gas leaving to the atmosphere and control the escape of solvent degradation products a wash section was added to the process sheet.

Another complex phenomenon difficult to estimate is solvent degradation. MCA is a secondary amine, therefore expected to degrade significantly in presence of oxygen. MCA reported to degrade 1.5-3 times more than MEA [2]. To estimate the oxidative degradation potential of S1N, degradation data on structurally similar compounds was used for calculation. Thus, it was assumed that the degradation rate is 3-10 times of MEA. It is reported that a product of oxidative degradation for MCA is ammonia [2], S1N might also produce a different degradation compound, allylamine. Scenarios considered cases of 85% and 65% of degradation products being volatile and the rest - heat stable salts (HSS) for MCA and vice versa for S1N, since it is believed that the majority if the S1N degradation products will stay in the liquid phase. Phase-change solvents can be recovered at lower temperatures; therefore the thermal degradation is expected to be generally lower than for systems using MEA.

During the capture with phase-change solvents part of the process stream is recycled back to the absorber and some part of the degradation products formed in the absorber including dangerous to health substances like nitrosamines, can follow the stream back to the absorber avoiding their removal in the reclaimer and also the thermal process of stripping responsible for partial destruction of the hazardous substances [5]. Additional safety measures and an extra reclaiming point might be required.

4. Conclusions

There are several aspects of the CO_2 capture of the process using phase-change solvents that can significantly influence the result of sustainability assessment. Extra equipment might be required to guarantee safety of the process. This will lead to added costs and should be considered already during the solvent selection and early design phase of the carbon capture process.

Fixed Bed Adsorption and Breakthrough Modelling of Activated Porous Carbon Derived from Compost for Post-Combustion CO_2 Capture

Mohsen Karimi[1], José A.C. Silva[2], Alírio E. Rodrigues[1]

1 Department of Chemical Engineering, University of Porto, Rua Dr. Roberto Frias, S/N, 4099-002, Porto, Portugal; 2 Department of Chemical and Biological Technology, Polytechnic Institute of Braganca, Campus de Santa Apolonia, 5300-857 Braganca, Portugal

**Corresponding author: mohsen.karimi@fe.up.pt*

Highlights

- Novel adsorbents were synthesized from derived compost in mechanical biological treatment.
- 5-samples were activated chemically and thermally in different procedures.
- Breakthrough experiments were performed in a fixed bed column.

1. Introduction

In the recent years, synthesis, preparation and development of valuable carbon materials have received much interest in the view of energy efficiency and sustainability for various applications in CO_2 capture, wastewater treatment and gas storage studies [1, 2]. On the other hand, based on European legislation to management of solid wastes and limiting the utilization of fertilizers from waste as well as finding approaches to manage these materials, novel approaches are required [3]. In this study, the obtained compost by mechanical biological treatment plant from municipal solid waste has been considered as a source of adsorbents for CO_2 capture.

2. Methods

The compost used was obtained in mechanical biological treatment plants for municipal solid waste, supplied by the company "Resíduos do Nordeste, EIM". In order to homogenize and remove the soluble compounds and suspended solids, the compost was first mixed with water and washed. Then, two different materials were prepared by carbonization at 400 (CMSW-400) and 800 ºC (CMSW-800). In addition, two materials were prepared with H_2SO_4 before and after the carbonization at 800 ºC (CMSW-S-800 and CMSW-800-S, respectively). Then, breakthrough measurements of CO_2 were carried at post combustion conditions (40ºC and 1-5 bar).

3. Results and discussion

Figure 1 shows the uptake capacity of proposed samples at 40 ºC. The results show the prepared sample by the subsequent treatments with acid sulfuric and thermal calcination has the higher uptake capacity than other ones and literature reports; which it can derived from several factors. Frist, better textural properties of proposed sample, including: higher external surface area (S_{ext}), microporous surface area (S_{microp}) and external surface area (S_{ext}). It can be also ascribed for desorption of weak superficial groups as consequence of the thermal treatment at 800 ºC.

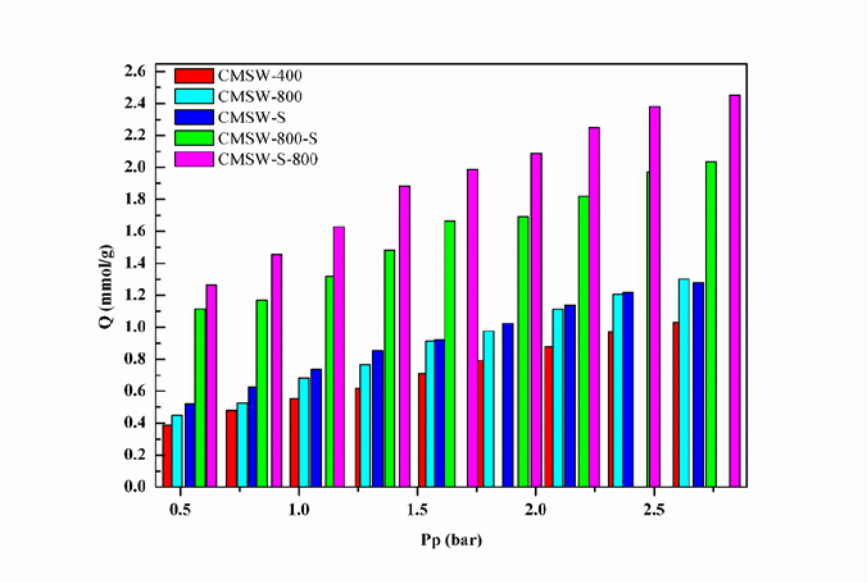

Figure 1. A comparison between CO_2 uptake capacity (mmol/g) of investigated adsorbents at 40 ^{0}C.

4. Conclusions

In this study, the potential of municipal solid wastes as a source of adsorbents for CO_2 capture were investigated at the post-combustion operational conditions. Then, the breakthrough measurements in the fixed bed adsorption column were performed. The equilibrium adsorption capacity of the considered samples revealed that the adsorption capacity of the sample which has been treated with the subsequent treatments with acid sulfuric and thermal calcination is the best one and its uptake capacity is comparable with commercial carbon materials. The results proved the proposed strategy can be a green route for integrated management of environment.

Acid gas removal in waste-to-energy plants via high temperature reaction with calcined dolomite

Alessandro Dal Pozzo*, Giacomo Antonioni, Valerio Cozzani

LISES – DICAM, Alma Mater Studiorum - Università di Bologna, via Terracini n.28, 40131 Bologna, Italy

**Corresponding author: alessandro.dalpozzo3@unibo.it*

Highlights

- The furnace injection of calcined dolomite was tested as acid gas removal method
- The test run campaign demonstrated high reactivity towards both HCl and SO_2
- A model for HCl and SO_2 removal was calibrated on test run data
- Adding furnace injection can reduce the overall cost of flue gas treatment

1. Introduction

Acid gases like HCl and SO_2 are typical pollutants arising from the combustion of municipal or industrial waste fractions having Cl and S content. The upcoming revision of the BAT (Best Available Techniques) for waste incineration sets high standards for the emission control of these contaminants [1]. Old waste-to-energy (WtE) plants might require retrofitting to obtain a renewal of their environmental permits. In this framework, the injection of calcined dolomite (CD) in the combustion chamber, as solid reactant for acid gas abatement, has been proposed recently as a simple approach to retrofitting, with minimal investment cost and without the need for additional equipment [2]. The current study aims to investigate the cost-effectiveness of CD injection.

2. Methods

The performance of CD as high temperature reactant for acid gas removal was tested in two WtE plants. Both plants adopted the injection of sodium bicarbonate at low temperature (180 °C) as acid gas abatement stage, as commonly performed in several European WtE plants [3]. As sketched in Fig. 1a, the tested configuration consisted in the introduction of CD as an additional acid gas abatement stage directly in the combustion chamber (T ~ 1000 °C). The concentration of HCl and SO_2 in the flue gas was measured downstream of the furnace (point SMP). Therefore, in order to assess the effect of CD injection on the acid pollutants, “on/off tests” were performed by alternating periods of injection and interruption of the CD feed rate, as shown in Fig. 1b. The removal efficiency of CD towards HCl or SO_2 at different feed rates was calculated considering the reduction in acid gas concentration at point SMP compared to the periods without injection of reactant. A previously formulated model for dry acid gas removal [4] was calibrated on the experimental data. The calibrated model was used to simulate the operation of the WtE acid gas removal line (furnace injection of CD + downstream bicarbonate injection) at different feed rates of CD. The simulations allowed to identify the operating point of the plant that minimizes the operating costs of acid gas removal.

3. Results and discussion

The results of the test run campaign are summarized in Fig. 3c, where the acid gas removal efficiency (for HCl and for SO_2) is plotted as a function of the stoichiometric ratio (SR) of reactant. Dolomite appeared particularly reactive towards SO_2: at SR = 1 (i.e. reactant feed rate without stoichiometric excess), the removal efficiency for SO_2 and HCl was 81 % and 29 %, respectively. Calibrating a performance model (continuous lines in Fig. 1c) on the experimental data (dots) allowed to study the process optimization of the two-stage acid gas removal system (dolomite stage + bicarbonate stage). The performance model for bicarbonate was obtained through a dedicated analysis as in [4]. A typical flue gas composition (HCl = 800 mg/Nm^3, SO_2 = 200 mg/Nm^3) resulting from municipal waste combustion was considered as reference case. The overall operating costs of the two-stage line (cost of the reactants plus disposal of process residues) were assessed as a function of HCl conversion in the CD stage, as shown in Fig. 1d, while keeping constant the overall acid gas conversion in the two-stage system. The minimum of operating costs was found for a 25 % HCl conversion in the CD stage, which realizes a 14 % cost reduction compared to the single-stage sodium bicarbonate acid gas removal system without dolomite injection.

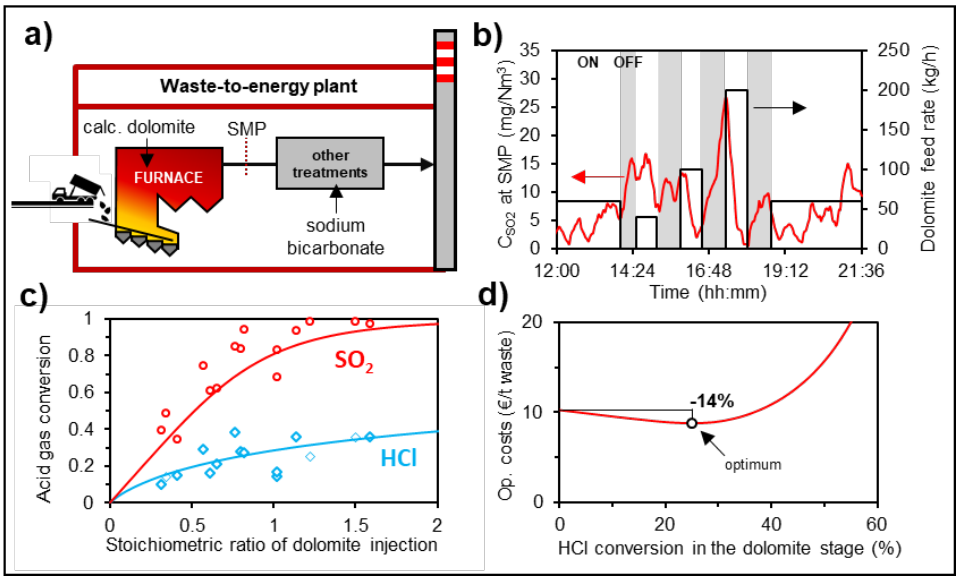

Figure 1. Framework of the study: a) sketch of the WtE plant configuration (dolomite + bicarbonate two-stage acid gas removal system); b) dolomite feed rate and SO_2 concentration over time during a typical test run; c) removal efficiency of calcined dolomite for HCl and SO_2; d) operating costs of the two-stage acid gas removal system as a function of HCl conversion in the dolomite stage.

4. Conclusions

The test run campaign conducted in WtE facilities demonstrated the cost-effectiveness of acid gas removal via the high temperature reaction with CD. Retrofitting a plant equipped with a sodium bicarbonate treatment stage with an additional dolomite stage as furnace injection can reduce the overall operating cost of acid gas treatment, if the feed rate of dolomite is properly optimized.

Adsorption of Active Trace Gases by Ensemble of Ultrafine Porous Particles with Impermeable Core.

Andrew Fominykh[1*], Itzhak Katra[2], Boris Krasovitov[1], Avi Levy[1]

1 Department of Mechanical Engineering, Ben-Gurion University of the Negev, P. O. B. 653, 8410501, Israel

Highlights

- Original model of gas adsorption by particles with non-uniform porosity is proposed.
- Effect of radioactive decay and kinetic effects on the rate of gas adsorption is studied.
- Gas adsorption by ensemble of particles is governed by integro-differential equation.
- Theoretical predictions are in good agreement with experimental results.

1. Introduction

Consider adsorption of atmospheric trace gas from a mixture with inert gas by a moving ensemble of porous particles. The size of the particles can be of the same order of magnitude as mean free path of molecules in air at normal conditions. The velocity of particles is equal to a gas velocity. At time t = 0 particles begin to adsorb active gas from the gaseous mixture. Gas adsorption inside a porous particle is determined by nonstationary equation of diffusion in spherical coordinates with a sink term. Equation of diffusion is supplemented by initial and boundary conditions – zero mass flux at a surface of impermeable core and to be determined from equation of mass balance for a unit cell time-dependent mass flux at gas-particle interface.

2. Methods

When the size of a particle have the same order of magnitude as a mean free path, the Fickian diffusion approach for the analysis of reactant molecules transport is not applicable. We overcome this difficulty applying the flux-matching theory (see [1]-[2]) which is a hybridization of the diffusion and the free molecule approaches. The concentration profile of radioactive gas far away from the particle is described by the diffusion equation. This profile coincides with the real one down to the distances of the order of the mean free path of molecules of adsorbate. A limiting sphere is then introduced inside of which the free molecule kinetics governs the adsorbate transport. Then the radius of the limiting sphere is obtained from the condition of equality of the fluxes in both zones.

3. Results and discussion

The developed model of radioactive gas adsorption by ultrafine porous particles is applied to investigation of scavenging of radioactive gases from a mixture with air by an ensemble of moving carbon-based aerosols. The results of calculations of concentration of I-132 gas in a gaseous phase as a function of time are shown in Figure 1. Calculations are performed for aerosol number density $1.2\cdot 10^{4}\,\mathrm{cm}^{-3}$, the specific surface area of a particle was assumed to be equal to $100\,\mathrm{m}^{2}\mathrm{cm}^{-3}$, and density of porous particle with radius a=50 nm is 1 $\mathrm{g}\cdot\mathrm{cm}^{-3}$. Analysis of Fig. 1 shows that

concentration of radioactive trace gas decreases rapidly at the initial stage of gas adsorption. Rapidly decreasing segment of the temporal dependence of concentration is followed by a shallow-slope segment. For large time the concentration of a radioactive trace gas vanishes due to radioactive decay. The slope of the curve at the steep-slope segment of the temporal dependence of concentration increases with an increase of Knudsen number. The magnitude of concentration at a shallow-slope segment of the curve decreases with a decrease of a Knudsen number. The larger the Knudsen number, the larger is a period of time required for concentration of active trace gas in a gaseous phase to reach a shallow-slope segment of the temporal dependence of concentration.

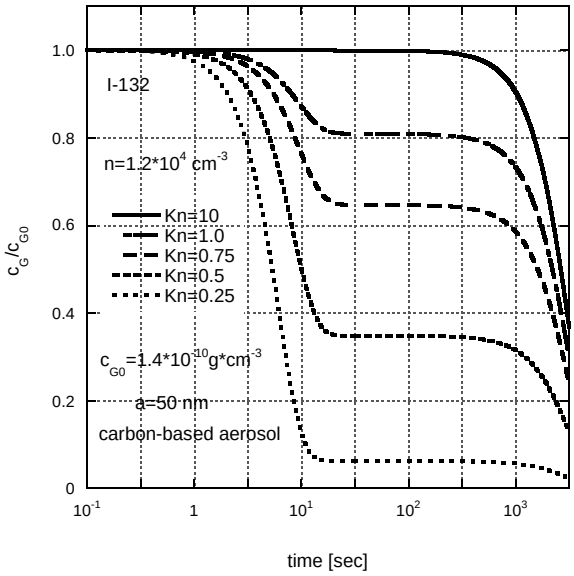

Figure 1. Concentration of active gas in a gaseous phase as a function of time.

4. Conclusions

We developed a model for adsorption of active atmospheric gases by an ensemble of solid porous particles taking into account radioactive decay in the dispersed and continuous phases. Using the developed model we calculated temporal dependences of concentration of adsorbed gas in a particle, concentration of radioactive gas in a gaseous phase and scavenging coefficient for adsorption of I-131, I-132, Rn-220 and Rn-222 by carbon-based aerosols. The obtained results can be summarized as follows:

1. Mass flux density at the particle interface is determined by integral equation while temporal evolution of concentration of an active trace gas in a gaseous phase is described by integro-differential equation.

2. Neglecting kinetic effects during gas adsorption by ultrafine particles leads to the overestimation of the rate of adsorption.

3. The developed model of radioactive gas scavenging by an ensemble of aerosols yields the same estimate of the dependence of the adsorbed amount of gaseous radioactive Iodine-131 in a particle vs. time as the measurements of Noguchi et al. [3].

Highlights

- Amount of produced water from oil exploration and production is increasing.
- A hybrid biological process was developed to treat oil produced water.
- Enhancement of oxygen transfer occurs in the presence of a packing material.

1. Introduction

Crude oil extraction leads to the production of produced water (PW). PW flowrate increases with oil field lifetime, up to more than 20 times the flowrate of crude oil. Since the regulations regarding PW disposal becoming more stringent, there is a big challenge in developing efficient treatment processes (i.e. physico-chemical and/or biological treatments). Among them, biological treatments (i.e. conventional activated sludge processes) are commonly installed in the industrial sector, due to cheaper operation costs and higher removal efficiencies of biodegradable compounds compared to those obtained by chemical treatments. However, critical parameters, such as the PW composition (i.e. salinity and low biodegradability of some compounds) and technology compactness for offshore implementation, have to be taken into account. Hybrid processes defined here, as the combination of two biotreatment processes (i.e. fixed and suspended microbial biomass in the same reactor) showed promising performances in terms of oxygen transfer [3]. Furthermore, this combination enhances treatment efficiencies as both, the biomass concentration and the microorganisms variety increase in the bioreactor [4]. Thus, this study relates the development of a hybrid biological process for oilfield produced water treatment.

2. Methods

Experiments were carried out by using a laboratory pilot plant, consisting of two bioreactors (30 L of working volume) and two clarifiers (5 L of working volume) in parallel (Figure 1). Reactor columns have an inner diameter of 19 cm and a total height of 107 cm. The aeration is supplied by compressed air flowing into a membrane to provide fine bubbles. The packing material, confined into the bioreactors, is made of cylindrical solid rings (AnoxKaldnes®). The air flowrate is controlled by a flowmeter. Preliminary experimental tests were conducted to determine the oxygen transfer rate (K_La) on clear water and on a physico-chemical Newtonian suspension (i.e. 3g/L bentonite suspension), by varying the air flow rate (4-10-16 L/min) and the packing height (0-17-34 cm). The oxygen transfer measurements were carried out by using the disulfite deoxygenation method followed by a re-oxygenation phase [3].

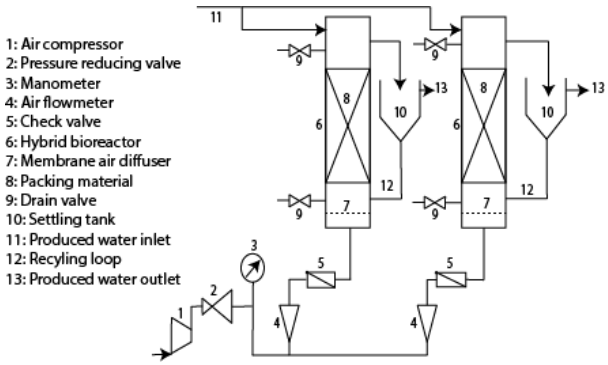

Figure 1. Experimental set-up of the two packed-bed bioreactors.

3. Results and discussion

Concerning the oxygen transfer, results showed that, in the presence of the physico-chemical Newtonian suspension (bentonite suspension) oxygen transfer is reduced compared to clear water at a same packing height and/or air flowrate (figure 2a and 2b). Furthermore, figure 2b shows that the oxygen transfer coefficient increases with the air flowrate (up to 60 %) but also with the packing height. Indeed, the presence of the packing bed is thought to induce a decrease in bubble coalescence, inducing in turn an increase in specific exchange area, thus of the K_La coefficient (up to 30 %).

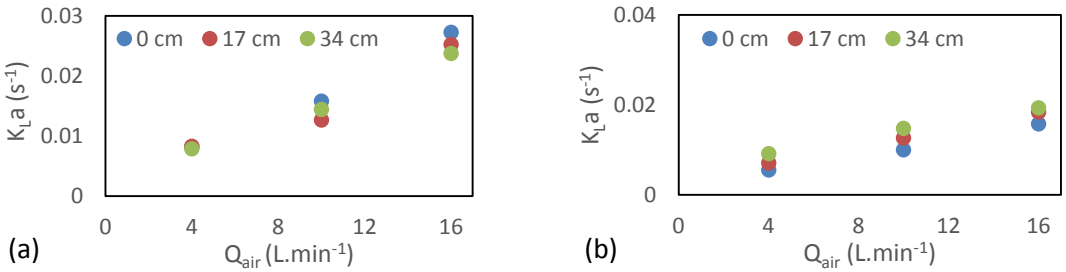

Figure 2. Evolution of oxygen transfer coefficient as a function of air flowrate and packing height for clear water (a) and bentonite suspension (b)

4. Conclusions

Results showed that the presence of the packing bed induce a 52-64 % increase in oxygen transfer for both clear water and bentonite suspension and for an identical energy input (constant air flow rate) due to the presence of the packing bed inducing a decrease of bubbles coalescence along the column. Further studies of oxygen transfer will be performed with a non-Newtonian bioflocs suspension, as well as biotreatment studies to assess the treatment efficiency of such a process for a synthetic produced water. During acclimation test, first results showed that the COD of produced water can be removed with high treatment efficiencies (>95 %).

Use of a filter press as a reactor for heterogeneous Fenton advanced oxidation: Experimental evaluation and CFD simulation

José Luis Trigueros Soto, J. Esteban Durán*

School of Chemical Engineering, University of Costa Rica, San José, 11501, Costa Rica

** Corresponding author: esteban.duranherrera@ucr.ac.cr*

Highlights

- A filter press was used as a reactor for heterogeneous Fenton AOP
- Caffeine degradation of 20% was achieved using 3 g of catalyst and 0.38 L/min
- CFD model provided insight on the hydrodynamics and multiphase interactions inside the reactor chambers

1. Introduction

Fenton process is a well-known technology that has been applied on the treatment of industrial wastewater containing non-biodegradable organic pollutants. However, because of the many drawbacks of conventional homogeneous Fenton process (e.g. sludge generation), considerable effort has been put in the development of heterogeneous Fenton systems. Unfortunately, most of the works has focused on catalyst development [1], and little research has been done on the development of proper reactor configurations for utilizing such heterogeneous catalysts. This study explores the use of a filter press as a heterogeneous catalytic reactor for the Fenton reaction utilizing iron-modified diatomite as catalyst [2]. Experimental data and computational fluid dynamics simulations (CFD) were used to characterize this novel reactor so it can be later scale up for commercial implementation.

2. Methods

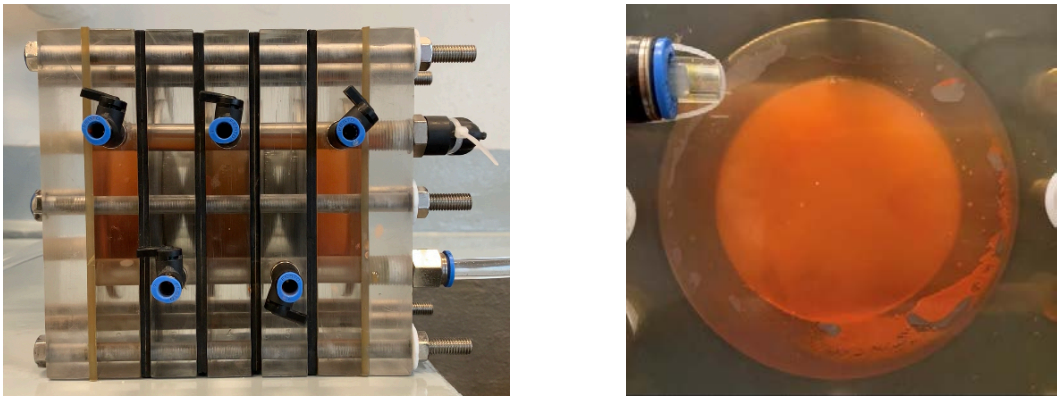
Residence time distribution (RTD) experiments [3] using one filter press frame were performed in order to understand the hydrodynamics inside the reactor and to evaluate the CFD model. NaCl was used as a tracer; after a concentrated salt shot was spiked at the reactor inlet, its concentration was measured at the outlet with a conductivity meter. Also, CFD simulations of this same experiment were performed using Ansys Fluent.

Different experiments were performed to determine the effect of various operational factors (number of filter plates, catalyst load per plate, and flow rate) on the reactor performance. To assess the reactor performance, the degradation of caffeine (as model pollutant) was spectrophotometrically measured under steady state conditions. With these data, it was possible to approximate reaction kinetics and to compare experiments with CFD predictions. A multiphase Eulerian approach was used for the CFD model and transient state simulations were performed using Ansys Fluent.

3. Results and discussion

Using the RTD experiment measurements, it was possible to obtain the *C* and *E* curves to characterize the homogeneous hydrodynamics inside of the filter press. With these experimental data, it was possible to evaluate the steady state simulation. CFD simulations were in close agreement with the experimental curves. Good-mixing patterns are found in the reaction chambers, mainly due to the tangential inlet flow.

Fig. 1 shows a picture of the filter press with five frames, three of them loaded with the iron-modified catalyst. The side view allows seeing particle suspension and mixing promoted by the tangential inlet flow (bottom right-side). Caffeine conversions of 20% were obtained using 3 g of catalyst per chamber and 0.38 L/min flowrate.



(a) (b)

Figure 1. Filter press reactor equipped with five frames, three loaded with iron-modified diatomite (a); side view of reaction chamber

In the congress presentation we will further discuss our experimental and simulation results.

4. Conclusions

A filter press used as a reactor for advanced oxidation processes using the heterogeneous Fenton reaction was characterized and simulated using CFD. The computational model was very useful for providing insight on the multiphase interaction and hydrodynamics inside the reaction chambers. It is recommended to further investigate the suitability of using this system in industrial scale water and wastewater treatment plants.

Highlights

- Organic synthesis pathways by sol-gel process for photocatalysts.
- Ag and/or P25 nanoparticles-doped TiO2 photocatalysts.
- Ozonation and Photodegradation of micropollutants in aqueous media.
- Very high degradation efficiency for all micropollutants in a pilot reactor.

1. Introduction

Pharmaceuticals, personal care products, pesticides and other chemicals used for domestic purpose or industrial or agro-food production are continuously discharged into wastewater and lead to global contamination of the aquatic environment all over Europe [1]. Removal during conventional wastewater treatment is unsatisfactory knowing that only 20 to 50% of micropollutants are removed in current waste water treatment plants [2].

The objective of the AOPTi project is to develop and validate an innovative technology to ensure efficient elimination of different types of micropollutants and toxic effects in waste water. The process is a tertiary treatment process, which can be easily integrated into municipal and industrial WWTPs. It is an economical physico-chemical treatment step after the conventional biological treatment [3]. The process is based on oxidation by ozone and a subsequent photocatalytic treatment. The technology is developed for companies involved in the water purification sector and for companies with toxic effluents loaded with micropollutants. Process parameters have to be determined depending on the type of waste water in order to lead to almost total degradation of all micropollutants and to ensure absence of toxicity of the resulting water. Treated water will be characterized in term of chemical transformation products (TPs) and toxicity.

2. Methods

At the pilot scale (flow rate = 150 L/h), 24 major micropollutants have been chosen to model waste water like pesticides (simazine, diuron, isoproturon, DTT, atrazine, lindane), plasticizers (DEHP, tributyl phosphate), brominated compounds (PBDE), pharmaceuticals (metoprolol, diclofenac, carbamazepine…), industrial chemicals (PFOS), contrast agent (iohexol, iopromide). Their degradations are quantified by GC-MS/MS and UHPLC-MS.

Photocatalysts have been synthesized by organic sol-gel methods [4] and deposited as thin transparent films by spray-coating inside the long alkaline-free tube for a pilot test: pure TiO2 and doped titanium dioxide (with Ag and/or commercial Evonik P25 nanoparticles). Samples were characterized by profilometry, GIRXD, UV-Vis transmission. The absence of leaching was characterized by ICP-AES and MS.

3. Results and discussion

The best photocatalyst for the degradation of the 22 micropollutants is TiO2 doped with 2 wt.% of Ag and 10 wt.% P25. The results are presented in Figure 1, in which the percentage of each micropollutant present in water is shown after different treatments (ozonation, adsorption and photocatalysis). In Figure 1 (on the left):

(i) Chlortoluron and isoproturon are totally degraded by ozonation for 30 min; (ii) atrazine, DDT and BDE are totally disrupted thanks to photocatalysis; (iii) for the other micropollutants, their percentage of degradation evolves from 10% to 90% after a photocatalytic treatment for 6 h.
In Figure 1 (on the right):

(i) Carmabazepine, diclofenac, sulfamethoxazole, clarithromicyn and terburtyn are totally degradated by ozonation for 30 min; (ii) metoprolol is partially degraded after a photocatalytic treatment of 6 h (about 12% remains); (iii) the other pollutants are totally disrupted thanks to the photocatalytic treatment and sol-gel coating.

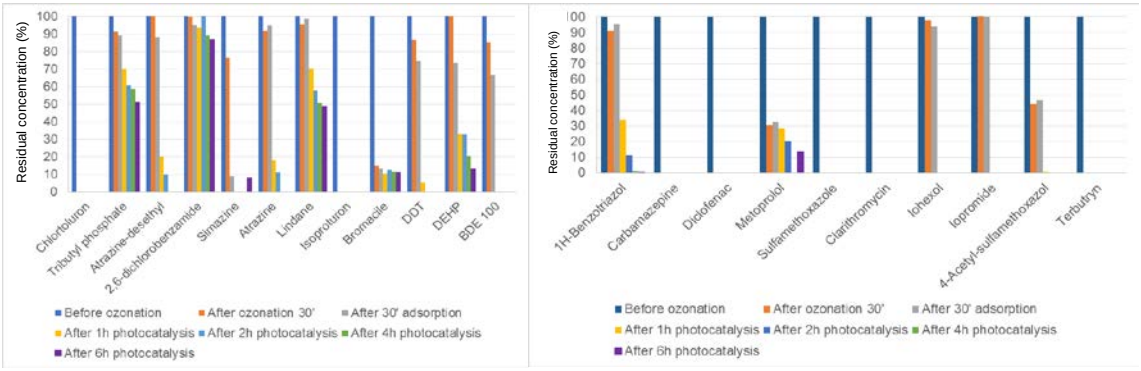

Figure 1. Evolution of 22 micropollutants concentrations during the ozonation and photocatalytic tests.

4. Conclusions

It is concluded that the use of an ozonation treatment followed by a photocatalytic treatment allow disrupting different micropollutants present in waste waters. And the toxicity of waters very strongly decrease during the AOP treatments.

ADSORPTION OF FLUORIDE AND ARSENIC (V) FROM AQUEOUS SOLUTION ON BONE CHAR MODIFIED WITH IRON SULFATE

Diana E. Villela-Martínez, Roberto Leyva-Ramos*, Carolina Vazquez-Mendoza

Centro de Investigación y Estudios de Posgrado, Facultad de Ciencias Químicas, Universidad Autónoma de San Luis Potosí, Av. Dr. M. Nava 6, Zona Universitaria, 78260, San Luis Potosí, S.L.P., MÉXICO.

Highlights

- Arsenic and fluoride can be removed from water by adsorption on bone char modified with iron sulfate.
- Solution pH plays a key role on the adsorption of these anions onto bone char.
- Adsorption of arsenic and fluoride is due to electrostatic interactions and ion exchange.

1. Introduction

The concentration of the arsenic in natural waters varies depending on the presence of arsenic species in the soil [1]. Diverse epidemiological studies have found that the exposure to arsenic via the consumption of drinking water can cause the illness hyperkeratosis and cancer in bladder, lungs, skin, kidneys, liver and prostate. Besides, arsenic exposure has been associated with cardiovascular, pulmonary, immunological, neurological, peripheral vascular and endocrine diseases. The presence of fluoride in drinking water is a crucial issue since both low and high concentrations can affect human health. When the fluoride concentration is less than 0.5 mg/L, the incidence of dental cavities increases considerably; however, consumption of water with fluoride concentrations ranging between 1.5 and 4 mg/L can cause dental fluorosis [2]. Another severe health problem caused by the fluoride excess ingestion is skeletal fluorosis [2].

The removal of these pollutants from drinking water can be accomplished by several separation processes. Nowadays, adsorption is considered one of the best methods available to eliminate arsenic and fluoride from drinking water because it can reduce the arsenic concentration to trace levels and its easiness of operation. However, it is necessary to find novel adsorbent materials, which have a high capacity for adsorbing arsenic and fluoride, and the novel adsorbents have to be inexpensive and efficient.

2. Methods

The granular bone char (BC) used in this work is commercially manufactured from cattle bones. The BC was modified (BCM) by contacting with a solution of $FeSO_4$ and $NH_4Fe(SO_4)_2{\cdot}H_2O$, and the modification procedure was similar to that described by Asfarama et al. [3].

The point of zero charge (pH_{PZC}) and surface charge distribution of the adsorbent was evaluated using the method described in Mendoza-Barron et al. [4]. The textural properties were determined using a surface area and porosimeter analyzer, Micromeritics, ASAP model 2020. A scanning electron microscope JEOL, model JSM-6610LV, was employed to analyze the surface morphology of BCM. The crystalline species were identified by employing an X-ray diffractometer Bruker, model D8 Advance.

3. Results and discussion

The pH_{PZC} of BCM is 10.3 indicating that the surface of the BCM is basic. The XRD analysis confirmed the presence of calcite, hydroxyapatite and sodium sulfate in the BCM. The BCM has an irregular morphology due to the agglomeration of the hydroxyapatite sheets and the iron deposited on the BC. The characterization revealed the BCM is mesoporous, and its surface was basic.

The adsorption of isotherms of As(V) on BC and BCM are depicted in Figure 1, and the adsorption capacity of BCM towards As(V) was enhanced about 10 times at an equilibrium concentration of As(V) of 100 µg/L. As shown in Figure 2, the capacity of BCM was almost enhanced 4 times compared to that of the BC. The effect of the solution pH on the adsorption of fluoride on BCM is also presented in Figure 2, and the capacity of BCM was decreased by raising the solution pH from 5 to 11. Similar behavior was observed for the adsorption of As(V) on BCM. At pH below the pH_{PZC}, the surface of BCM was positively charge due to the protonation of the phosphates and hydroxyl groups contained in the material and As(V) and fluoride were present as anions. Thus, the predominant adsorption mechanism was the electrostatic attraction between the anionic species in solution and the positive charge of the BCM.

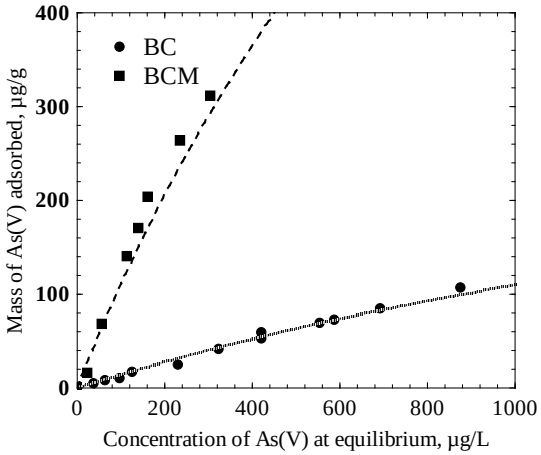

Figure 1. Effect of modification on the adsorption capacity of BC towards As(V) at T = 25 °C

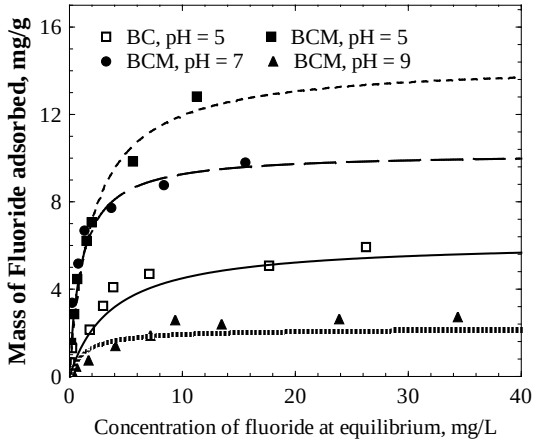

Figure 2. Effect of modification on the adsorption capacity of BC towards fluoride, and effect of pH on the adsorption capacity of BCM at T=25°C.

4. Conclusions

The modification of BC by $FeSO_4$ improved the adsorption capacity of BCM towards As(V) and fluoride considerably. The predominant adsorption mechanism was the electrostatic attraction between the anionic species in solution and the positive charge of the BCM. The adsorption capacity of BCM towards As(V) and fluoride was considerably reduced by increasing the solution pH.

Efficient modification of montmorillonite with Sodium Lignosulfonate to adsorb Cd^{2+}.

Jianzhe Ma[1]

1 School of Chemical Engineering, Nanjing University of Science and Technology, Nanjing 210094, Jiangsu, China.

**Corresponding author: 748447353@qq.com*

Highlights

- Preparation of the modified Na montmorillonite with sodium
- Lignosulphonate-montmorillonite composites increase the heavy metal retention.
- The key parameters that control the chelation are determined.

1. Introduction

The remediation of wastewater containing Cd^{2+} has attracted much attention due to the harm of Cd^{2+} to the environment and human health[1]. Montmorillonite could be a kind of potential low cost sorbent for various kinds of heavy metals since it is abundant in nature and only needs little processing[2]. In spite of the huge amounts of papers reporting the use of untreated clay minerals for the heavy metal retention, the cation exchange capacity is not enough for large-scale applications. In order to increase the selectivity and the adsorption capacity for heavy metal cations, a promising adsorbent, functionalized montmorillonite modified with sodium lignosulphonate (Na-LS) was prepared under mild reaction conditions.

2. Methods

The Na-LS modified Ca-montmorillonite (denoted as NA-LS-MMT) was synthesized by mixing 5.00 g of Ca-MMT and 1.00 g of Na-LS in a 250-mL glass bottle. Then, the pH of the mixture of Na-LS and Ca-MMT suspension was adjusted to 5.0 using 1.0 M NaOH and 1.0 M HNO3 solutions. Afterwards, the suspension was shaken in a water bath shaker at 25 °C for 20 h. Subsequently, the resulting material was collected by centrifugation at 4000 rpm for 10 min, washed out the excess of Na-LS on the surface of Ca-MMT with deionized water for several times, so as to remove excess HA. Finally, the precipitate was air-dried at 45 °C, pulverized to pass through a 200-mesh sieve, and stored for future use.

3. Results and discussion

The batch adsorption experiments illustrated that the removal capacity of Cd^{2+} was crucially dependent on pH and the initial concentration of solution and it was favorable with an increase in pH in acidic solution. The adsorption thermodynamics of Cd^{2+} by NA-LS-MMT showed that the adsorption process was an endothermic reaction. The adsorption kinetics of NA-LS-MMT showed a better fit with the pseudo-second-order model. The adsorption isotherm data of NA-LS-MMT

followed the Freundlich isotherm better, which inferred that more than one kind of adsorption site happened on NA-LS-MMT (ion exchange and chelation).

4. Conclusions

In conclusion, composite adsorptive materials based on lignosulphonate and montmorillonite have been successfully prepared and characterized in depth. The raw montmorillonite and the composites were tested for heavy metal retention. The experimental results indicate the capacity of our composites to chelate heavy metal cations. Indeed, a high affinity between the lignosulphonate and all heavy metal cations was observed.

Ciprofloxacin photocatalytic degradation present in water using MOCVD deposition of TiO_2 and UVA LEDs

Thibaut Triquet[1], Claire Tendero[2], Romain Richard[1], Marie-Hélène Manero[1], Caroline Andriantsiferana[1*]

1 Laboratoire de Génie Chimique, Université de Toulouse, CNRS, INPT, UPS, Toulouse, France; 2 Centre Inter-universitaire de Recherche et d'Ingénierie des Matériaux, Université de Toulouse, CNRS, Toulouse, France

Highlights

- CIP is degraded by photolysis with 365 nm UV but not its intermediates
- Photocatalysis with TiO_2 deposits is efficient to mineralized CIP
- Very low quantities of TiO_2 are sufficient to degrade CIP and its intermediates.

1. Introduction

Nowadays, many toxic molecules particularly micropollutants (pharmaceuticals products such as antibiotics, anti-inflammatory, analgesic) are present in waterways and underground water, causing serious consequences for the environment. Advanced Oxidation Processes (AOP) and particularly the photocatalysis are promising processes to eliminate such molecules by generating powerful and non-selective radical oxidants through UV irradiation of the catalyst (commonly powder of titanium dioxide TiO_2) [1]. When implemented in water treatment process, an expensive filtration step is then necessary in order to remove the catalyst. In this context, a deposit of TiO_2 on a support could propose a competitive industrial implementation. In this study, two different morphologies of TiO_2 coating were studied to eliminate a target antibiotic: the ciprofloxacin (CIP). Both compact and columnar coatings were synthetized using Metal Organic Chemical Vapor Deposition (MOCVD) [2]. The aim of this study is to compare the efficiency of TiO_2 powder and both coatings on the degradation of CIP using LEDs (365 nm).

2. Methods

Analytical grade ciprofloxacin, $C_{17}H_{18}FN_3O_3$ (CIP, 98% purity) and TiO_2 powder (DEGUSSA-P25) were purchased from Sigma Aldrich. The deposition of TiO_2 on glasses surface were obtained by MOCVD [2]. Figure 1 represents the experimental set-up used for all photolysis and photocatalysis experiments. The top of the photo-reactor (130x10x12mm) is a window made of glass which is irradiated by LEDs (365 nm). The loop reactor is composed of the photo-reactor (V=15.6 mL) and a storage tank (V=100mL). The liquid flows via a peristaltic pump at a constant rate (200 mL/min). For each experiment, a 20mg/L CIP solution (100mL) was used and the temperature was maintained at 25°C (±1°C). For photolysis (without TiO_2), two irradiations were studied: 3mW/cm² and 10mW/cm². For photocatalysis (I=10mW/cm²), P25 was added (11.5mg and 5.6mg). In all experiments, an adsorption step of 1.5h was carried out before switching on the UV LEDs during 8h. The liquid samples were collected in the storage tank and filtered through a 0.45 µm membrane before being analyzed. The CIP concentration was

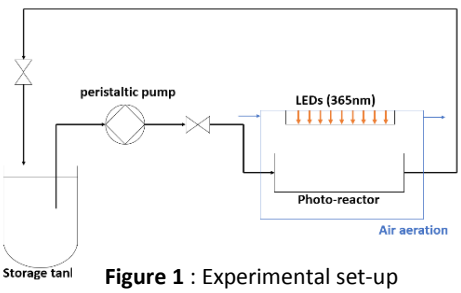

Figure 1 : Experimental set-up

determined by HPLC-UV (detector at 280 nm) and a C18 column. A measurement of Total Organic Carbon (TOC) was implemented before and after treatment.

3. Results and discussion

Figure 2a shows the evolution of CIP concentration for both photolysis and photocatalysis experiments with TiO_2 powder and using glass TiO_2 deposits. Without photocatalyst, after 10h, 75% of CIP is degraded. In presence of a small quantity of TiO_2 powder, 100% of CIP degradation was obtained after 2h (11.5mg) and 4h (5.6mg). After 8h of irradiation, the COT removal is higher than photolysis: 55-61% with P25 powder *vs* 8% without TiO_2. Even if the target molecule is easily degraded by photolysis, the problematic intermediates have not been eliminated [3]. In presence of low amount of catalyst, a total mineralization is not reached for both cases, in agreement with literature [4]. In addition, refractory aliphatic acids with small carbon chain remain generally in solution [4]. Indeed, as shown in Figure 1B, the areas, of the chromatogram pics associated to the intermediates, decrease and after 6h, these intermediates have almost disappeared. The efficiency of TiO_2 deposits is comparable to the one of P25: the amount of carbon removal is 55% for columnar coating and 64 % for the compact one. However, the degradation kinetic is slower than experiments with P25, probably due to a lower surface available for photocatalysis reaction. This could be explained by (i) the inaccessibility of the part of TiO_2 fixed on the glass and/or (ii) a possible recombination of the electron-hole pair due to the low quantity of O_2 near the glass.

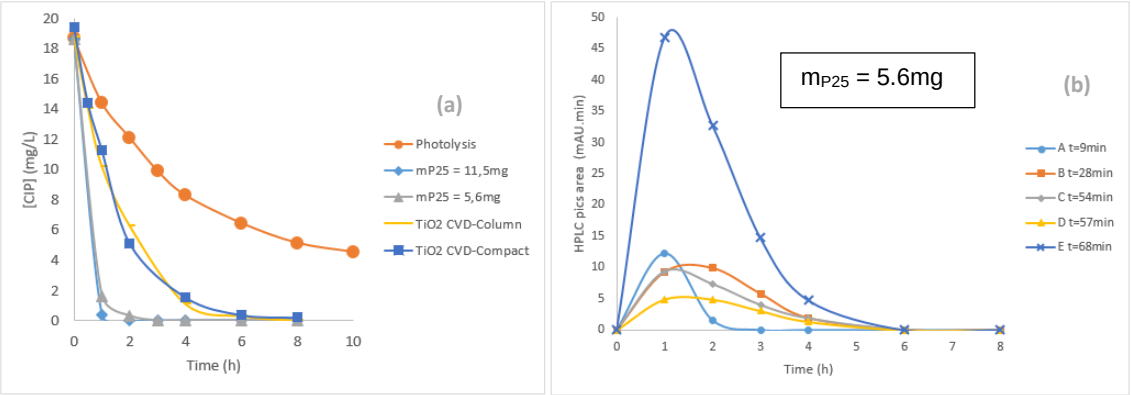

Figure 2 : Photolysis ant photocatalysis kinetics **(a)** and HPLC peaks area of principal intermediates A, B, C, D and E **(b)**

4. Conclusions

It has been shown that ciprofloxacin can directly react with 365 nm UV but a total mineralization of CIP cannot be achieved (8h/8%). In presence of a low TiO_2 powder quantity (11.5mg), photocatalysis is efficient: a total CIP degradation (2h) and a high TOC removal (8 h/61%). Both TiO_2 coatings on glass present the same photocatalytic activities and a total elimination takes 3 times longer than with powder. To go further, another support will be tested: activated carbon (AC). Indeed, previous studies have demonstrated the synergistic effect of AC and TiO_2 [5, 6].

Highlights

- Data Driven Models
- Process control
- Dynamic risk management

1. Introduction

In these last years, on one hand the industrial world experienced radical technological advances in connection with communication and fast-developing societal progresses requiring further research and applications for sustainability and process safety improvement. On the other hand, especially in Europe, a large part of industrial process facilities date back to the 1960's and 1970's. Operational errors are identified as one of the most important causes of the deterioration of the plant equipment, consequently, the operational control is one of the main systems to manage and slow down the effects of aging [1],[2]. This paper reports a first step towards the implementation of a digital twin of an upper tier Seveso plant, which can predict the behavior of the system (failures, risks, malfunctions, errors) in order to operate effectively in safety. The system, based on machine learning algorithms and Bayesian reasoning, learns continuously from the data provided by the physical system. From the operational experience of the coastal storage facility, it is clear how most of the accidental events are due to a wrong arrangement of the valves, to abnormal transfer pressures, to pump failures and pipe deterioration. This paper is focused on building an operational management system, based on the operational instruction, suitable to predict operational errors and accordingly avoiding them and thus protecting asset integrity and improve aging management.

2. Methods

Data-driven modelling can be considered as an approach to modelling that focuses on using the Machine Learning methods in building models that would complement the "knowledge-driven" models describing physical behaviour. Bayesian Networks (BBNs) were proven to be a robust probability reasoning method under uncertainty, providing a tool for incorporating these types of evidence [3]. Starting from the operating manual, various coupled Bayesian Belief Networks were built. So, the asset integrity management was an upper layer which receive and send data to the lower levels. Top events and risk assessment for the case-study of the discharge of diesel oil from a ship moored at the "Beta-ponente" pier were evaluated. The BBNs were then updated, on one hand, with the reliability parameters (results of the inspections or failures on demand - hard evidences) and, on the

other one, with the evidences of the ongoing activities, which represent the likelihood coefficients (soft evidences).

3. Results and discussion

The decision-making network carried out the steps reported in Figure 1.a, which is the BBN structure as learned from the operating manual. The networks were then updated by the data from the plant (state of the valve – open, close, pressure in the pipelines), which are hard evidences and, on the other hand, with the evidences of the ongoing activities, which represent the likelihood coefficients (soft evidences).

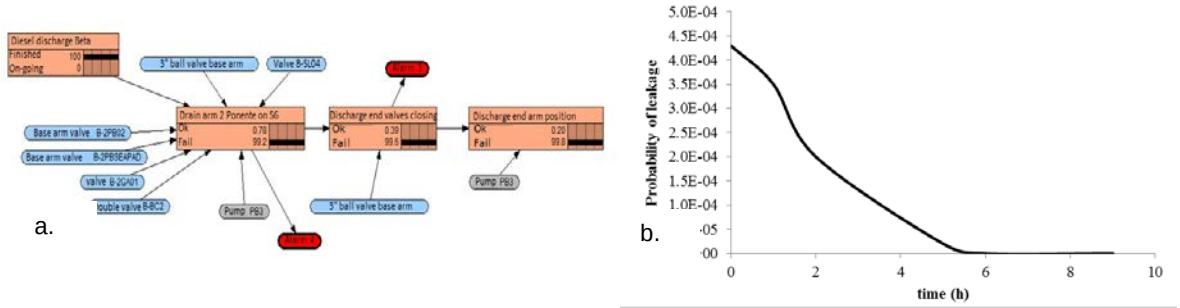

Figure 1. a) Decision-making BBN for ending the diesel discharge from BETA pier; b) "Good" evidences: trend of the posterior probability failures in the collectors pit.

The combination of the risk analysis BBNs and the operational BBNs allowed to manage the whole cycle of the operations, giving, step by step, the updated probability of failure (Figure 1.b). The proposed system represents a tool that in real time allows to manage the operations focusing on safety and, combined with proper advanced analytics applications, allows anticipating what should be done to avoid upcoming incidents.

4. Conclusions

Data Driven BNs are a robust method for modeling complex systems in the probability and uncertainty analysis. The results of the application of the method allow identifying which, among the basic failures, are the most influencing on the probability of the top events occurrence, and therefore, to have a more precise indication on the maintenance priorities. Additionally, the relationship between the risk trend represented as a probability function and the evidences during the operation in progress was analyzed. So both aspects (risk management and operational management) can be improved together.

HazOp Analysis: going beyond traditional goals

Stefano Milanese[1], Andrea Casalli[2], Emanuele Salvador[1*], Michele Piola[1]

[1]*Arthur D. Little S.p.A., Corso Monforte 54, 20122 Milan (Italy)*

[2]*Eni SpA, Piazzale Enrico Mattei 1, 00144 Rome (Italy)*

**Corresponding author: salvador.emanuele@adlittle.com*

Highlights

- Arthur D. Little supported a major refinery in the EPC[1] phase HazOp[2] of a plant
- The review integrated several aspects (asset integrity operations, operating manual, safety report development, etc.) not typically included in such an assessment
- The integrated approach supported the client in managing the multiple activities required for the construction and startup phase, making up for some EPC delays.

1. Introduction

In 2018, risk management consulting firm Arthur D. Little was tasked to carry out a HazOp assessment on the EPC design of a plant in a major Italian refinery. The plant, built according to an innovative hydrocracking process, underwent major modifications: there was considerable interest at site, Business Unit and HQ levels to ensure a thorough HAZOP review.

In accordance with the client, Arthur D. Little's framework included additional discussions and analysis, allowing an early start on future activities such as asset integrity checks, alarm management, layers of protection improvement.

2. Methods

The HAZOP was carried out according to international standards ([1] and [2]). The analysis was «full recording», noting all discussions even when no credible scenarios would emerge. Both consequences on occupational and process safety, asset integrity and on operability have been taken into consideration. Therefore, a comprehensive assessment was carried out not only on Top-Events, but also on other scenarios typically not assessed during a HazOp due to time and resources constraints.

A comprehensive set of recommendations was issued regarding design and instrumentation modification to be implemented prior to start-up. Furthermore, suggested improvement actions gave relevant contribution on the following aspects:

- Asset integrity. Whenever a scenario was at risk of going beyond design conditions, the equipment and lines were included as "Safety Critical Elements" and/or "Operational Critical Elements" (SCE/OCE) to be subject to dedicated monitoring. Arthur D. Little also recommended additional verifications on the asset integrity whenever such alarms were activated (e.g. registration and analysis of integrity operating windows)

[1] Engineering, Procurement & Construction
[2] Hazard & Operability

- Transient states. Startup/shutdown procedures, as well as safety operations such as slow and fast depressurization, were included in the study. These operations typically involve less than 10% of the operating time, but account for more than 50% of incidents ([3]). Through the assessment of these procedures, some deficiencies were noticed and countermeasures were considered and included in the operating manuals
- Operating manuals. They had been issued in preliminary versions: the inclusion in the HAZOP highlighted the need of further integrations
- Training. A specific list of recommendations was drafted to ensure that future training programs included special operations following the activation of alarms or emergency procedures.
- Safety Report. The HazOp assessment was included in the Safety Report, as defined by European legislation Seveso-III-Directive [4]. From it, quantitative risk assessments were carried out on the key scenarios, using the Fault Tree Analysis methodology.

3. Results and discussion

The HAZOP team divided the recommendations in 10 categories and additional 35 sub-categories and conducted the complete follow-up activities.

The assessment was also fundamental to strengthen the interaction between the process design team (a mixed team with internal and external resources) and the production internal team.

4. Conclusions

Throughout this project, the fruitful collaboration between Arthur D. Little and client representatives allowed the HazOp assessment to go beyond its original goals. It can be used as a tool to highlight the “typical” deviations and also to assess and integrate in safety management several other aspects that are not typically considered in the traditional approach.

This way, the client got a head start on follow-up activities, allowing to recover the delay in the EPC process and to start construction activities as planned.

Wood Wastes Valorization Through the Development of Eco-Friendly Cellulose-Based Polyelectrolytes for Potential Industrial Applications.

Kinga Grenda[1,2], Julien Arnold[2], José Gamelas[1], Maria G. Rasteiro[1]

[1,2] University of Coimbra, Chemical Eng. Dep - CIEPQPF, Portugal, [2] AQUA+TECH Specialities, Geneva, Switzerland

*Corresponding author: mgr@eq.uc.pt

Highlights

- Wood wastes valorization, evaluation of influence of lignin content.
- An alternative replacement for traditional, oil-based, synthetic polyelectrolytes
- Environmental friendly cationic bio-polyelectrolytes for industrial applications.

1. Introduction

Low biodegradability, being harsh to the environment or to human health, are just some of the drawbacks when traditional synthetic polyelectrolytes (PEL) are used. There is then, a strong need for the replacement of oil-based materials by more eco-friendly, biodegradable, non-toxic, easy available solutions. Bearing in mind wood is the world's most important source for industrial purposes, not only for furniture or pulp and paper production, but also as a feedstock for the extraction and production of chemicals for various industries [1], the production of cellulose-based added value materials, reusing lignocellulosic wastes, appears as a viable and added value solution to deal with such wastes, and is going to be addressed here, especially production of cellulosic PELs.

Unmodified cellulose presents insolubility in water and in most organic solvents [2]. Consequently, introduction of new functional groups into the cellulose backbone is required to improve the cellulose properties, which will strongly depend on the types of substituent groups and on the degree of substitution (DS), as well as on their distribution in the cellulose backbone. As a result, new applications of cellulose can be achieved with potential replacement of oil-based materials. Regarding PELs production, the path of oxidation/cationization with sodium periodate and Girard's reagent T (GT) was used to produce highly charged water soluble cellulose based PELs. The aim of this study was to establish a procedure to successfully prepare cellulose-based PELs, with diverse DS, starting from more complex cellulosic raw materials with higher content of lignin and lower cellulose content, thus minimizing pre-extraction procedures. Some studies in the literature refer cationization of cellulose [3][4], but, as far as we know, these reactions have never been performed starting from highly complex cellulosic materials, with a low degree of cellulose purity.

2. Methods

Eucalyptus wood chips wastes were submitted to soft kraft pulping using 14 % or 19 % active alkali charges to previously hot water extracted and non-extracted wood. The produced pulps were thoroughly washed with water and dried. Resulting materials were characterized and corresponded to different lignin content based on kappa number, being 10.2 or 13.9 (pulps with hot water pre-

treatment) and 16.1 or 26.7 (pulps without hot water pre-treatment). Highly oxidized pulps were first produced from those raw materials, by oxidation using $NaIO_4$. After 3 h at 75 °C, the dialdehyde cellulosic product (DAC) was filtered and washed with water. The aldehyde content of DAC was determined based on the oxime reaction [5]. Cationization of non-dried DAC followed through reaction with GT in aqueous media [5]. After 1 h at 70 °C the soluble products from reaction mixture were precipitated with isopropanol and centrifuged and the cationic product was oven-dried. The GT/aldehyde ratio varied from 0.975 to 3.9 to obtain bio-PELs with different cationization degree.

3. Results and discussion

Modification of cellulosic-rich materials (obtained from *Eucalyptus* wood wastes with various lignin levels) by introduction of charged quaternary ammonium groups was chosen, as these groups are widely present in successfully applied synthetic PELs. The main objective was to allow the introduction of high content of ionic groups to obtain sufficiently charged cellulose-based materials. The pre-modification to DAC, by selective oxidation with periodate, allowed a high modification degree, since two highly reactive aldehyde groups were introduced per AGU unit. Finally, for the cationization, reaction of DAC with GT was conducted. This treatment allowed to introduce more than one cationic group per AGU unit, yielding highly charged end products which were soluble in in water at room temperature. The charge density and DS of the end product depended on the cationization conditions (temperature, time, pH, molar ratio GT/aldehyde) and also on the properties of the pre-treated cellulosic sample, used as starting material. Typically with the increase of kappa number the DS and charge of PEL decreases when applying the same GT/aldehyde ratio. However, even when using cooked pulp with the highest lignin content (kappa 26.7) and for the lowest GT/aldehyde ratio of 0.975, water soluble PEL with DS of 0.79 and zeta potential of 40±3 mV was produced. When applying the same low GT/aldehyde ratio to the hot water pre-treated/cooked pulp with the lowest kappa of 10.2, the produced PEL exhibited DS of 0.96 and zeta potential of 51±2 mV. Moreover, the obtained PELs, independently of the chemical complexity of raw pulp used in the modification procedure, showed high performance in the treatment of several model coloured effluents and in a real industrial effluent treatment, namely in colour removal.

4. Conclusions

Valorization of cellulosic wastes to provide end products with higher added value (PELs) by applying a sequence of two reactions, oxidation followed by cationization, was investigated. Cellulosic raw materials with different lignin content (kappa number 10.2-26.7) were used. The cationic bio-PELs proved to be efficient biopolymeric flocculation aids in the tested model waters and in an industrial effluent. The developed products can be considered as an alternative to traditional synthetic PELs.

Highlights

- Persistent organic pollutants
- Polybrominated diphenyl ethers
- Environmental pollutants
- Health, safety and wellness

1. Introduction

Persistent Organic Pollutants (POPs) are a group of organic compounds that possess toxic properties, persist in the environment, bio-accumulate through the food web and pose a risk of causing adverse effects on human health and the environment. The European Union (EU) coordinates its Member States being parts to the global Stockholm Convention (SC) on POPs. The Conference Of the Parties (COP) to the SC is cooperating closely with the appropriate bodies under the Basel Convention (BC) on POPs waste to develop guidelines for what is considered Environmentally Sound Management (ESM) of POP containing waste and to establish destruction limits for such wastes. The BC is a global environmental treaty on the control of transboundary movements of hazardous wastes and their disposal. The POPs listed in the two Conventions are to date 26, including some of the PolyBrominated Diphenyl Ethers (PBDEs) (UNEP/POPS/COP.7/INF/27), an important class of Brominated Flame Retardants (BFRs). The last BDE listed in Annex A, to the SC (UNEP/POPS/COP.7/INF/27) in 2017 was decaBDE component (BDE-209) of c-decaBDE with specific exemptions for the production and use. Under the REACH Regulation, decaBDE was registered in 2011 and identified as a Persistent, Bioaccumulative and Toxic (PBT) and very Persistent and very Bioaccumulative (vPvB) substance (UNEP/POPS/COP.7/INF/22).
The Department of Technological Innovations (DIT) of INAIL, for several years, has been part of the Small Intersessional Working Group (SIWG) for the development of Technical Guidelines (TG) on the ESM of wastes consisting of, containing or contaminated with POPs. Considering this background, the present work summarizes and gives an overview on the commercial identity, production and use of POP-BDE potential exposure to them through environmental contamination and, in particular, management of waste contaminated by them, with particular reference to decaBDE. The main purpose of the present work is to make available, in aggregate and immediately usable form, information and useful data for identifying risks to health and the environment and for the adoption of suitable prevention interventions to protect the exposed receptors.

2. Methods

Starting from the regulatory framework with which the European Union implement the provisions of the Convention about substances, mixtures, and wastes, the sound management of the POP waste will be illustrated, including information and data for 1) Articles, waste and recycled materials containing PBDEs; 2) Uses and industrial productions; 3) Life-cycle; 4) PBDEs levels in the waste. Moreover, information about the latest activities on the TGs for the ESM of POP wastes as result of the most recent amendments to the Annexes of the Stockholm Convention will be given. Finally, advices about human health and the environment from the adverse effects of hazardous wastes will be provided.

3. Results and discussion

The production, marketing or use of decaBDE as a substance or as an element of other substances, in mixtures and in products, is set out in Annex XVII (list of limitations), of the REACH Regulation, which prohibits the production and placing on the market of decaBDE as a pure substance from March 2nd 2019. Directive 2011/65/EU (RoHS Directive) restricts the use of PBDEs, as a substance group, in Electrical and Electronic Equipment (EEE). As this directive restricts PBDEs as a substance group, it also applies to decaBDE. The maximum concentration value for PBDEs is 0.1 % by weight (1,000 mg/kg) in homogeneous materials. According to Annex VII of Directive 2012/19/EU on Waste Electrical and Electronic Equipment (WEEE), on the selective treatment of materials and components of EEE, plastics containing BFR have to be removed from any separately collected WEEE. If the total bromine concentration is below 2,000 mg/kg, it is considered that the treatment operator complies with the de-pollution requirements for BFR according to the WEEE Directive. Regarding ESM for WEEE plastics, there is a risk that contaminated recycles enter in the product cycle. The risk can be minimized as far as possible through a higher degree of separation of plastic WEEE containing decaBDE. The current POP Regulation does not yet include decaBDE, but in the specific TGs developed under the Basel Convention it was proposed to include deca-BDE for the sum of POP-BDEs, already limited to 1000 mg/kg

4. Conclusions

In waste streams are still introducing goods containing C-decaBDE. Emissions of c-decaBDE to the environment occur at all its life-cycle stages, but they are assumed to be the highest during service-life and during the waste phase. Production and use of c-decaBDE is decreasing but still ongoing in significant quantities. The production and use of the other commercial PBDEs has been stopped in the first decade of the 2000s at a global level. As a consequence, levels in products and wastes, as well as recycled (secondary) materials, are expected to decrease continuously in the coming years. In addition, an extensive POPs contamination of sites in Countries with transition or development economies has recently emerged. In these Countries POPs wastes are frequently exported, without being adequate capacity to manage them in safety, also due to the scarcity of the controls and to the inadequate implementation of the Conventions [1, 2].

Catalytic Wet Air Oxidation of Effluent Containing 2, 4, 6-Trichlorophenol Using Bimetallic Feru/Carbon Xerogel Catalyst.

Manjari Kumari, Anil K. Saroha*

Department of Chemical Engineering, Indian Institute of Technology, Delhi, India

**Corresponding author: aksaroha@chemical.iitd.ac.in*

Highlights

- A low-cost carbon xerogel was prepared using resorcinol, tannic acid and formaldehyde.
- Iron-ruthenium/carbon xerogel catalyst was used in CWAO of TCP solution.
- A TCP and COD removal efficiency of 95.82 % and 93.14 % respectively were obtained.

1. Introduction

Chlorophenols are a group of toxic and recalcitrant compounds commonly found in the effluent of industries such as pesticides, petrochemical, pulp and paper, dye, olive oil, pharmaceuticals, etc. (Olaniran & Igbinosa, 2011). The permissible limit of chlorophenols in drinking water is 10 µg/L (Pera-Titus et al., 2004). Therefore, it is mandatory to treat industrial effluent containing chlorophenol before its discharge in the environment. Advanced oxidation processes have proved to be a successful method for the treatment of high strength and toxic effluents. Wet air oxidation involves oxidation of pollutant at elevated temperature and pressure conditions but oxidation in presence of suitable catalyst, catalytic wet air oxidation (CWAO), can be performed at mild conditions of temperature and pressure leading to a substantial reduction in capital and operating costs. The use of carbon materials (activated carbon, carbon nanotubes, carbon gels, etc.) as catalyst support is advantageous as they are prepared from natural materials, possess high specific surface area and the precious active metals impregnated on the carbon support can be recovered from the spent catalyst (left over ash) by its oxidation in presence of oxygen (air). Carbon gels, commonly prepared from natural materials, are advantageous as they possess high surface area & pore specific volume, mechanical strength and are stable at high temperatures. The bimetallic catalysts, often referred to as 'alloy catalysts', show synergistic effect. The addition of a small amount of the second metal to a monometallic catalyst causes better dispersion of the metal particles and reduces the size of metal particles on the support surface resulting in an increase in active specific surface area of the catalyst which leads to better activity (Garrido-Ramirez et al., 2016). Thus, in the present study, the carbon xerogel (MCXO) based bimetallic (FeRu/MCXO) catalyst was prepared and used in the CWAO of an aqueous solution containing 100 ppm 2, 4, 6-trichlorophenol (TCP).

2. Methods

Xerogel was prepared by a sol-gel reaction of a natural precursor tannic acid (67 %), resorcinol (33 %) and formaldehyde. The water content of the wet organic gel was exchanged using a solvent (such as t-butanol, acetone, toluene and ethanol) of lower surface tension. Later, the carbon xerogel was modified using an acid (such as o-phosphoric acid, nitric acid and sulphuric acid) in order to enhance its surface properties. The active metals Fe and Ru were impregnated on the surface of the xerogel support material by co-impregnation method. The catalyst was characterized using various techniques such as BET, XRD, SEM & TEM analysis, FTIR, TGA, etc. The CWAO of TCP was carried out and the results were interpreted in terms of TCP and COD removal efficiencies. The effect of various operating parameters such as metal loading, initial pH of TCP solution, air flow rate, catalyst dose, reaction temperature and operating pressure on TCP and COD removal efficiencies was studied. The kinetics of the degradation of TCP was studied. The reusability and stability of the bimetallic catalyst was also studied.

3. Results and discussion

A low-cost carbon xerogel was prepared by partially replacing the costly resorcinol with a low-cost precursor tannic acid. The solvent exchange with t-butanol conserved the porosity of the xerogel and modification with o-phosphoric acid induced oxygenated functional groups on the surface of the carbon xerogel. The bimetallic catalyst (FeRu/MCXO) having a high specific surface area (562 m^2/g) and pore specific volume (1.51 cm^3/g) showed the maximum TCP and COD removal efficiency of 95.82 % and 93.14 % respectively at the optimum value of operating parameters. The optimum value of metal loading, initial pH of TCP solution, air flow rate, catalyst dose and operating pressure for FeRu/MCXO catalyst were found to be 4 wt. % iron and 0.3 wt. % ruthenium, 4, 3 L/min, 0.8 g/L and 1 bar respectively at 75 °C. The kinetics of the degradation of TCP by CWAO was studied and it was found that the reaction followed pseudo-first order kinetics with respect to the concentration of TCP in the aqueous solution. The FeRu/MCXO catalyst was found to be stable with a marginal decrease (3.11 %) in its activity after third reuse of the spent catalyst.

4. Conclusions

A novel bimetallic FeRu/MCXO catalyst was prepared having high specific surface area (562 m^2/g) & poro specific volume (1.51 cm^3/g). The CWAO of aqueous solution containing TCP resulted in good removal of TCP (TCP-95.82 % & COD-93.14 %) at the optimized value of operating parameters. The catalyst was found to be stable and suitable for use in continuous processes.

**Corresponding author: simeone.chianese@unicampania.it*

Highlights

- Electrochemical removal of humic acids was investigated.
- The effects of NaCl and NaClO4 electrolytes were studied.
- Humic acids removal was faster in the presence of NaCl.

1. Introduction

Humic acids (HA) are the soluble fraction of humic substances at alkaline and neutral pH and are produced by biotic and abiotic degradation of dead organic matter. HA have a broad molecular weight distribution and contain several functional groups such as aromatic, carboxylic and phenolic groups [1]. Owing to their solubility, HA are common water contaminants, hence procedures for their removal from water have been extensively investigated [2,3]. Among them, electrochemical treatment is very promising because of its efficiency and ease of use. Depending on the operating conditions and the type of pollutant, a diversity of reactions can occur at the electrodes and in solution [4]. Recently, the removal by electrocoagulation of humic acids (HA) has been analyzed using aluminum as sacrificial electrode, indicating that HA removal rate increased with ionic strength and electric current density [5].

2. Methods

In the present work, the electrochemical treatment of HA solutions has been investigated in the presence of different electrolytes (i.e. NaCl and $NaClO_4$) using a platinum-coated titanium anodic electrode and a graphite cathodic electrode, under amperostatic conditions. Investigations were carried out with the following experimental conditions: HA concentration = 50 mg L^{-1}; salt concentration = 0.08 mol L^{-1}; current density = 6.12 A m^{-2}; ΔV = 5.0 V; pH =7.0. HA concentration was measured by using spectroscopy technique.

3. Results and discussion

Fig. 1 shows the time-dependence of humic acids concentration, as determined by the absorbance signal at 320 nm, in the presence of NaCl and $NaClO_4$, respectively. As it can be seen, during the electrochemical process, HA concentration rapidly decreases with both electrolytes; interestingly, when NaCl is used, HA concentration reaches a stable value in about 2 h. The results indicate that

humic acids removal is faster in the presence of NaCl, probably as a consequence of chlorine formation by oxidation of Cl^-, which acts as oxidizing agent for HA. The UV-Vis spectra of HA at time zero and at the end of the electrochemical treatment are reported in Fig.2. The figure shows a marked blue shift of HA spectrum with both electrolytes, which is probably associated with the reduction of the conjugation of HA aromatic groups during the oxidation process. Detailed products characterization of the electrochemical treatment of HA is under investigation.

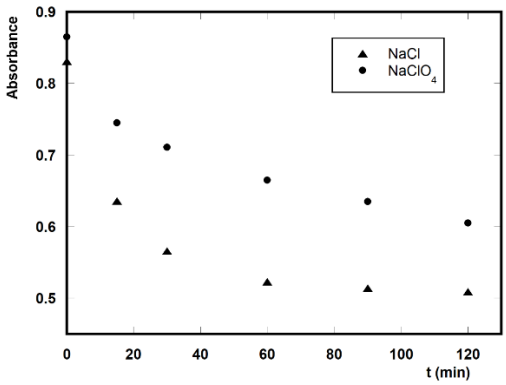

Figure 1. Time-dependence of HA concentration in the presence of different electrolytes; λ = 320 nm, [HA] = 50 mg L^{-1}, salt concentration = 0.08 mol L^{-1}, current density = 6.12 A m^{-2}, ΔV = 5.0 V, pH =7.0.

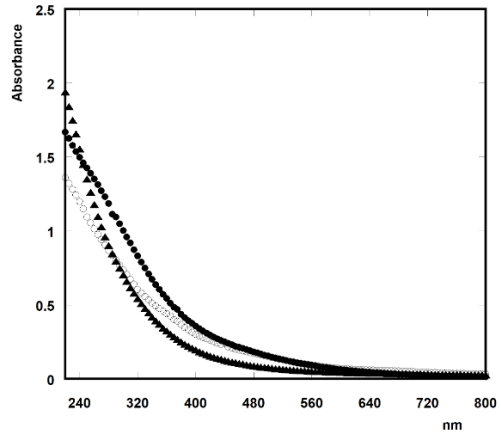

Figure 2. UV-Vis spectra of HA at time zero (●), in the presence of 0.08M NaClO4 at 2h (○) and in the presence of 0.08M NaCl at 2h (²); [HA] = 50 mg L-1, current density = 6.12 A m-2, □V = 5.0 V, pH =7.0.

4. Conclusions

The effects of NaCl and $NaClO_4$ electrolytes on HU removal from wastewater was investigated. Findings highlighted that with both electrolytes HA concentration rapidly reduced. In particular, humic acids removal was faster in the presence of NaCl. A blue shift of HA spectrum was observed probably due to the reduction of the conjugation of HA aromatic groups during the oxidation.

Highlights

- Electrochemical oxidation of triclosan in aqueous phase is investigated.
- The influence of initial concentration of triclosan, supporting electrolyte and presence of copper in the solutions has been studied.
- The formation of highly toxic PCDD/Fs congeners within the oxidation is assessed.

1. Introduction

Triclosan (TCS), 5-chloro-2-[2,4-dichlorophenoxy]-phenol, classified as a PPCP (pharmaceutical and personal care product) is widely used as a broad-spectrum antimicrobial and antifungal agent in many professional and personal products (deodorant soaps, toothpaste and mouthwash, plastic consumer goods…) [1]. Triclosan and related compounds are characterized by acute resistance to biodegradation, environmental persistence and high lipophilicity. Therefore, in order to protect the environment from the harmful effects caused by the discharge of wastewater containing triclosan, the application of efficient technologies able to mineralize this type of compounds becomes crucial. Advanced Oxidation Processes (AOPs) have emerged as powerful alternatives to remove many chlorinated organic compounds. Electrochemical oxidation, among them, has been successfully applied to remediate aqueous solutions containing TCS [2]. However, powerful oxidation media can favor the formation of minor and more harmful byproducts such as polychlorinated dibenzo-p-dioxins and furans (PCDD/Fs); thus, the traceability of the formation of this kind of by-products during the oxidation treatment has become an issue of concern [2,3]. In this work, the influence of the supporting electrolyte (NaCl and Na_2SO_4), the presence of copper in the aqueous solution and the initial concentration of TCS on the potential formation of PCDD/Fs has been studied. Finally, based on previous literature, a reaction mechanism describing the formation of PCDD/Fs from triclosan solutions in aqueous and gas phase is proposed.

2. Methods

The electrochemical oxidation experiments were carried out in batch mode in a laboratory system with a labELOX 1/176 cell (APRIA Systems S.L.). The cell consisted of two regular electrodes: BDD as anode and titanium as cathode. An initial volume of 1 L was treated. Initial concentrations of TCS were 10, 100 and 150 mg L^{-1}, and the current density applied was 6, 60 and 90 A m^{-2}, respectively. The concentration of the two supporting electrolytes was 56.34 mM NaCl and 21.11 mM Na_2SO_4. In the solutions were the copper salt was present, its concentration was 39.63 mg L^{-1} (10 mg L^{-1} of Cu). TCS removal has been quantified in a HPLC using the original standard. PCDD/Fs analysis have been performed following USEPA 1613 method by high-resolution gas chromatography coupled with high-resolution mass spectrometry (HRGC-HRMS) [3].

3. Results and discussion

Complete degradation of TCS was achieved after 2, 3 and 4.5 hours when its initial concentration was 10, 100 and 150 mg L^{-1}, respectively. Total concentration of PCDD/Fs achieved values up to 3.68 x 10^2, 3.42 x 10^4 and 1.64 x 10^5 pg L^{-1} when the initial concentration of TCS was 10, 100 and 150 mg L^{-1}, respectively. The results confirmed the dominance of tetrachlorodibenzo-p-dioxin (TCDD) in the homologue profile of the total PCDD/Fs, reaching values up to 1.11 x 10^5 pg L^{-1} in samples with initial TCS concentration of 150 mg L^{-1} and NaCl as electrolyte (Figure 1 (a)). The International Toxicity Factor (I-TEF), as expected, increased with the initial concentration of TCS from 4.8 to 379.7 pg L^{-1} for 10 and 150 mg L^{-1} TCS samples, respectively. This value is much higher than the maximum contaminant level established by the USEPA for drinking water, 30.0 pg L^{-1}. However, the presence of copper in the oxidation medium tends to reduce I-TEF values.

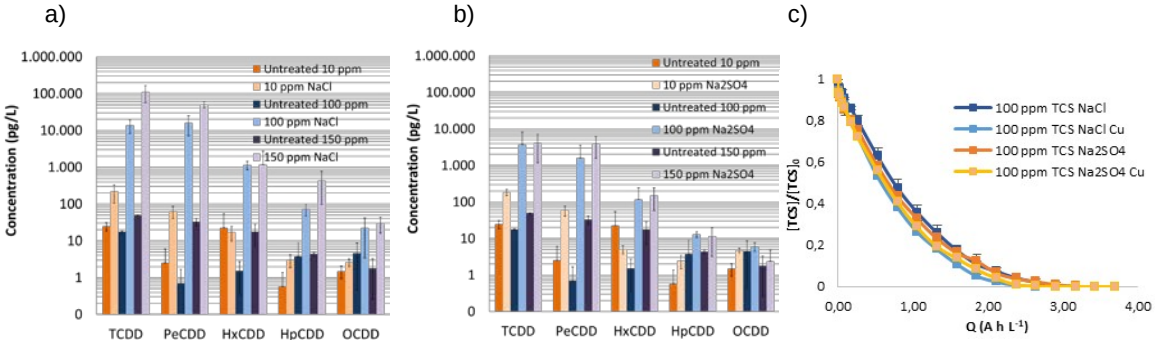

Figure 1. PCDD concentration after electrochemical oxidation of 10, 100 and 150 mg L^{-1} of triclosan using NaCl (a) and Na_2SO_4 (b) as supporting electrolytes; c) Influence of the supporting electrolyte and the presence of copper in the aqueous medium on the removal of triclosan with the specific charge.

The presence of copper did not show influence on the TCS degradation rate (Figure 1 (b)); however, the total concentration of PCDD/Fs was reduced by 55.26 % and 18.06 % for NaCl and Na_2SO_4 as supporting electrolytes, respectively. Finally, a detailed reaction mechanism describing the formation of PCDD/Fs from triclosan was proposed and supported by the experimental results [4,5].

4. Conclusions

Electrochemical oxidation allowed complete elimination of triclosan in all experiments. However, it has to be highlighted the increased concentration of PCDD/Fs in comparison with the untreated samples, specially the concentration of TCDD homologues. The comparison between the results obtained using two broadly applied electrolytes, NaCl and Na_2SO_4, emphasizes the role and importance of the chloride concentration on the formation of chlorinated byproducts during the electrochemical oxidation of triclosan; when NaCl was used as supporting electrolyte, I-TEF levels increased from values closed to zero for the untreated solution to 379,7 pg L^{-1} when complete removal of 150 mg L^{-1} triclosan was achieved. Finally, the reaction pathway leading to the formation of PCDD/Fs from TCS oxidation has been proposed.

Numerical studies of CO_2 capture by enhanced weathering of carbonate minerals

Lei Xing, Aidong Yang, Richard Darton

Department of Engineering Science, University of Oxford, Parks Road, Oxford, OX1 3PJ, United Kingdom

**Corresponding author: aidong.yang@eng.ox.ac.uk*

Highlights

- Weathering of calcite is used to model CO_2 capture in an aqueous environment.
- Intrinsic kinetics of calcite dissolution is coupled with mass transfer processes.
- Passive absorption and reinforced bubbling of CO_2 were numerically compared.
- Mass transfer of CO_2 from air to aqueous solution can be the rate-limiting step.

1. Introduction

The target of restricting global mean temperature rise to around 1.5 C will require draw-down of some 810 Gt CO_2 from the atmosphere by 2100 according to climate models [1]. The capture and storage of atmospheric carbon dioxide could thus become a very large industry later this century. Various methods and technologies have been suggested for this process, and have been recently reviewed [2,3]. The weathering of natural minerals like carbonate and silicate offers one possible route. The chemistry involves dissolution of CO_2 in water and subsequent reaction to bicarbonate and carbonate as balancing cations are solubilised from the rock. However, in order to play a significant role, this very slow natural process needs to be dramatically accelerated, affordably and without causing unacceptable environmental damage. A key aspect of designing and assessing a suitable reaction scheme and equipment is to identify the rate-limiting step in this three-phase system, so that further enhancement measures can be introduced accordingly.

2. Methods

In this work, we consider two reactor schemes with respect to gas supply. One uses passive diffusion of CO_2 at the air-water interface, the other is by active supply through gas bubbling. The three-phase bubble reactor provides greater gas/liquid contact area, and higher rates of CO_2 absorption [4]. The effect of mass transfer rate of CO_2 from atmosphere to aqueous solution on the overall reaction rate was numerically studied for the two schemes. Calcite ($CaCO_3$) is used as the model mineral for the calculations due to its relatively fast weathering rate. The reaction scheme and all chemical rate constants are taken from the work of Plummer et al [3].

Calcium ions are formed at the surface of the mineral particles, at a rate which depends on the composition of the bulk water phase. CO_2 which is transferred into the water through the gas/liquid interface is ionized to bicarbonate and carbonate. The kinetic scheme accounts for the presence of H^+, OH^-, HCO_3^-, CO_3^{2-}, in addition to physically dissolved CO_2 and Ca^{2+}. A charge balance is maintained. Diffusion of CO_2 from gas to liquid takes account of resistance in both gas and liquid phase, using the two-film theory.

3. Results and discussion

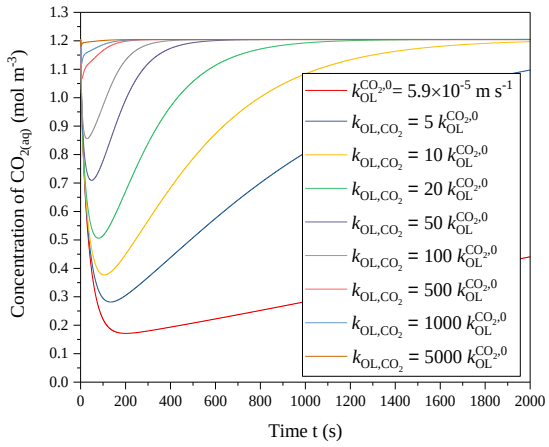

Figure 1. Dependence of $CO_{2(aq)}$ conc on k_{OL,CO_2}

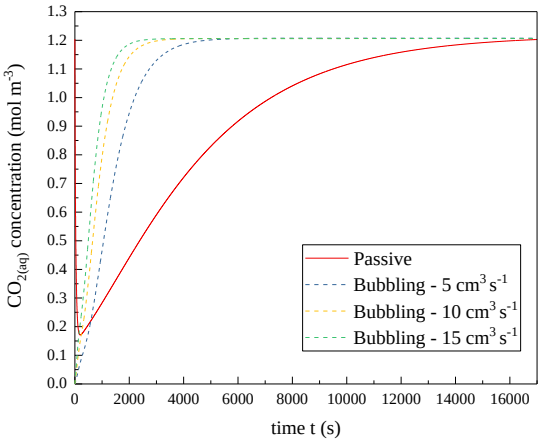

Figure 2. Effect of gas rate on $CO_{2(aq)}$ conc

Fig. 1 shows the concentration of aqueous CO_2 in the passive diffusion case. As the mass transfer coefficient increases, the aqueous CO_2 concentration approaches the equilibrium level at a steadily faster rate. This suggests that in this case the rate of absorption of CO_2 is the limiting factor, and not the rate of dissolution of mineral. The grinding of rock to create small particles, and thus high particulate surface area is an expensive process. It is thus important to establish, for any particular mineral and reactor configuration, what particle size is required. Fig. 2 compares the two CO_2 supply modes, passive diffusion and bubbling, and shows, as expected that gas bubbling improves the mass transport rate and leads to a faster process. In practice, given the very large scale of reactors that will be needed, the improved rate of absorption will have to be balanced against the extra cost of air compression for bubble injection. Further calculations, including a trickle-flow scheme that will be matched with experiment, are planned.

4. Conclusions

Calculations of CO_2 mass transfer rates in the absorption of atmospheric CO_2 during mineral weathering show that in passive diffusion it can be the rate-limiting step, rather than chemical reaction or mineral dissolution. An enhanced weathering reactor with air bubbling significantly improves the mass transport, but at the cost of greater cost and complexity. The mass transfer and mineral reaction model developed will be useful for scoping other, novel reactor designs.

Preparation of Carbon Nitride Composite and Its Application in Electrochemical Detection.

Chenglong Chen, Wu Lei*

School of Chemical Engineering, Nanjing University of Science and Technology, Nanjing 210094, Jiangsu, China.

**Corresponding author: leiwuhao@njust.edu.cn*

Highlights

- Carbon nitride quantum dots is used to prepare electrochemical sensors for the determination of ascorbic acid.
- Optimized various factors affecting the electrochemical performance of the electrode to achieve the best detection results
- The proposed ascorbic acid sensor has outstanding sensitivity, wide linear range and low detection limit.

1. Introduction

Ascorbic Acid (AA) is an important antioxidant widely present in biological systems, which is an essential substance to maintain normal physiological function of human body. Abnormal contents of AA may cause several symptoms, including fatigue, infertility and scurvy. Therefore, it is imperative to develop a fast and sensitive analysis approach for AA quantitative determination.[1-6]

2. Methods

Carbon nitride quantum dots (CNQDs) were prepared by hydrothermal method using sodium citrate and urea as raw materials, and characterized by transmission electron microscopy (TEM) and fluorescence spectroscopy. Then, the electrochemical sensor (CNQDs/PEDOT/GCE) for the determination of ascorbic acid was prepared by in situ polymerization. The cyclic voltammetry was used to study the effect of ascorbic acid on the electrode electrochemical behavior.

3. Results and discussion

The optimum material ratio and the best experimental environment were obtained by the optimization experiment. The CVs of AA acquired at CNQDs/PEDOT/GCE were shown in **Fig. 1**. Under the optimal experimental conditions, the anodic peak current exhibited a linear response to the increasing concentration of AA in the range of 50-1500 μM and the linear equation can be elucidated as: $I_{pa,\ AA}$(μA) = 0.0185 C_{AA} (μM) - 0.1019 (R^2 = 0.9999). The limit of detect (LOD) were calculated as low as 6.38 μM for AA (S/N = 3).

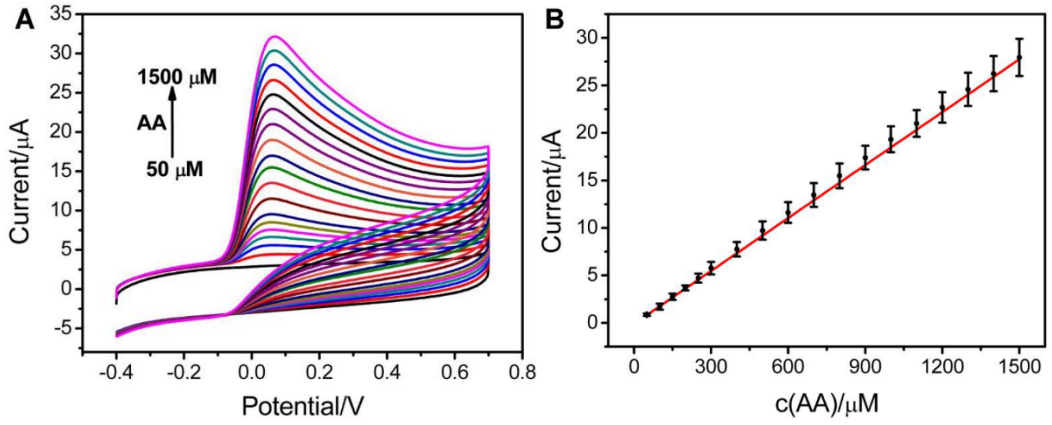

Figure 1. A) CVs at CNQDs/PEDOT/GCE in 0.2 M PBS (pH =7.4) containing different concentrations of AA from 50 μM to 1500 μM. D) The linear relationship between anodic peak current and the concentration of AA.

4. Conclusions

The results show that the modified electrode has many advantages, such as outstanding sensitivity, wide linear range, low detection limit and so on. Based on the excellent properties of carbon nitride quantum dots, a new type of electrochemical sensor was established to determine the concentration of ascorbic acid in human body.

An Novel Electrochemical Sensor Based on ErGO/MWCNTs to Detect 2, 4-dinitroanisole.

Shasha Feng, Yong Ding, Wu Lei*

School of Chemical Engineering, Nanjing University of Science and Technology, Nanjing 210094, People's Republic of China

**Corresponding author: leiwuhao@njust.edu.cn*

Highlights

- Detection of 2, 4-dinitroanisole by the electrochemical method for the first time.
- Construct a sensor based on electrochemical reduced graphene oxide–multiwalled carbon nanotubes nanocomposite.
- Facile, cost-effective, and rapid manufacturing route.

1. Introduction

2, 4-Dinitroanisole (DNAN) as a low sensitivity melt-cast formulation, is a promising replacement for 2, 4, 6-trinitrotoluene (TNT). It is reported that DNAN is metabolized to 2, 4-dinitrophenol (2, 4-DNP) in the body, which is a chemical with high acute and chronic toxicity[1, 2]. Graphene is a two-dimensional material with a single layer of carbon atoms tightly arranged honeycomb lattice[3]. The conductivity of the electrochemical reduced graphene oxide (ErGO) is higher than that of graphene oxide[4]. Carbon nanotube is a kind of one-dimensional material, which is made of single-layer graphene reel[5]. The combination of the two materials not only preserves their respective properties, but also increases the energy transfer force of the electron and the binding sites to the electrically active substance[6]. The synergistic effect of ErGO and multiwalled carbon nanotubes (MWCNTs) obviously increases the catalytic activity for DNAN. In this work, a novel electrochemical sensor was developed based on ErGO/MWCNTs to detect DNAN by linear sweep stripping voltammetry (LSSV).

2. Methods

The prepared GO/MWCNT/GCE was electroreduced to obtain ErGO/MWCNTs/GCE by cyclic voltammetry. Sensitivity of the sensor was quantified through the LSSV method using electrochemical workstation. Measurements were taken at a constant potential of -0.4 V and in 0.1 M PBS (pH = 7.0, containing 0.1 M NaCl).

3. Results and discussion

Experimental conditions are optimized, such as accumulation time and accumulation potential. Under optimal experimental conditions, as depicted in Figure 1, the current linearly increased with incremental DNAN concentration from 0.1 to 30 μM, and the limit of detection (LOD) was calculated to be 0.084 μM（S/N = 3）.

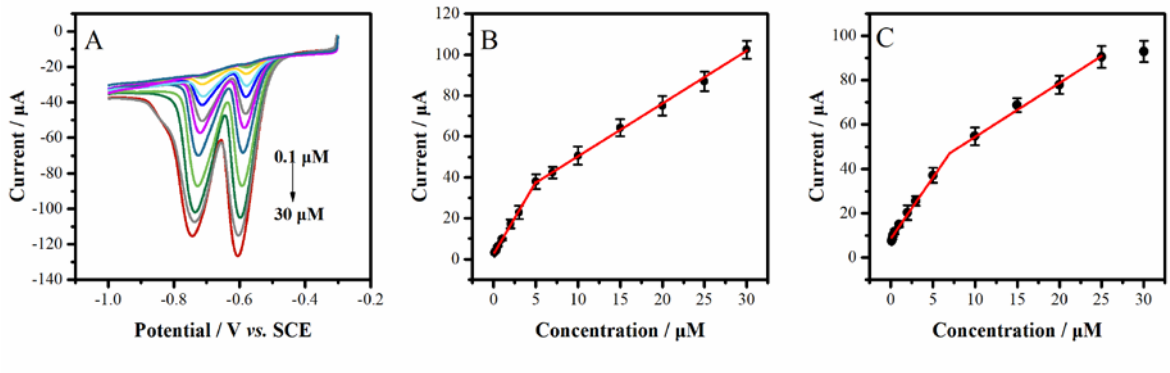

Figure 1. LSSV curves of the sensor in the presence of DNAN with different concentrations (A). The calibration curves for DNAN detection about peak α (B) and peak β (C). DNAN concentrations: 0.1, 0.2, 0.3, 0.5, 1.0, 2.0, 3.0, 5.0, 7.0, 10.0, 15. 0, 20.0, 25.0, 30.0 μM.

4. Conclusions

A novel efficient electrochemical sensor, ErGO/MWCNTs/GCE, was successfully constructed to analyse the low concentration levels of DNAN. The sensor got high sensitivity due to the excellent catalytic activity of ErGO/MWCNTs nanocomposite. The sensor was successfully applied to determine DNAN in water samples with the advantages of anti-interference performance, good reproducibility, and acceptable stability.

Incipient Fault Detection Based on Exergy Efficiency and Support Vector Data Description.

Mengfei Zhou, Haitian Pan, Zhihong Liu

College of Chemical Engineering, Zhejiang University of Technology, Hangzhou, Zhejiang 310014, PR China

**Corresponding author: htpan@zjut.edu.cn*

Highlights

- Exergy-data abstraction using mutual information.
- Reduce complexity of the SVDD model based on process exergy efficiency
- Detect incipient faults with different severity based on EESVDD

1. Introduction

In the paper, a novel fault detection method based on exergy efficiency and support vector data description (EESVDD) for incipient fault is proposed. The complexity of the SVDD model is reduced based on process exergy-data abstraction using mutual information (MI) method. Additionally, the proposed method presents great fault detectability and isolability and can detect incipient faults with different severity and indicate the evolution direction of faults. The effectiveness of the proposed method is illustrated by an industry distillation column system.

2. Methods

Exergy loss is the opposite of exergy efficiency, which represents the loss of process effective energy. Actually, the concept of performance degradation is intrinsically included by exergy, which can be used to explain the performance changes of incipient fault processes. In our work, MI is used to get the correlation between measured variables and exergy efficiency. Generally, MI can be composed of marginal entropy and joint entropy, it is possible to use K-nearest neighbor statistic to estimate entropy and then to obtain MI value. It is meaningful to compare which of the measured variables contain more information of exergy efficiency. After the MI values are obtained between each measured variable and the exergy efficiency, a set of measured variables that are most relevant to exergy efficiency is identified for improving the validity of datasets according to the cumulative percent mutual information (CPMI).

And then, the corresponding SVDD state models can be established with the feature sample sets of different fault states. The main idea of SVDD is to find a sphere region that contains most of the target samples with the smallest volume. Given a train set $\mathbf{x}_i \in R^{N\times m}\ \ (i=1,2,\ldots,N)$, where N is the number of samples. The radius minimization problem of the sphere can be formulated as the following quadratic programming problem with inequality constraints.

$$\min F(R,\mathbf{a},\xi_i) = R^2 + C\sum_{i=1}^{N}\xi_i \tag{1}$$

$$\text{s.t.}\left\|\mathbf{x}_i-\mathbf{a}\right\|^2 \le R^2+\xi_i \qquad (\xi_i \ge 0) \tag{2}$$

where, C is a penalty factor and ξ_i are the slack variables. The sphere can be described by radius R and center $\mathbf{a}$. The fault can be detected according to the principle of minimum relative distance and identify qualitatively the severity of the fault.

The overall framework of the proposed method is shown in Figure 1.

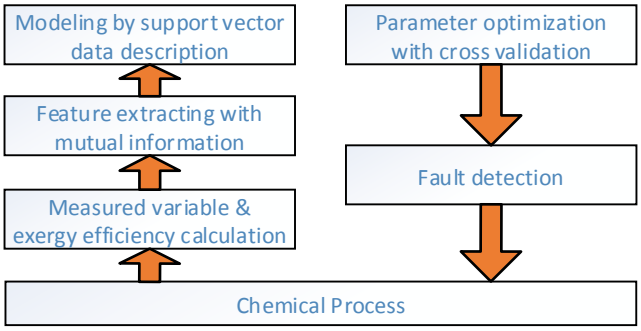

Figure 1. The overall framework of the proposed algorithm

3. Results and discussion

The proposed method has been illustrated by an industrial distillation process, which consists of two distillation columns which is used to separate propane and propylene, as shown in Figure 2. In this case, the faults are generated by stepping the fouling factor of the shell and tube side. And the different severities of fault can be also obtained. For the sake of convenience, the fault detection rate (FDR) is used to quantify the detection performance for different fault states. The FDRs of SVDD, principal component analysis and SVDD (PCA-SVDD), EESVDD in different incipient fault states have been compared in Table 1. From Table 1, it is obvious that the EESVDD method is better than the other two methods in the FDRs of three fault states. The exergy-data abstraction based method draws on the process physical and thermodynamic knowledge, and reveals the performance degradation information of process.

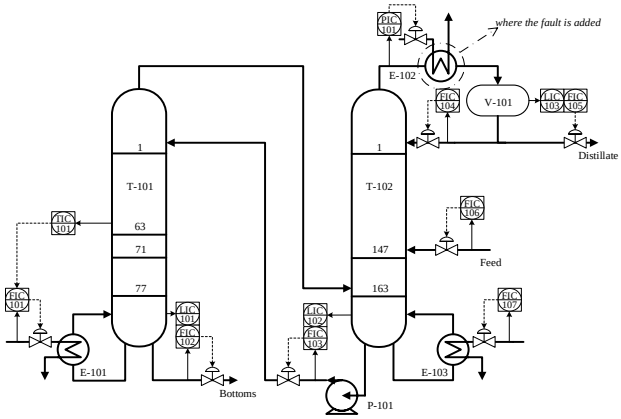

Figure 2. The flowchart of the industrial distillation columns

Table 1. The FDRs of SVDD, PCA-SVDD, EESVDD on different incipient fault states

	Normal condition	Moderate degradation	Severe degradation
SVDD	0.8654	0.9091	0.8830
PCA-SVDD	0.9038	0.9394	0.9474
EESVDD	0.9679	0.9848	0.9766

4. Conclusions

The key idea of the proposed method is that the relationship is constructed between the exergy efficiency and measured variables using MI method, and the SVDD detection model is established by replacing the principal component vectors with the exergy efficiency feature. Besides, the method can detect the severity of incipient faults and point out the evolution direction of faults. The method extends the application for incipient fault detection based on exergy-data abstraction. The case have been showed the effectiveness of the proposed method.

Mass Transport of Micro- and Macro-Molecule Compounds of Phosphorous Base Fertilizer Fortified With Protein in Soil Matrix.

Maksymilian Olbrycht[1], Michał Kołodziej[1], Roman Bochenek[1], Mateusz Przywara[1], Maciej Balawejder[2], Dorota Antos[1]*, Wojciech Piątkowski[1]

1 Department of Chemical and Process Engineering, Faculty of Chemistry, Rzeszow University of Technology, 35-959 Rzeszow/PL; 2 Chair of Chemistry and Food Toxicology, University of Rzeszow, 35-601 Rzeszow/PL

Highlights

- Microgranule phosphorous soil fertilizer based on a post-production waste was developed
- Diffusion of micromolecule components of the granule in soil matrixes was measured
- Degradation and diffusion of protein components in soli matrix was determined

1. Introduction

In recent years there has been a significant increase in the prices of phosphorous fertilizers, which made it necessary to seek alternative, more cost-effective solutions in the field of plant fertilization. Much cheaper fertilizers containing partially decomposed phosphorite, have become an alternative to the existing phosphorus sources, such as superphosphate [1-3].

Raw material for the production of such fertilizers can also be obtained from animal bones containing natural hydroxyapatite. The benefit of this natural source is the lack of fluoride in the raw material of animal origin, which greatly simplifies production. Therefore, we developed a mineral phosphate fertilizer based on ash obtained by incinerating the meat industry wastes. The fertilizer in the form of a microgranule was supplemented with additives sourced from natural raw materials, i.e., protein preparations based on post-production waste (milk serum, soy paste, eggs).

In this project we measured the mass transport of the microgranule components in two different model solid matrixes composed of sand and standardized soil. The mechanism of protein decomposition during the fertilization process was proposed.

2. Methods

Microgranules were prepared using a laboratory pan granulator. The granule was composed of incinerated and grounded bones, lake chalk and protein isolates from milk serum, soy and chicken egg proteins. A microgranule (0.5 g mass) was placed on the bottom of a 15-ML cylinder with piston and a matric scale on the side-wall. Seven identical cylinders were used for the experiments. The cylinders were filled with wet sand or wet standardized soil (both with a predefined moisture content) with the height of 4.5 cm. The samples of the solid matrixes (sand and soil) were withdrawn at different time intervals; 5 mL slices of matrixes were acquired at different distances from the microgranule (from the bottom of the cylinder). Next, the samples were mixed with 5 mL

of 0.1 M NaCl solution and vortex-homogenized. The supernatants obtained were subjected to HPLC, HPLC-SEC and Lowry method analyses, to determine the mass transport of ions and proteins through the matrix.

3. Results and discussion

Typical results of the concentration analysis of a protein from milk serum isolate and micromolecule components of microgranules in the matrix samples that were acquired at different distances from microgranule and different time intervals are presented in Fig.1 and Table 1. It can be observed that the maximum of the protein concentration is reached after 48 h at the distance of 1.5 cm from the microgranule. The concentration of the protein drops rapidly with increasing the distance, and practically vanishes at 4.5 cm away from the microgranule. Moreover, the concentration of the protein decreases in time, which is caused by its degradation. The latter is confirmed by increasing ammonia ion concentration with increase in time (Table 1). The concentration of other ions reaches quickly its maximum due to fast diffusivity of small ions in the solid matrix. The results obtained for other protein isolates were similar to those reported above.

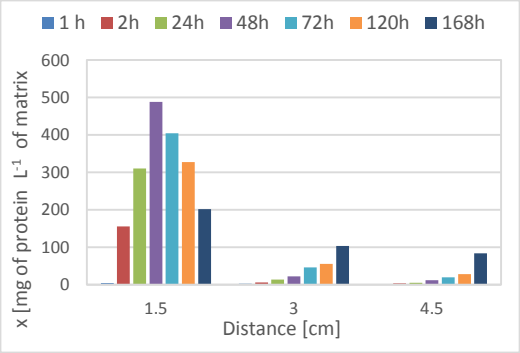

Figure 1. Protein concentration at different distances from microgranule containing milk serum isolate.

Table 1. Concentration of ions at the distance of 1.5 cm away from the microgranule measured at different time intervals.

Time	ammonium	potassium	magnesium	calcium	nitrate	phosphate	sulphate
[h]	mg of ion L^{-1} of matrix						
6	0.45	62.46	7.52	15.95	2.01	1.43	449
24	0.43	79.48	8.58	19.69	1.47	3.36	366
48	2.35	72.09	9.42	27.45	0.82	4.05	334
72	4.29	68.18	10.72	24.57	0.94	3.80	354
120	40.79	71.33	26.91	34.02	0.76	3.26	391
168	41.27	66.87	31.86	43.75	1.91	3.66	544

4. Conclusions

The macromolecule components of the microgranule fertilizer diffuse through the solid matrix very slowly. The transport of the proteins is accompanied with their degradation, which induces formation of ammonium ions. The maximum of the protein concentration and ammonia ions is reached at very close distance from the microgranule, therefore, the fertilizer granule should be placed in vicinity to the plant grain.

Antimicrobial Effect of Extracts from Leaves of Native Brazilian Plants

Bárbara Ponzilacqua[1], Sarah Lee[1], Roice Rosim[1], Carlos Corassin[1], Carlos Oliveira[2]*

[1] *Department of Food Engineering, School of Animal Science and Food Engineering, University of São Paulo, Pirassununga, Brazil*

Highlights

- Leaves from sweet passion fruit and araçá tested against *S. aureus* and *A. parasiticus*.
- Crude and lyophilized extracts from Araçá had highest inhibitory activity on *S. aureus*.
- None of the extracts demonstrated effective results against *A. parasiticus*.

1. Introduction

Staphylococus aureus and *Aspergillus parasiticus* are important causative agents of foodborne diseases and mycotoxin-producing in cereals [1], respectively. In the food industry, antimicrobial agents are generally not permitted as additives in raw or processed products. Thus preventive measures to control the microbial contamination of foods are of particular importance to avoid foodborne infections. The possibility of using natural antimicrobial agents is an attractive alternative to control or reduce the bacterial and fungal load in food products, provided that they are biodegradable, environmental friendly, and biologically safe [2]. Previous studies indicated that essential oils and plant extracts containing secondary metabolites have antimicrobial properties similar to common antimicrobials [3]. The Brazilian native flora is very rich in diversity of species due to the presence of different regions and biomass in the country. A large number of Brazilian plants are popularly used as medicinal herbs, although the pharmacological bases of action for some plants are not completely understood. The objective of this study was to evaluate crude and lyophilized extracts of leaves from two Brazilian native plants with little information regarding their antimicrobial action, sweet passion fruit and araçá, regarding their *in vitro* antimicrobial effects on planktonic cells of *S. aureus* and *A. parasiticus*.

2. Methods

Leaves from *Passiflora alata* (sweet passion fruit) and *Psidium cattleianum* (araçá) were collected during the summer and fall period of 2017 in the Southern region of Brazil. Extracts were prepared according to recommendations of the Brazilian Pharmacopeia (20), after the leaves were dried, grinded and mixed (4 g) with 100 mL of ethyl alcohol (96 °GL). The organic solvent was evaporated by fractional distillation under reduced pressure in an evaporator (Heidolph, Schwabach, Germany). Next, the aqueous extract from each plant was divided into 2 aliquots, one (crude extract) reserved for direct evaluation of antimicrobial activity, and the other submitted to freeze-drying (lyophilized extract) (lyophilizer LC 1500, Terroni Equipment Ltda., São Carlos, Brazil) before running the antimicrobial evaluation. The concentrations of dry matter in crude extracts of

sweet passion fruit and araçá were 28.3 and 60.0 mg/mL, respectively. The lyophilized extracts were re-dissolved in sterile water at 40 mg/mL.

The antimicrobial activities of crude and lyophilized plant extracts were evaluated using strains of *S. aureus* (ATCC 29213) and *A. parasiticus* (NRRL 2999), previously cultured until reaching the turbidity of 0.5 on the McFarland scale. The minimum inhibitory concentration (MIC) of plant extracts was tested using the broth microdilution reference technique [4]. Data were analyzed by the MIXED procedure of Statistical Analyses System, considering $P<0.05$ (28).

3. Results and discussion

Table 1 presents the in vitro antibacterial activities of crude and lyophilized extracts against *S. aureus* and *A. parasiticus*. Extracts from sweet passion fruit had no antibacterial activity against the S. aureus strain tested, since its MIC values could not be determined (>14.15 and >20 mg/mL for crude and lyophilized extracts, respectively). However, crude and lyophilized extracts from leaves of araçá inhibited *S. aureus*. Similarly to results obtained in the antibacterial assays, both types of extracts from araçá had lowest ($P < 0.05$) MIC values against *A. parasiticus*.

Table 1. Mean values of minimal inhibitory concentration of plant extracts against *Staphylococcus aureus* (ATCC 29213) and *A. parasiticus* (NRRL 2999).

Plant extract	Minimum inhibitory concentration (mg/mL)	
	S. aureus	*A. parasiticus*
Crude extracts:		
Sweet passion fruit (*P. alata*)	> 14.15 [a]	> 14.15 [a]
Araçá (*P. cattleianum*)	0.39 [b]	3.12 [b]
Standard error	0.12	0.44
Lyophilized extracts:		
Sweet passion fruit (*P. alata*)	> 20.00 [a]	> 20 [a]
Araçá (*P. cattleianum*)	0.45 [b]	10 [b]
Standard error	0.11	0.31

[a-b] Mean values within each column with no common superscript differ significantly ($P < 0.05$).

4. Conclusions

Sweet passion fruit showed no action against any of the micro-organisms tested. However, crude and lyophilized extracts from Araçá had the highest antimicrobial effects against two microorganisms of public health importance, *S. aureus* and *A. parasiticus*. This is the first preliminary evidence of antibacterial effects of extracts from Araçá leaves.

Urban atmospheric dispersion modeling with artificial neural networks: using the Indianapolis data set.

Pierre Lauret[1], Frederic Heymes[1], Laurent Aprin[1]

[1] LGEI, IMT Mines Ales, Univ Montpellier, Ales, France

*Corresponding author: pierre.lauret@mines-ales.fr

Highlights

- Artificial neural networks are used to forecast dispersion concentrations
- Two dimensional model is used
- Results show improvement compared to Gaussian models while keeping low computing time

1. Introduction

Atmospheric dispersion modelling in complex environment is a tricky task because of the number of parameters involved. Indeed, dispersion in the free field is highly influenced by stability of the atmosphere. Moreover, when complex terrain is considered, the process of dispersion may be considered as non-linear due to the directivity of the flow with buildings. In order to evaluate the performance of atmospheric model, different data set are used. One of them is helpful to deal with dispersion around urban area. The Indianapolis dataset correspond to a 170 hours recording of SF6 concentration with 160 ground level monitors. The SF6 source was released from the top of an elevated stack inside the urban area. While Gaussian models are usually applied very fast, they present low level of performance. On the other hand, models from Computation Fluids Dynamics (CFD) are accurate but requires high expertise and important computer resources. In this paper, we investigate the potential of a neural network to predict concentrations in the urban field, using the Indianapolis experiments as a database for the training process.

2. Methods

The EPRI Indianapolis field study involved SF6 tracer releases from the 83.8 m stack at the Perry K power plant in Indianapolis, Indiana, USA in a typical urban area with many buildings within two kilometers of the stack. 170 hours of tracer data are available from September and October, 1985, and represent all stability classes and most wind speed ranges. Meteorological observations were taken from a 94 m height at the top of a building in the middle of the urban area. Concentrations were measured on a network of about 160 ground-level monitors on arcs at distances ranging from 0.25 to 12.0 km from the stack.

Before training the neural network, the example database has to be built from the initial one. Several recordings exist for the meteorological data. A correlation matrix including measured concentrations is made in order to established the weather station to use. The inputs selection is made through this use. Inputs used are related to the weather, the release and the location where the concentration has to be predicted. In order to compare ANN method to Gaussian models, we

use same inputs as Gaussian models to train a Multi Layer Perceptron (MLP). The training phase is optimized through the variation of three parameters: initialization, number of neurons in hidden layer and variable selection. Evaluation of the model performance is done through the use of Hanna and Chang criteria.

3. Results and discussion

To select the best model, several initializations are made. The influence of this parameter on the result is emphasized through the value of the coefficient of determination. Moreover, increasing the number of neurons in hidden layer shows an improvement in the results. For each best initialization, the best model is obtained with less than 10 neurons in hidden layer. Finally, the selection of the variables shows that the best variables to be selected as inputs are those traditionally used in Gaussian model. This model shows an improvement compared to Gaussian model.

4. Conclusions

The model presented here uses neural networks to forecast concentration on the two dimensional dispersion field. It improves the results of Gaussian models giving the maximum concentration by searching in the entire database of the Indianapolis data set. Finally, the model gives the opportunity of building a two dimensional map of the concentration through time.

Highlights

- Capture and sequestration of CO_2 is priority for the coming years.
- Capture of CO_2 to form metal carbonates is an interesting mitigation of Climate Change.
- Perfect mixing semibatch reactor is a simple device for capturing CO_2.
- Metal carbonates are interesting in various industrial sectors.

1. Introduction

Climate change due to global warming is one of the most important problems that humanity currently faces, regionally and globally. The physico-chemical consequences associated with the absorption of infrared radiation and the amounts emitted by different sources are the main cause of global warming, as reported by the Intergovernmental Panel on Climate Change in recent years (1). There are several processes for the capture and sequestration of CO_2, (2) one of the simplest processes for the latter comprises its adsorption and chemical reaction. In this work, we present results of the capture and sequestration of CO_2 through metal hydroxides aqueous solutions to obtain metal carbonates.

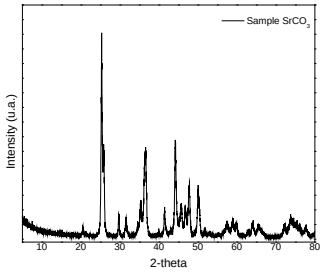
2. Methods

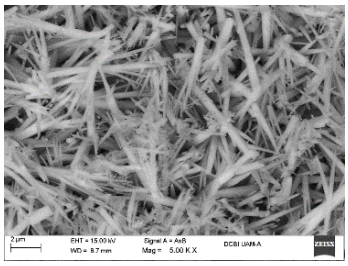
The capture and sequestration tests via reaction between metals hydroxide solutions with gaseous CO_2, were performed in a perfectly mixed semibatch reactor, with 15.17 ml min^{-1} CO_2 continuous flow at atmospheric pressure and two reaction temperatures: 25 and 30 °C. In all the tests 250 ml of 0.06 and 0.07 M Sr, Ba, Mg hydroxide aqueous solution were used, which corresponds to the saturated solutions, the variation of pH, temperature and the mass of dry metal carbonate formed according to the reaction time. All the solids were characterized by X-ray Diffraction (XRD), Scanning Electron Microscopy (SEM), elemental analysis by means of Energy Dispersive Spectroscopy (EDS) and Fourier Transform Infrared Spectroscopy (FTIR).

3. Results and discussion

In each capture and sequestration test, the reaction between the gaseous CO_2 and the alkaline metal solutions formed solid precipitates, which after filtering, washing and drying were weighed to calculate the reaction yield; during the reaction, a decrease in the pH of the solution was observed, as well as an increase in temperature as a function of reaction time. The analysis of the

solids by XRD shows that the corresponding metal carbonate was formed, as shown in figure 1a, where the characteristic peaks of the metal carbonates can be identified, the analysis of the samples by SEM / EDS, shows that the solid formed presents different morphologies, such as that shown in figure 1b, where the solid appears as acicular crystals with longitudinal dimensions of 3 µm by 0.15 µm; the elemental analysis shows the presence of C, O and metal, which can be attributed to the carbonate formed, while the FTIR results shows the characteristic bands of the carbonates at the most intense wavelengths at 1442 cm^{-1} to 20 min, at 1440 cm^{-1} to 30 min and at 1452 cm^{-1} to 40 minutes of reaction and at 854 and 705 cm^{-1}, for all reaction times.





(a) (b)

Figure 1. a) XRD diffraction pattern, b) SEM microscopy of strontium carbonate

The capture of CO_2, to form strontium carbonate ($SrCO_3$) is of interest in various industrial sectors such as: in the refining of sugar and the manufacture of military rockets. Magnesium carbonate ($MgCO_3$) is used as a reinforcing agent in neoprene rubber, as a drying agent and for color retention in food and cosmetics, it is also used as an antiacid in medicine, these capture alternatives give value added to CO_2 sequestration products via carbonate formation

4. Conclusions

Through a simple system of perfectly mixed semibatch reactor, it is possible to capture CO_2 to form metal carbonates under simple conditions at atmospheric pressure and temperature, which represents a sustainable process due to its low energy consumption. According to the results of X-ray diffraction, the solids formed are the metal carbonates of the metal hydroxide solutions. The formed solids present different morphologies according to the results of scanning electron microscopy.

Challenges during the Start-up of Anaerobic Reactors for Wastewater Treatment

Borja Ojembarrena[1]; Noemi Merayo[1,2]; Angeles Blanco[1]; Carlos Negro[1]

1 Complutense University of Madrid, Dpt. Ingeniería Química y de Materiales, Avda. Complutense s/n, 28040, Madrid, Spain; 2 Universidad Politécnica de Madrid, ETSIDI, Dpt. Ing. Mecánica, Química y Diseño Industrial, Ronda de Valencia 3, 28012 Madrid, Spain

**Corresponding author: cnegro@ucm.es*

Highlights

- Start-up of anaerobic reactor is a critical stage
- Time required for start-up is one of the main limitations for anaerobic process
- Time required for the start-up depends on the scale of the treatment
- At full scale, start-up time increases regarding pilot plants and laboratory

1. Introduction

The start-up of the anaerobic reactors is a critical stage to assure a good performance of the anaerobic treatment during normal operation. Contrarily to aerobic reactors, anaerobic ones require long time to growth the appropriate consortia of microorganisms that are able to degrade the substrate provided (the wastewater) and additionally, to generate the maximum amount of biogas to be used as source of energy [1]. Not only are the anaerobic conditions that should be maintained constrain for the start-up process, but also the acclimatization and adaptation to a particular wastewater. The relevance of the start-up phase in anaerobic reactor is related to the operability of the reactor, because if the start-up is not well performed, this will affect the subsequent process operation [2].

2. Purpose

Both the lag between research and development levels, in terms of overall start-up strategies, and the challenge to obtain good quality anaerobic inoculum, particularly in developing countries, prove the necessity of further investigation in the field of the reduction of acclimation period [3].

Therefore, the aim of this work is to evaluate different factors of the anaerobic process, such as microorganism population, reactor design, treated wastewater, etc. that can affect the start-up of the anaerobic process; establishing the degree of influence they have on this step, considering the time required for the start-up, the stability of the microorganism population and any difficulties found. Furthermore, approaches to improve start-up step of the anaerobic treatment were analyzed and compare to show their actual effect.

3. Results and discussion

A successful start-up leads to improve methane production by the biomass, requiring at the beginning both low loads and long time for acclimatization and adaptation of the biomass [4].

Furthermore, the lack of acclimated biomass must be considered because it further leads to instability and failure, [5].

As it can be seen in figure 1, the scale of the treatment has a considerable effect on the time required for the start-up step of the anaerobic treatment. As long as the scale grows, the start-up time tends to increase as well. Therefore, it is important to consider that the results obtained at the laboratory scale for the start-up step of the process must be further checked at bigger volumes to predict what will happen at the full scale.

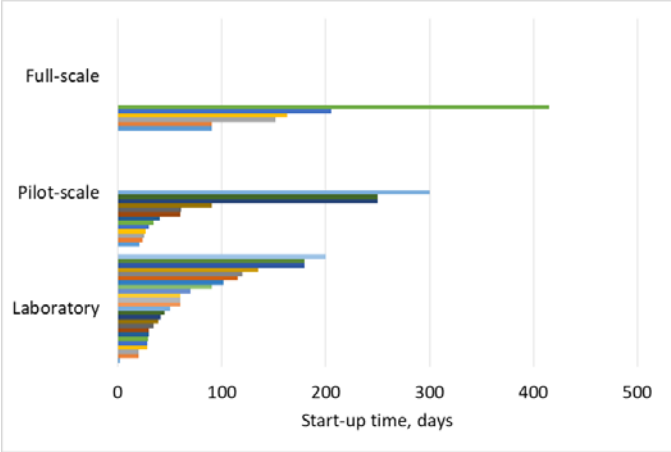

Figure 1. Effect of the scale of the anaerobic treatment on the time required for the start-up step.

The configuration and design of the anaerobic reactor also have a significant impact on the start-up of the process, such as the case of using of multistage reactors, which favors an acidification zone at the front of the reactor and a methanogenic zone at its end and improving the pH control in the reactor [6].

4. Conclusions

Start-up of the anaerobic treatment is a key factor to make this process available and easily implemental. In this communication, several factors will be presented and analysed to show their effect on the time required for the start-up step of the anaerobic treatment of wastewater.

Zero-valent iron (ZVI) activation of persulfate (PS) for degradation of Para-chloronitrobenzene in soil

Changxun Dong [1], Linghong Lu [2*]

1 College of Sciences, Nanjing Agricultural University, Nanjing 210095, China];

2 College of Chemical Engineering, Nanjing Tech University, Nanjing 211816, China

** Corresponding author: Linghonglu@njtech.edu.cn*

Highlights

- The p-CNB removal rate increased significantly from 10.8% to 90.1% with an increase of ZVI dosage from 0.1 mmol•g-1 to 1.0 mmol•g-1..
- The p-CNB removal increased with the decrease of initial solution pH and a removal efficiency of 85.3% was obtained.
- the ZVI-persulfate system showed more sufficient p-CNB removal capacity and the removal rate of p-CNB was 88.7%.

1. Introduction

Para-chloronitrobenzene (p-CNB) in soil has posed significant health risks because of its persistence and high toxicity. Chemical oxidation by means of persulfate (PS) has received considerable attention for organically contaminated groundwater and soil remediation. Recently, it has been found that Zero-valent iron (ZVI) or metal iron can activate persulfate at room temperature, and it can gradually release Fe^{2+} to produce sulfate radicals during a long time length, via reactions with water and oxygen in air. ZVI can restore Fe^{3+} to Fe^{2+} while reducing hydroxide precipitation during the oxidation. Meanwhile, ZVI is an alternative source of Fe^{2+} and can serve as an electron donor for the reaction. The objective of this study was to determine the feasibility of p-CNB polluted soil remediation by ZVI-persulfate systems.

2. Methods

The naturally contaminated soil of p-CNB were prepared for each batch experiment. Several sets of the experiments were conducted to determine the effects of various parameters on p-CNB degradation. Dynamics experiments were performed to study the difference between the removal of p-CNB by single persulfate, ZVI and ZVI-persulfate system. The reactions were carried out in 100 mL centrifuge tube. Reaction mixtures were obtained by taking an appropriate amount of 50 g contaminated soil and mixed with the 50 mL deionized water on a rotary shaker at 125 rpm and 25°C. During the experiment, 1.0 mL of solution sample was periodically withdrawn from each reactor with a glass syringe and then filtered through a 0.45 μm membrane for immediate analysis. The pH value was monitored by a pH electrode.

3. Results and discussion

The results of initial ZVI dosage suggest that the degradation efficiency was heavily influenced by the ZVI when the concentrations of persulfate and p-CNB were fixed. In this system, ZVI play two

roles, reducing chloronitrobenzene to chloroaniline and providing Fe2+ for the activation of persulfate (Zhao et al. 2010). Higher initial ZVI dosage provided more active sites on ZVI surface to persulfate, and the persulfate was activated by the release of Fe2+ from Fe0 in the ZVI-persulfate system. Fe2+ is one of the strongest species that can catalyze persulfate to sulfate radicals, the Fe2+ is continuously supplied to the system to ensure the efficiency of degradation of p-CNB. However, at higher initial dosage (1.0 and 1.5 mmol g−1), the degradation rate was similar. Thus, for economic reasons, 1.0 mmol g−1 was chosen as the best dosage.

The removal rate was markedly increased when ZVI and persulfate coexist due to the generation of •OH and SO4−• in combine system. The increased ZVI dosages resulted in enhanced p-CNB degradation benefiting by increased activation of persulfate by ZVI. Combined with the results of SEM, the increase of ZVI could provide more reactive sites for the activation of persulfate, producing more SO4−• and increasing the efficiency of p-CNB degradation. The removal of p-CNB was advantageous in acid condition. At pH 3.0, 90.3% degradation was achieved in 8 h. The results of EPR showed that acidic conditions were beneficial to the activation of persulfate by ZVI to produce more sulfate radicals. In addition, acidic conditions reduce the precipitation of Fe2+ and Fe3+ facilitate reaction. MS analysis in combination with literature review of p-CNB degradation, intermediates identified in this work include p-chloroaniline, 1, 4-benzoquinone and 5-chloro-2-((3-chlorophenyl) diazenyl) phenol..

4. Conclusions

The p-CNB removal rate increased significantly from 10.8% to 90.1% with an increase of ZVI dosage from 0.1 mmol•g-1 to 1.0 mmol•g-1. The p-CNB removal increased with the decrease of initial solution pH and a removal efficiency of 85.3% was obtained at an initial pH value of 6.8 in this combined system. Compare three systems, the p-CNB removal rate in the persulfate oxidation system and the single ZVI system was 36.5% and 60.2%, while the ZVI-persulfate system showed more sufficient p-CNB removal capacity and the removal rate of p-CNB was 88.7%. Scanning electron microscopy (SEM) was adopted in order to observe the changes of surface morphology of ZVI before and after reaction. The results showed that with the reaction prolonging, the surface of ZVI changed from smooth to uneven. The generated radical species were identified by Electron paramagnetic resonance (EPR) technique, and the results showed that sulfate radicals (SO4-•) were predominant under acidic condition and hydroxyl radicals (•OH) were predominant under basic condition, revealing the potential reduction and oxidation reaction mechanism responsible for p-CNB removal by ZVI-Persulfate in soil..

1. Introduction

Water is a basic resource for society, ecosystems and climate. Nevertheless, water is limited, both in quantity and quality terms, where climate change aggravates the situation. The Water Framework Directive (Directive 2000/60/CE) has supposed a radical change in the focus of management of water resources, changing utilitarian view to protective view of resource. Within main pressures which affects superficial subterranean water bodies in the UE, founding waste from urban and industrial wastewater. The control of waste and the protection of recipient mass of water was regulated with the directive 91/271/CEE, today in force, which bind an adequate treatment of all wastes generate by urban congestion regardless size. The Wastewater treatment (WWTP) is considered a crucial step in the safety and qualities of the environment, for that reason, some studies are focused on the improvement of depurative efficiency. One of them could be the addition of hydrolytic enzymes which stimulate the assimilation of organic matter.

The treatment of urban and industrial wastewater is commonly based on biological processes where determinate microorganisms digest organic or inorganic material from them, which uses for their metabolism. Degradation of organic contaminants by microorganisms requires the pass across cellular membrane of these substances. For that reason polymeric substances must be degraded previously by the actuation of hydrolytic extracellular enzymes (Nybroe et al, 1992).

The improvement is expected like in conventional system (activated sludges) as natural or extensive systems (constructed wetlands). Enzyme's hydrolysis has been applied in industrial effluents with high levels of fat and oils, with low level of biodegradability like alternative for conventional systems (Becker et al, 1999) and for sludge digestion (Aragón et al, 2009) to solubilize organic material reducing sludge production until 30% in pilot scale (Bermúdez et al, 2013). Nevertheless, enzyme catalysis in WWTP is limited by high cost of commercial enzymes. In this sense, previous works have allowed the production of enzymes from organic by-products' fermentation, like sludge from sewage treatment (Rodríguez-Morgado et al, 2015). The addition of these enzymes could improve the process, obtaining water with better quality, in less time and with a low price.

This study aims at (a) the determination of the optimum conditions for the application of enzymes in the wastewater treatment (b) the assessment of the effects on both intensive

(activated sludge) and extensive treatment systems (constructed wetlands) and (c) environmental protection.

2. Methods

In a first stage, lab scale pilot plants are employed for the assessment of the application enzymes to biological reactors. Both commercial enzymes and by-products of the sludge fermentation are being tested. Physicochemical and microbiological parameters are monitored. Besides, sludge production and "clogging" phenomena are being studied. Then, the results are being extrapolated to a several real scale treatment plants.

3. Results and discussion

Initial results show a slight increase in the treatment efficiency in both systems (larger organic matter removal) after the enzyme dosage. Besides, a reduction in sewage sludge production is observed in the SBR unit. Finally, it is observed a delay in the appearance of the clogging phenomenon in the horizontal flow constructed wetlands.

4. Conclusions

As The Water Framework Directive (Directive 2000/60/CE) aims protection of water bodies, that are highly contaminated due to conventional water treatment systems, innovative techniques are being studied. It has been proven that hydrolytic enzymes stimulate organic matter assimilation, so that the efficiency of the treatment increases. This research studies the effect of addition of hydrolytic enzymes in the treatment process. The results show that adding enzymes into the treatment system, supposes a very important improvement in the quality of effluents, providing water protection and a reduction in economic costs.

Adsorption of Anionic Surfactant on Activated Carbon inside a Semipermeable Membrane.

Israel Chavez-Sumarriva[*,1,2], Teodardo Cardenas[1], Luz Eyzaguirre[2]

1 Faculty of Chemical and Textile Engineering. National University of Engineering. Av. Tupac Amaru 210. Rimac, Lima, Peru; 2 Graduate Unit of the Faculty of Petroleum, Natural Gas and Petrochemical Engineering. National University of Engineering. Av. Tupac Amaru 210. Rimac, Lima, Peru

**Corresponding author:*

Highlights

- Adsorption of Sodium dodecylbenzenesulfonate (SDBS) on activated carbon.
- Activated carbon was placed inside a semipermeable membrane.
- The adsorbed amount of SDBS does not decrease with the use of a semipermeable membrane.

1. Introduction

Surfactants are chemical compounds used in many chemical processes *e.g.* enhance oil recovery in petroleum industry, textile and paper industry, etc. Surfactants are also used in many products and formulations, such as detergents, cosmetics, paints, inks, etc.[1] Unfortunately, large usage of surfactants has led to water pollution. Sodium dodecylbenzenesulfonate (SDBS) is a widely used anionic surfactant. SDBS is biodegradable under anaerobic conditions[2] but the amount of this anionic surfactant in water is high and therefore is still difficult to eliminate them. Nowadays, SDBS is removed by different methods, such as chemical oxidation,[3] coagulation,[4] biological degradation,[5] electrochemical removal[6] and adsorption on soils,[7] clay[8] and carbonaceous materials.[9,10] Adsorption on carbonaceous materials such as activated carbon is widely used because is easy to operate and cheap but sometimes the activated carbon used for eliminate the SDBS can polluted the aqueous media. A solution is proposed in this research, the activated carbon is placed inside a semipermeable membrane for avoid pollution of the aqueous media.

2. Methods

Determination of SDBS Concentration

The SDBS concentration in solution before/after adsorption with activated carbon without/inside semipermeable membrane (regenerated cellulose) was determined using a Shimadzu UV−Vis spectrophotometer at 224 nm.

3. Results and discussion

Based on adsorption kinetics studies of activated carbon inside a semipermeable membrane, the time to reach the equilibrium adsorption capacity was 24 hours, a security factor was added and the time used in all adsorption tests was 30 hours. Adsorption tests were made (T = 298 K) to

determine if the semipermeable membrane decreases the equilibrium adsorption capacity. Figure 1 shows the adsorption tests of Sodium Dodecylbenzenesulfonate (SDBS) on activated carbon without / inside semipermeable membrane, it can be seen that the equilibrium adsorption capacity (q_{eq}) does not change when the activated carbon is placed inside a semipermeable membrane. The influence of temperature was studied with activated carbon inside a semipermeable membrane at 298 K, 308 K, 318 K and 328 K. The results showed that when the temperature increases the adsorption capacity decreases. The influence of pH was also studied with activated carbon inside a semipermeable membranes (T=298 K). The pH was varied between 4 and 11; the results showed that the adsorption capacity does not change with pH which confirms that there are no electrostatic interactions between the SDBS and the activated carbon. After determining the optimal adsorption parameters (time, pH, Temperature) an adsorption isotherm was made (see Figure 2). The adsorption capacity of activated carbon inside semipermeable membrane founded was *ca.* 271 $mg_{SDBS}\ g_C^{-1}$.

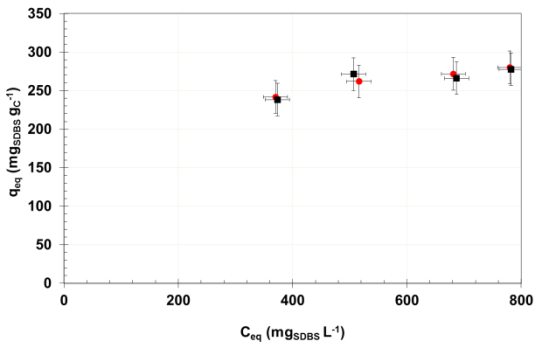

Figure 1. Effect of semipermeable membrane on the adsorption capacity of SDBS on activated carbon; red circles: without semipermeable membrane; black squares: with semipermeable membrane.

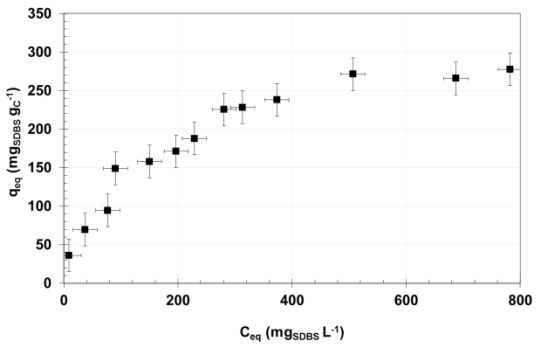

Figure 2. Adsorption isotherms of SDBS on activated carbon placed inside a semipermeable membrane (initial conditions; T=298 K, pH=7, 30 h contact time).

4. Conclusions

The results demonstrated that the amount absorbed of the anionic surfactant Sodium Dodecylbenzenesulfonate (SDBS) on activated carbon does not change with the use of a semipermeable membrane, therefore the proposed method could be used in industrial applications in which is needed to remove SDBS from an aqueous solution and it is not desired to contaminate this aqueous solution with small particles of activated carbon.

Zeolitic imidazole frameworks-8 derived ZnO/carbon nanocubes: a broad-spectrum solid-phase microextraction coating

Xingru Hu, Jiansheng Li *

Key Laboratory of Jiangsu Province for Chemical Pollution Control and Resources Reuse, School of Environment and Biological Engineering, Nanjing University of Science and Technology, Nanjing 210094, China.

**Corresponding author: lijsh@njust.edu.cn*

Highlights

- ZIF-8 derived ZnO/C was prepared and used as adsorbent for SPME.
- The dispersed composition endows ZnO/C with broad-spectrum extraction capability.
- The double-shelled hollow structure is beneficial for the sensitive extraction.
- The resultant fiber is applied for the determination of the analytes from water samples.

1. Introduction

Development of high-efficient determination of the environmental pollutants is of great significance. [1] Solid phase microextraction (SPME), as a solvent-free extraction method, is very widely used for the sensitive detection of emerging pollutants.[2] The properties of the coating materials generally determine the extraction performance.[3] It is thus a marked research interest in developing a kind of SPME fiber coating that can provide sensitive extraction capability for broad-spectrum analytes from the complex samples. Recently, metal-organic frameworks (MOF) has been considered as the promising precursor to synthesize functional materials directly by high-temperature pyrolysis.[4] In order to broaden the utilization and improve the performance of the MOFs-derived materials, hollow structure with abundant active sites has been designed and fabricated.[5] Encouragingly, the MOF-derived double-shelled hollow materials seems to be a potential choice for the broad-spectrum and sensitive SPME of the environmental pollutants. In this study, we develop a SPME fiber based on zeolitic imidazole frameworks-8 (ZIF-8)-derived double-shelled hollow ZnO/carbon (ZnO/C) materials. The ZnO/C coated fiber is used to investigate its simultaneous extraction ability for polar and nonpolar compounds. The highly synergistic effect of carbon networks and ZnO crystals leads to the broad-spectrum extraction of the ZnO/C-F. Moreover, the double-shelled hollow structure improves the sensitive extraction for the analysts.

2. Methods

The ZIF-8 nanocubes were first prepared by mixing the HMI, Zn(NO3)2•6H2O and CTAB. After tannic acid etching treatment, these nanocubes could be converted into double-shelled hollow structure. Then the DSH-ZIF-8 experienced a thermal annealing at 500 °C to synthesis the ZnO/C. Finally, the resultant ZnO/C was directly coated on the SSW by the glue method to form the SPME fiber.

3. Results and discussion

As shown in Fig. 1a, the morphology of ZnO/C is kept after carbonization. Besides, the broken particle (inset in Fig. 1a) suggests the presence of the double-shelled structure. From TEM characterization (Fig. 1b,c), the void space and structure can be clearly testified. Obvious lattice fringes with an spacing of 0.25 nm in the high-resolution TEM image (Fig. 1d) and bright diffraction rings in SAED pattern (Fig. 1d inset) have been observed for the ZnO/C, corresponding well to the (101) planes of ZnO. The elemental mapping data presented in Fig. 1e reveals that the C, O and Zn elements are distributed uniformly on the particle. As shown in Fig. 1g, the sharp peaks of ZnO/C show the typical structure for ZnO crystal phase, which is consistent with the SAED pattern.

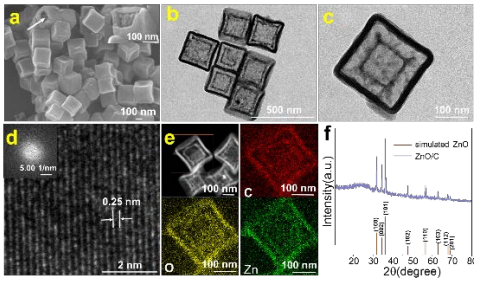

Figure 1. (a)SEM image, TEM images at low (b) and high (c) magnification, (d) high-resolution TEM image (inset: SAED pattern), (e) elemental mapping showing C, O and Zn of ZnO/C. (f) XRD patterns of simulated ZnO and ZnO/C.

To evaluate the extraction performance, ZnO/C-F was compared with the commercial PDMS/DVB fiber, which has been proved for SPME of both nonpolar and polar compounds. The ZnO/C-F displays a prominent advantage in extracting both the BTEX and CPs (Figure 2). The excellent performance could attribute to the combined effect of the ZnO/carbon composition and double-shelled hollow structure.

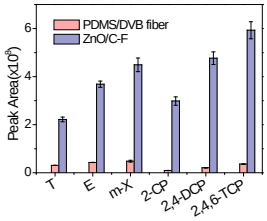

Figure 2. Peak areas comparison of ZnO/C-F with S-ZnO/C-F and commercial PDMS/DVB fiber.

4. Conclusions

In conclusion, the MOF-derived double-shelled hollow ZnO/C materials have been prepared. Then they were coated on the surface of a stainless steel wire to form the SPME fiber. Compared with the commercial fiber, ZnO/C-F displayed superior extraction efficiency owe to the combined effect of the ZnO/C composition and double-shelled hollow structure.

Highlights

- Comparison of several different extraction techniques under various conditions
- Performing the stability tests on extracted stilbenes
- Light induced formation of *cis*-viniferin by dimerization of resveratrol

1. Introduction

Czech Republic belongs among countries with long winemaking tradition. Unfortunately, the wine-processing industry produces large amounts of waste, which is usually burnt or used in compost [1]. However, wine waste formed during wine production can comprise valuable bioactive substances e.g., resveratrol and viniferin, important in food production and very useful in various branches of science including medicine, pharmacy and cosmetic industry thanks to their potential antioxidant activity [2]. The great interest in these compounds also stems from their biological properties and chemical stability. The mechanism that leads to production of these antimicrobial compounds synthesized and accumulated in different parts of the plant in response to biotic or abiotic stress is based on self-defense potential of the plants [3, 4]. This work is focused on the combination of several extraction techniques for the isolation of polyphenols with subsequent induction of stress conditions. Concern these factors, stability study is the basis for optimizing conditions of extraction methods of resveratrol and viniferin.

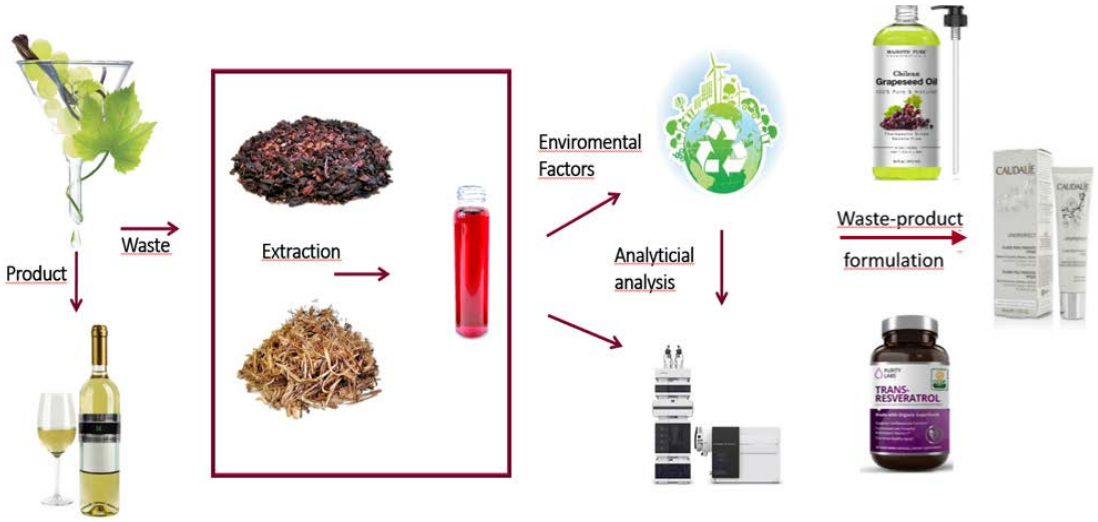

Figure 1. From grapes to main product and by-products.

2. Methods

To obtain a usable amount of stilbenes for subsequent processing it is essential to use highly effective extraction methods. Considering that, a comparison of several different extraction such as maceration, ultrasonic extraction, Soxhlet and pressured liquid extraction has been performed. The effects of stress conditions used in stability study were monitored and performed by newly developed HPLC-MS method, which is proved to be accurate, reproducible and efficient for determination of resveratrol and viniferin.

3. Results and discussion

Among extraction methods, the most noticeable results were obtained using maceration in dark and Soxhlet extraction method at atmospheric pressure providing the highest concentration of resveratrol. The outcome of stability study showed, that storage in dark didn't affect the concentration of monitored compounds but light exposure induced visible decreasing in resveratrol and *trans*-viniferin concentration while the concentration of *cis*-viniferin increased considerably. The explanation of this phenomenon is lying in possible dimerization of two molecules of resveratrol induced by light and also photoisomerisation of *trans* form of stilbenes into *cis*, resulting in observable concentration increase of *cis*-viniferin [5]. To confirm this thesis, the sample without *cis*-viniferin was exposed to sunlight and UV light for defined time intervals. Process of formation of *cis*-viniferin was confirmed as well as supposed distinction between sunlight and UV light: UV light accelerates the entire process. Already known fact that higher temperature leads to degradation of stilbenes was also confirmed. Nevertheless, the short-time exposure of plant material to heating in solution enhances the release of resveratrol from other plant structures, such as carbohydrates.

4. Conclusions

Based on the stability study, the optimal conditions for obtaining individual stilbenes from grape cane extracts of *Vitis vinifera* L. cv. Cabernet Sauvignon were determined. Results showed that light-induced dimerization of *trans*-resveratrol leads to inverse concentration change between viniferin and resveratrol, while high temperature test showed complete degradation of stilbenes. Following photoisomerisation of *trans*-stilbenes into *cis* form also induced by light, explained the increase of *cis* form versus *trans.* Due to this, the basis for optimizing extraction conditions of resveratrol and viniferin was obtained.

Explosibility characterization of combustible dusts from Italian industries

Luca Marmo[1], Almerinda Di Benedetto[2], Roberto Sanchirico[3], Valeria Di Sarli[3], Enrico Danzi[1]

1 Applied Science and Technology Dept. Politecnico di Torino, Cso Duca degli Abruzzi 24, 10129 Turin (Italy); 2 Dipartimento di Ingegneria Chimica, dei Materiali e della Produzione Industriale, Università Federico II Napoli, P.le Tecchio 80, 80125 Naples (Italy); 3 CNR IRC, P.le Tecchio 80, 80125 Naples (Italy)

**luca.marmo @polito.it*

Highlights

- Dust explosion hazard
- Testing the explosibility of industrial dust waste may not be completely fulfilled by current norm
- Explosion hazard assessment requires proper dust characteristics measurement

1. Introduction

The first documented dust explosion in the world is that occurred in Turin (Italy) in 1785. Many years have passed since then, but dust explosion phenomena are still being investigated as they pose several open issues. Literature studies have been mostly focused on how to deal and protect industrial equipment, where fine solid particles are involved, both as processing powder and as waste material to be disposed. Powdered materials could also be produced accidentally, due to mechanical or thermal stress, such as working operations aiming to refine or reduce shape of raw materials, but also when brittle solid materials are handled or stored. Most of the dusts generated by these operations are heterogeneous in shape and particle size distribution, as well as in volatile content and chemical composition. Testing combustible dusts coming from industries means to deal with samples which are mostly not pure, but mixture of combustible and inert materials. The assessment of the likeliness of a combustible dust to explode in certain conditions is not an easy task, even though several standards could be used to determine the explosive properties, such as the recent ISO 80079-20-2:2016. Nevertheless, dust explosion hazard is based on the known "pentagon", a side of which represents the dispersibility of the material that often plays a critical role. Non-spherical dusts, such as fibers, scraps or shavings from finishing operations are difficult to disperse with traditional testing procedures, but this could not a priori exclude their unsafe behavior in industrial equipment, or in peculiar conditions: dispersibility dynamics of such type of dusts is not well understood.

This paper summarizes results and draw conclusions obtained from the testing of over two hundred of dust samples, collected in industrial facilities from all over Italy, deriving from different type of processes, with different chemical nature and morphology.

2. Methods

Dust samples were subjected to preliminary characterization tests, as to measure those properties which could significantly influence dust explosivity parameters. Metal oxide content was measured when dealing with dust coming from metal industrial plants, while CHN analysis was performed on most organic dusts. Moisture content was also determined for all samples as to verify its inerting effect on the explosion strength of dusts. PSD was obtained for all samples, both through a pile of sieves, operated by a mechanical sieving machine, and by laser granulometric

analysis (ISO 13320:2009). Dust ignition sensitivity was evaluated through the measurement of Minimum Ignition Temperature (in cloud and in layer), Minimum Ignition Energy and with the Explosibility screening test (ISO 80079-20-2:2016). Dust explosion violence was measured according to EU standard 14034:2011, defining maximum rate of pressure rise (or K_{ST}, deflagration index), maximum pressure rise and Lower Explosibility Limit (LEL).

3. Results and discussion

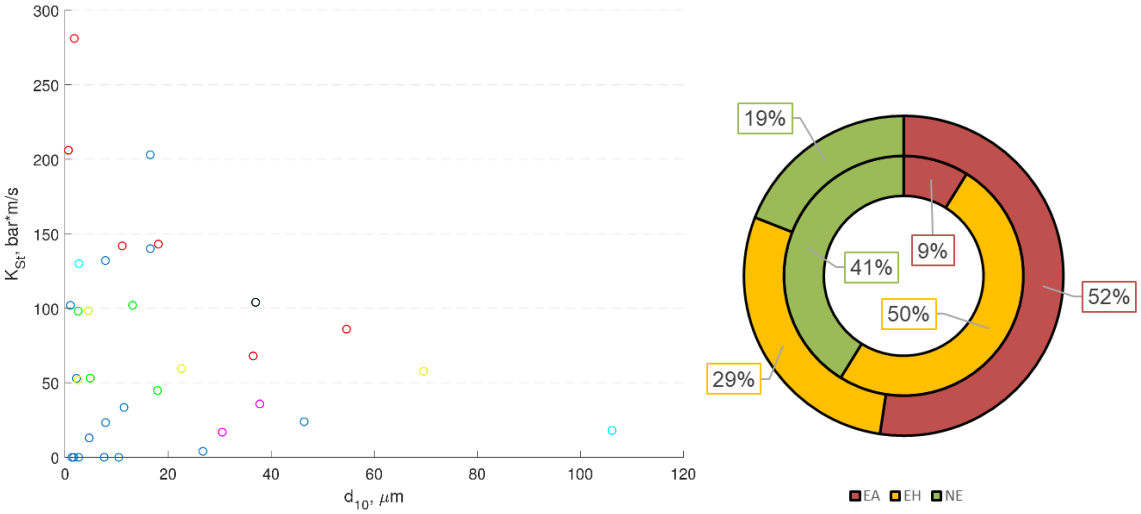

Figure 1. K_{St} value vs tenth percentile diameter of particles, where red dots represent plastic samples, blue metal, green textiles, black wood, yellow food, magenta feed, cyan others (left); Speditive explosibility test results sort by sample origin (inner ring inorganic samples, outer ring organic samples) (right).

4. Conclusions

Assessing the explosion hazards related to combustible dusts derived from industrial processes and waste is a challenging task for many reasons: samples are rarely pure dusts, but mixtures; PSD and morphology, among other variables, could vary extensively through the dust sample due to collecting procedures; actual industrial conditions and material handling are difficult to recreate in laboratory scale [1]. In this work, more than hundreds of samples were tested, deriving from different industrial realities: dusts produced by plastic manufacturing plants presented higher hazards in terms of explosion violence (K_{St} class 2), followed by samples from metal waste, with higher metallic content [2]. Organic samples constituted a potential explosion risk, as only about 20% of them did not imply an explosion behavior, while inorganic non explosible samples are two times higher. Care must be paid when dealing with non-traditional dusts (such as those generated from manipulation of textile fibers), as relative high value of K_{St} are registered, even though standard explosibility test devices could not disperse efficiently those type of samples [3].

NOx Trap and Removal Performance on Barium and Barium-Ceria Containing SCR Catalysts

JinWoo Kim[1,2], Bora Ye[1], Taewook Kim[1], Heesoo Lee[2], Hong-Dae Kim[1,*]

1 Green Materials and Processes Group, Korea Institute of Industrial Technology, Ulan 44413, Republic of Korea; 2 School of Material Science & Engineering, Pusan National University, Busan 46241, Republic of Korea

**Corresponding author: hdkim@kitech.re.kr*

Highlights

- Barium and barium-ceria containing V_2O_3-WO_3/TiO_2 SCR catalyst was synthesized.
- Baium-ceria containing catalyst has improved NOx storage performance than barium containing catalyst.
- NOx desorption occurs at SCR activation temperature range.
- No significant deactivation even after NOx desorption.

1. Introduction

Recently, the importance of reducing nitrogen oxides (NOx) has been emphasized because atmosphere regulations are enhanced [1,2]. Selective catalytic reduction (SCR) is a representative technology for converting harmful NOx into harmless water and nitrogen by reducing agents such as NH_3 [2,3]. The optimum activation temperature of the V_2O_5-WO_3/TiO_2 SCR catalysts (VWTi catalysts) is a range of 300-400 °C, which requires a lot of energy and time to raise the temperature. However, it generated under low-temperature operating conditions, such as start-up and shut-down procedures of equipment, is a problem as it is not removed by catalyst and released into the atmosphere [4]. Therefore, NOx trap technology is required at low temperatures.

Barium is an alkali metal having the NOx storage properties. In the case of alkaline and alkaline earth metals such as K and Cs except Ba, the NOx occlusion ability increases but the catalytic activity decreases by increasing the basicity. However, Barium oxide converts NOx to nitrate ($Ba(NO_3)_2$) form and stores NOx. Currently, it is used as NOx Trap material of Lean NOx Trap (LNT) catalyst [4,5]. Ceria is a coagulating agent that supplies oxygen needed for reaction to the active material [6]. In this study, Barium and Barium/Ceria are impregnated into VWTi catalyst, and the adsorption / desorption behavior of the catalyst was confirmed.

2. Methods

TiO_2, $Ce(NO_3)_3$, and BaO are dispersed in ethanol with stirring. Ammonium metavanadate (AMV), and Ammonium metatungstate (AMT) are separately stirred for 1 hour in a solution of oxalic acid dissolved in ethanol. The solutions are treated with ultrasonic for 1 h after mixing each solution. Then, they are stirred for 6 hours at 60 °C. After the evaporation of ethanol at 60 °C using a rotary evaporator, the synthesized powder is sintered at 500 °C with a rate of 3 °C/min for 2 hours. Figure

1 shows the experimental flow chart scheme for the preparation of the NOx Trap functional catalyst.

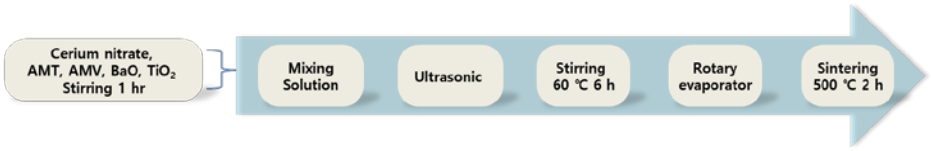

Figure 1. Experimental flow chart for preparation NOx trap functional catalyst

3. Results and discussion

The storage and desorption characteristics of Barium and Barium/Ceria doped VWTi catalyst are affected by reaction temperature, space velocity and catalyst content. Figure 2 shows the adsorption characteristics according to the composition of the catalyst at a space velocity of 36,000 h^{-1} and a temperature of 200°C. In the case of barium containing catalyst, barium increase the NOx adsorption property compared with the non-containing catalyst (VWTi catalyst). In addition, the barium-ceria containing catalyst showed better adsorption performance than barium containing catalyst.

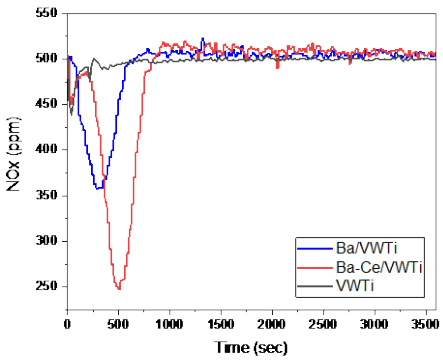

Figure 2. NOx adsorption profile of V_2O_5-WO_3/TiO_2 (VWTi), BaO/VWTi, and BaO–CeO_2/VWTi (SV : 36,000 h^{-1}, O_2 : 10 vol%, NOx : 500 ppm, N2 : Balance gas, 200 ℃)

Desorption behavior was occurred at 300-350 °C, which is the catalytic activation temperature range. Furthermore, about 90% efficiency was measured in the denitration rate evaluation. It was confirmed that the activity did not decrease after desorption.

4. Conclusions

Due to the additional role of ceria, the adsorption property of barium-ceria containing catalyst was found to be higher than that of Barium containing catalyst. NOx desorption was observed at 300 - 350 °C, which is the catalyst activation temperature, and it was confirmed that there was no decrease in the activity of the SCR reaction.

Ferroniobium of the Colombian Guania Shield for obtaining rare earth metals: crystallographic analysis

Michelle Chico[1*], Aida Liliana Barbosa[2]

[1] Chemical Program. Faculty of Exact and natural sciences. Laboratory of research in catalysis and new materials (LICATUC). Universidad of Cartagena. Colombia.
abarbosal@unicartagena.edu.co

Highlights

- Niobium ore deposits in the Guinía-Colombia were studied founded niobium, zirconium, cobalt and titanium.
- The presence of radioactive elements in trace (uranium, thorium, curium, praseodymium) was evidenced in the materials using Raman spectroscopy and FRX.
- Solvometallurgy techniques were used for the separation of REEF and oxide of Nb and Ta, obtaining a solid yellow corresponding with the FeC_2O_4

1. Introduction

The Guinia Shield in the area of Inírida-Colombia has been found pirocloros with the presence of oxides of Ti, W, Ta and Nb often enriched with U, Hf, Zr and rare earth elements. 1

The most effective and frequently applied solution method for mineral specimens containing Ta and Nb implies the use of HF as a leachate reagent, experiencing the formation of different soluble metal fluoride complexes such as Heptafluoruros, Hexafluoruros or Oxifluoruros, [6]. Solvometalurgicos processes are presented as an alternative to conventional metallurgical, which impact environmentally by the use of polluting inorganic acids.

2. Methods

The samples of niobium ore were collected on "El Zancudo" Guinía (Colombia). The specimen was dried and pulverized, passed by sieve 100mesh and was characterized by stereoscopic microscopy, Laser-Raman spectroscopy, and X-ray diffraction powder (XRD) and X-ray fluorescence (FRX)). The extraction of Nb and Ta of Ferriniobio use solvents 2-octanol and Metilisobutilcetona, as extraction agents. [2.4]

3. Results and Discussion

FRX analysis showed high percentages of SnO_2, TiO_2, Nb_2O_5 and Ta_2O_5, percentages about 8% of Fe_2O_3 and ZrO_2, below 3% w/w MnO, W, Al_2O_3, SiO_2. Stereoscopic optical microscopy, show presence of transparent quartz, iron ore with uneven surface, grey metals with metallic sheen that were related to niobium, tungsten and zirconium.

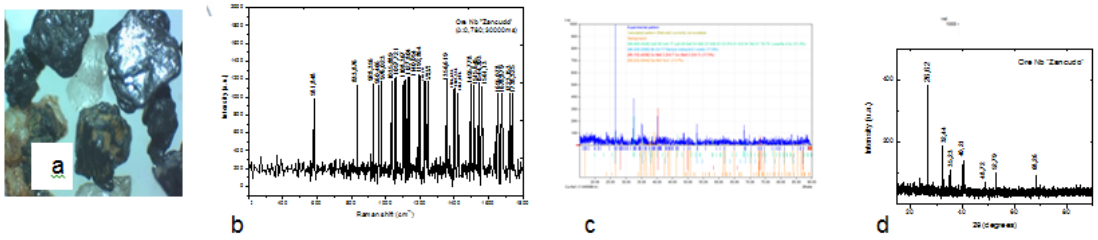

Figure 1. (a) External of optical microscopy Nb ore 3.5x. (b) Raman spectrum of outer layer (0.780- 30000ms). (c) and (d) DRX pattern Ore Nb

Feldspars were seen as subhedral-shaped crystals of white and pink color, together with magnetite with rhombic faces of metallic luster and black color. Raman signals features in 581.848 cm^{-1} it associated with stretch Nb-O, possibly of the NbO_2, one observes two bands located both with approximately 677cm^{-1}, assigned to phases of magnetite Fe_3O_4, the peaks or signals quite intense at 1037 cm^{-1}, 1113 cm^{-1} and 1235 cm^{-1} were characteristic of hematite Fe_2O_3, the band 833.876 cm^{-1} was reported to be consistent with uranium oxide [3]. XRD analysis record peaks in 2 θ = 26.62, 2 θ = 32.44, 2 θ = 35.23 and 2 θ = 40.21, were characteristic of metals such as zirconium, titanium, niobium and cobalt.

4. Conclusions

The method of extraction with solvents led to two major products one of them iron oxalate, which was extracted to treat the leachate with metil butyl ketone and the subsequent washing of the loaded metil butyl ketine, which allowed the obtaining of a solid Niobium white, when the solution reached pH 7 by adding ammonia. These results show that the proposed method is potential for the purification of the native mineral.

Highlights

- Tested Cu:M:Ti oxide catalysts (M=Sr, Ba, Ca) with various compositions.
- Investigated structural properties by CO_2 TPD, N_2O chemisorption and other techniques.
- Copper particle size and basicity important for the methanol synthesis.
- Observed trends incorporated into the multi-site microkinetic model.

1. Introduction

Methanol is important industrial chemical with the annual production of 110 Mton [1]. Development of new catalysts with enhanced properties is a key for an efficient methanol synthesis. Additionally, microkinetic models built on trends from experimental work, with reaction rate constants from quantum chemical calculation [2], can be used to obtain insights into catalytic reaction mechanisms and for further plant operation optimization.

The beneficial influence of the basicity of the copper catalyst on the methanol synthesis was previously reported [3,4]. In our work we prepared and tested different Cu:M:Ti oxide (M=Sr, Ba, Ca) catalysts. Catalysts were characterized by N_2 physisorption, N_2O pulse chemisorption, CO_2 TPD and H_2 TPR. We investigated structure-activity relationship for the preparation of the microkinetic model.

2. Methods

Catalysts were prepared by solution combustion synthesis with citric acid and calcined at 650 °C. We pelletized powders and reduced them at 300 °C for 12 h. For the catalytic tests, the temperature was varied at pressure 20 bar, GHSV = 6000, 12000 1/h and inlet gas composition H_2:CO_2 = 3:1. Outlet gas composition was determinate using gas chromatography. N_2 physisorption was performed using ASAP 2020, H_2 TPR was executed in 50 mL/min flow of 10% H_2/Ar gas with heating rate of 10 °C/min from 60 °C to 300 °C, N_2O pulse chemisorption was performed after H_2 TPR, in the 20 mL/min flow of He at 90 °C. The consumption of N_2O was determined using daily calibrated mass spectrometer. CO_2 TPD were performed from -40 °C to 600 °C with heating rate of 20 °C/min in the 20 mL/min of He. Mass spectrometer was also used to analyze results. N_2O pulse chemisorption, CO_2 TPD and H_2 TPR were performed on Autochem 2920.

3. Results and discussion

Methanol and carbon monoxide production at 220 °C and 20 bar were used and normalized to copper surface area obtained from N_2O pulse chemisorption to calculate turnover frequency (TOF). We tested catalysts at various copper loadings (Figure 1), different Sr/Ti ratio (Figure 2) and different earth alkaline metals (Ca, Sr, Ti) (Figure 3). We observe, that at different Cu loadings, Cu particle size increase which increases TOF for MeOH, while TOF for CO remains constant. This suggests that larger copper particles expose surfaces, which are more selective for MeOH synthesis. Turnover frequency for MeOH increases with increasing Sr/Ti ratio, while CO TOF remains almost constant. This suggests that Sr promotes adsorption of CO_2 and further reaction with adsorbed H* species through Langmuir-Hinshelwood mechanism. Much larger benefits are obtained using Ca, which much strongly adsorbs CO_2. Therefore for the development of the microkinetic model is important incorporation of multiple sites, such as basic sites with various copper metal sites.

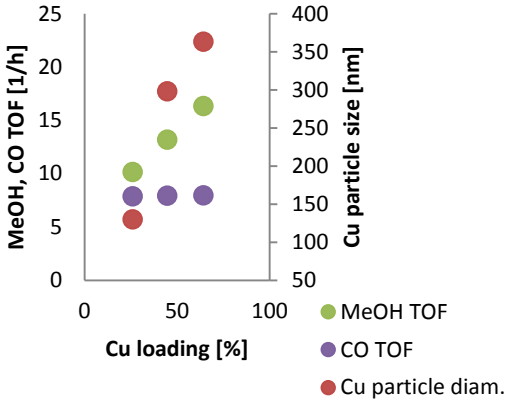

Figure 1. Influence of copper loading on TOF for MeOH and CO at constant Sr/Ti. (GHSV=6000 1/h)

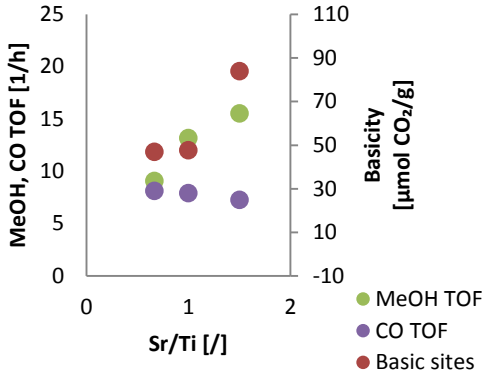

Figure 2. Influence of Sr/Ti ratio on TOF for MeOH and CO at constant copper loading 50 wt%.(GHSV=6000 1/h)

4. Conclusions

Important catalyst properties were investigated to obtain structure-activity relationships. We found out that the basic sites importantly influence the catalyst activity and should be included into microkinetic model, beside copper sites.

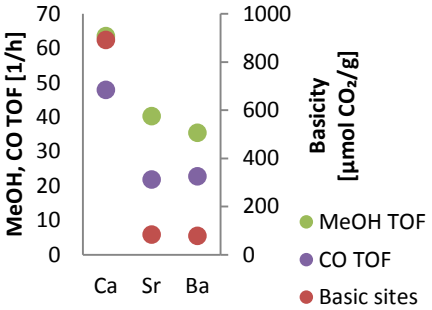

Figure 3. Influence of different earth alkaline metals for Cu:M:Ti=5:3:2. (GHSV=12000 1/h)

AUTOMATIC DETECTION OF SCORCHED OR OTHER FOREIGN PARTICLES IN GRANULATION PROCESS USING INLINE PROBES

Mirco Wegener[1], Sebastian Maaß[1]

1 SOPAT GmbH, Boyenstraße 41, 10115 Berlin, Germany

**Corresponding author: mirco.wegener@sopat.de*

Highlights

- Live imaging ensures the view into the process
- Differentiation of different colors, shapes and sizes possible in a real time monitoring
- Quality assurance is used for optimization and feedback control

1. Introduction

Granulation, the process of particle enlargement by agglomeration technique, is one of the most significant unit operations in the production of pharmaceutical, chemical or food products. These process transforms fine powders into free-flowing, dust-free granules that are easy to compress. Nevertheless, granulation poses numerous challenges due to high quality requirement of the formed granules in terms of content uniformity and physicochemical properties such as granule size, bulk density, porosity, hardness, moisture, compressibility, nonexistence of foreign particles etc. together with physical and chemical stability of the drug, the chemical component or food ingredient.

Realtime monitoring of the named parameters using inline measurement technologies was discussed in general but not implemented throughout the industrial community due to severe technical challenges. Especially the measurement of granule size, granule shape and colour (implying scorched or other foreign particles) has not been implemented successfully in industrial granulation processes. The presentation will give a brief overview of existing measurement techniques developed for the above mentioned tasks, as different techniques based on different physical principles for measuring particle size distributions are available. The authors did compare several measurement techniques and will provide those results.

2. Methods

The mainly used system for this presentation is a newly developed photo optical in-line measurement technology combined with an innovative image processing and analysis software. These analyses show exactly the size, shape and colour of the granules. Additional parameters like local concentration or moisture can be derived from the image analysis. This makes it possible to monitor and to optimize granulation processes in a feedback loop, as the particle data are available in real time.

3. Results and discussion

The quality and variability in quality of the images obtained by the camera computer system (see Fig. 1) greatly influences the success of the automated interpretation. All important step will be discussed and presented in detail. A first example is given in the following figure.

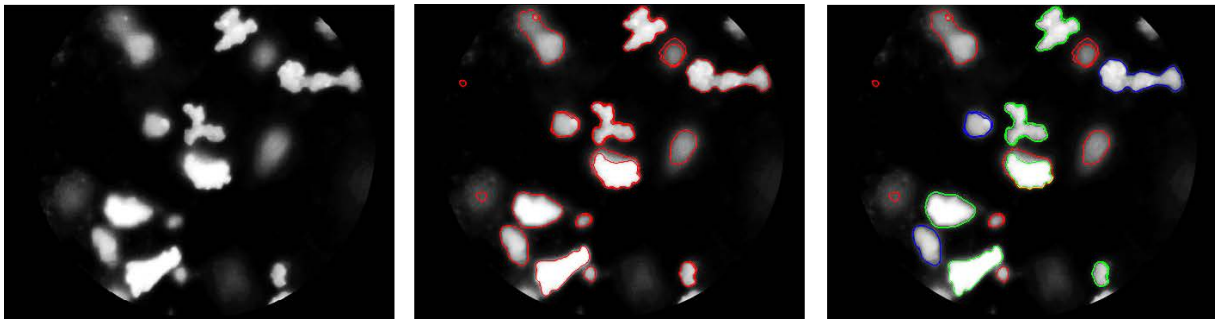

Fig. 1 image analysis steps for irregular shaped particles: (a) – original image; (b) – segmented image; (c) – classified image; only classified particles are used for the size distribution (green and blue; red are excluded)

The particle size and number are tracked over time and the information of the amount of foreign particles did lead to significant savings.

Going digital changes the game – teaching fundamental chemical engineering for the digital age

I.-S. Porschewski[1]

1 Dr.-Ing. Ingrid S. Porschewski, Technische Hochschule Bingen, Berlinstr. 109, 55411 Bingen, Germany;

Highlights

- going digital requires a rethinking of education
- basic units have to be linked to show dependencies
- arrangement of knowledge and documentation of thoughts have to be dealt with

1. Introduction

Industrial settings change over time due to economic and environmental demands or new products. Today we find ourselves in a situation where data-sets and their interpretation is focused upon. The goal is to optimize process behavior as to stability of quality, maintenance and in case of multi-purpose-plants to switch the production process automatically. All this sounds familiar, although the working environment has changed. Modern software packages allow to simulate models, calculate statistics and look up data to manage the production on an everyday basis. This changes the speed of decision making and the kind and amount of knowledge which is needed to perform. On viewing this my colleagues and I decided to adapt the bachelor and master study courses accordingly. What followed was a turmoil of changes and a new concept of the courses which development is still in progress, since process engineering is on its way to create a digital twin.

2. Methods

In the former courses the topics were presented via static sheets, for each topic a problem was solved using a pocket calculator. Optimizations or variations of the problem were roughly estimated, some of the solutions were shown on slides or using an excel-worksheet. Graphs were drawn to show dependencies or to construct thermal stages. Handling of the pocket calculator, drawing the graphs and documenting the solution took more than 50% of the time. This led to a demonstration of idealized problems (only one basic unit in its clear definition). The students were in a receptive partly passive state and rarely interacted in a discussion. Yet, the lack of understanding was not clearly visible, routinely done calculations with some luck in guessing advanced questions was enough to pass the course. This dissatisfying situation was contradicted by experiences in supervising bachelor / master-thesis as well as lab-courses. Students worked in interdisciplinary teams, were interested in models and discussed their problems. A conceptual change was more than necessary.

For a deeper understanding of the theoretical background it is necessary to build a theoretical classification before working on an exemplary problem, otherwise a selective search for information or solutions would be hindered in future times [1]. Research on causes of study termination show that the main reasons are pressure to perform, dominance of formulas, irrelevance of topics and lacking supervision [2]. Countries with high scores in the TIMSS-study 2015 teach mathematics and

sciences by showing how the solution is achieved and allowing students time to try for themselves followed by a discussion and subsequent variations of the problem [3].

The idea was to create a course where the models can be used in a more creative way, this should lead to a way of technical thinking and posing the right questions. An independent working group found the same concept for a future work environment and called it “Funky Prototype” [4]. The idea to calculate with Excel-Worksheets was abandoned, although stage construction was quite comprehensive, because easy to use predefined functions and interdependence of worksheets was hard or impossible to handle. This would set a focus on programming skills not on mechanical and thermal engineering. The software used is MATLAB or for training at home the comparable freeware-tools OCTAVE and SCILAB. The models are held simple but can be used in a modular way, because they are included in predefined functions. Basic programming skills and commands to call for functions, graphs or other in- and output are taught in an introductory lecture. The first two solutions are explained in detail, then the way to solve the problem is briefly outlined before the students start on their own. The outcome is discussed and later an optimization or a different setting is explored.

3. Results and discussion

Most students are eager to follow and start to develop own questions and approaches while communicating more intensely with me and with each other. Insecure students need more support while interested students excel. The sensitivity of parameters is visible more easily and the problems later in the course resemble case studies. Surprisingly almost everything, including the presentation of the theory, had to be changed. Instead of bothering with an idealized approach, approximations are applied where thinking about a meaningful threshold value is important. Optimization and interpretation of the graphs is focused upon, which shows very clearly who understands the model and the concept. Usage of model-functions (e.g. thermal equilibrium, distributions of particles) is discussed in contrast with using experimental data.

4. Conclusions

The complexity of the problems is higher, which should to be handled with care. Control of basic units and consecutive units can be integrated in the future. The idea to create a learning environment like at starship “Enterprise” in the Star Trek series, where modular solutions are recommended by a board-computer and selected by an engineer who is solely responsible for arranging the information in a meaningful way, is enchanting. Questions as to how the decision is documented, data is treated and exams are to be taken are still discussed. Students need to acquire basic digital key competences as soon as possible but not later as during their Bachelor courses.

Immersive learning: Way forward in chemical engineering education and operator training?

Jarka Glassey[1], Daniel Cermak-Sassenrath[2], Jean-Luc Dubois[3], Kevin Haelterman[4], Liesbeth Kester[5], Thies Pfeiffer[6], Michael Wilk[7], Tom van Gerven[8]

[1]School of Eng., Newcastle Uni, UK; [2]Center for Computer Games Research, IT Uni Copenhagen, [3]HR Dept, Arkema, [4]LuGus Studios, [5]Dept. of Education, Uni Utrecht, [6]Centre of Excellence for Cognitive Interaction Tech, Bielefeld Uni, [7]Performance Materials Operations Organics, Merk, [8]Dept of Chem Eng, KU Leuven

**Corresponding author: Jarka.glassey@ncl.ac.uk*

Highlights

- Benefits of immersive learning technologies in chemical engineering education highlighted.
- Overview of current attitudes to safety training provided.
- Challenges in measuring learning gain through these approaches discussed.

1. Introduction

Chemical engineering education is influenced not only by the significant changes in the process industries, including Industry 4.0 concept, but also in rapidly changing educational experiences and expectations of the future chemical engineers. A 2016 survey by Hanover Research and McGraw Hill Education shows that 84% of college students report that the use of technology improves their education, 81% report that digital learning technology helps save them time and be more efficient, and 81% claim that digital-learning technology is helping them boost their grades [1].

Digital game-based learning is an excellent tool to teach conceptual and procedural knowledge and competences in an interactive and participative manner, hence complementing conventional teaching methods in the acquisition of experience in meta-level thinking, on-going learning and constructive problem solving [2]. Digital games contribute to the intrinsic motivation of the student to learn; they appeal to intuition to learn complex and abstract concepts; and the methods that are applied are considered to be very relevant by the population under the age of 25, who are growing up in a digital and mediatized environment. Virtual reality (VR) technology increases implementation efficiency, as the interactive learning material is of a digital nature and can thus be distributed to (teams of) trainees more efficiently than physical training installations.

This contribution reports on a subset of activities of an MCSA ETN Charming, which addresses this challenge by developing learning strategies, content and prototypes for the application of games and VR/augmented reality (AR) for motivating, teaching and training children, students and employees in chemistry, chemical engineering and chemical operations (Fig 1). In particular, this contribution sets out to explore the benefits of games, VR and immersive learning in safety teaching and operator training. This research builds on the results of an EIT Raw Materials sponsored project, which explored the use of gaming in engaging young pupils in concepts of recycling and thus encouraging them into chemical engineering careers. The learnings from this project were invaluable in the development and the evaluation of the work reported here.

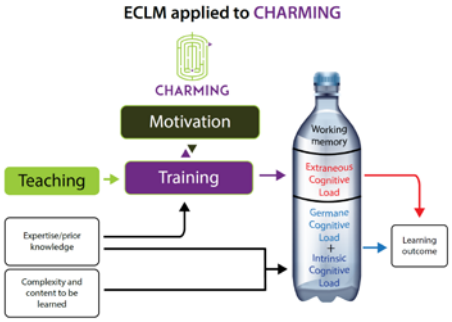

Figure 1. Motivation, Teaching and Training in the Updated and Extended Cognitive Load Model (adapted from [3]).

2. Methods

Review of current literature and case studies on the use of VR/AR in tertiary education and continuous professional development (CPD), together with latest developments in psychology, e.g. in the field of situational judgement, facilitated the development of the questionnaires to establish the current attitudes of students/operators to the use of technology for safety training. Statistical analysis of numerical responses, together with the thematic analysis of open text responses provides the starting point for the development of the VR/AR based safety training system.

3. Results and discussion

The previously mentioned research on gaming in inspiring young generation of chemical engineers by engaging them a highly topical area of recycling of various materials indicated high levels of engagement in an appropriately designed virtual environment can be achieved. With the technology savvy generation of University students and early stage professionals, this is a useful approach to engaging the professionals with the aim of increasing retention of knowledge. The analysis of industrial case studies using technology enabled safety training indicate positive impact of technology on retention of important concepts.

4. Conclusions

The VR training environment can present content for learning in new ways, thus providing grounds for creativity and innovation of new learning technologies based on an available platform. Simulation-based immersive VR training allows the trainees to explore the use of the simulated systems freely, learning about the effects and consequences, which provides them with more flexibility and deeper learning than case-based learning. This is particularly important in the highly ‘risk averse’ industry, such as the chemicals sector, where innovation is often stifled by (frequently overestimated) fear of safety issues associated with particular solutions. The results of the questionnaire analyses to establish current attitudes to technology enabled safety training will be presented. The challenges in measuring learning gain through these approaches will by highlighted in the context of these results and initial methodology of VR/AR enable training framework will be highlighted.

Birth of a Serious Escape Game for Chemical Engineering Labs

Lilian BEZARD[1], Marie DEBACQ[1], Astrid ROSSO[1]

1 Cnam, 292 rue St Martin, 75003 PARIS, France

**Corresponding author: marie.debacq@lecnam.net*

Highlights

- Increasing motivation to prepare labs.
- Promoting exchanges and cooperation between peers.
- Emulation through the game + emotions that promote learning.

1. Introduction

Starting from Japan, the United-States and different places in Europe, the escape rooms have flourished in the last decade, for fun adventure experiences with family or friends or for professional team building activities. Players work together in a team of few people, solve puzzles with the help of clues, in order to escape from a locked room, in a given period (usually about one hour). At the same time, the concept of gamification is developing in pedagogy. Nothing surprising indeed in the appearance of “serious escape games”.

It is often difficult to motivate learners to prepare the practical sessions. This is the starting idea of this project, currently under development: first experiment will take place in April-May 2019.

2. Methods

We first read some literature on the subject (for example [1-2]). Then we experimented card-based games such as Unlock [3] and Exit [4]. The playing team was composed of teachers and pedagogical engineers. During this stage, we tried to understand the “mechanics” of these games and identify types of enigmas that can be applied to a learning topic. The Mécanicartes [5] (under Creative Commons license BY-NC-SA and also provided in English and Dutch) are a relevant tool to understand and “husk” the game process. Then we set up a “scenario” for the game, based on reviews needed to prepare the labs and required preliminary calculations before moving to pilot plants experiments. We also found useful help on a French web site dedicated to pedagogical escape games [6].

3. Results, discussion and conclusions

are of course not currently available and will be presented during the congress.

The 12th EUROPEAN CONGRESS OF CHEMICAL ENGINEERING
Florence 15-19 September 2019

Mastering Digitized Chemical Engineering

Dr. Hermann J. Feise[1], Eric Schaer[2]
1 European Federation of Chemical Engineering, Rugby, United Kingdom and BASF SE, Ludwigshafen, Germany

2 Université de Lorraine, Nancy, France

**Corresponding author: Hermann.Feise@basf.com*

Highlights

- Digitization transforms the Chemical Industry rapidly across its entire chain
- New competencies will be required from chemical engineers to interact with new colleagues. The specific Engineering competencies needed for digitized Chemical Engineering are necessarily unknown, because of the fast-changing digital environment
- Data analytics tools will become standard engineering tools like CAD, FEM. The fundamentals will keep their importance, nevertheless.
- More and better lifelong learning will be required. Universities can and possibly must develop new offerings for the new learners.

1. Introduction

The chemical industry with its large world scale production units and its multi-purpose facilities is one of the energy-, raw materials- and capital-intensive industries, which currently face the challenges of the digital transformation. In these conditions, the chemical engineer's activities also have to evolve.

2. Digital Transformation

The digital transformation or Industry 4.0 is expected to change business models, allowing new efficiency gains and improving European competitiveness. In the chemical industry much of the key aspects of the digital transformation are not foreign: Internet of Things, Industrial Internet or automated ordering, have a strong history in process optimization and -automation. However, logistics and maintenance are the only two fields which have developed truly digital workflows. The way to a truly digitally transformed plant is still very long.

3. Skills and Competences

A digitally transformed chemical plant will lead to new challenges and new opportunities for chemical engineers. New tasks will be developed and colleagues with new competencies and different skills will work together with chemical engineers. This will require additive knowledge from the chemical engineer which are not part of today's engineering skill set, although some of them have been for previews generations of chemical engineers.

Drivers for the digital transformation can be found in various areas, e.g. data management systems, digital data, improved sensors for control, connectivity, simulation, spatial data. While the use of smart sensors for control has always been part of chemical engineering, neither their design or their use for simulation and optimization tools are mainstream chemical engineering tasks. Digital transformation will logically lead to the use and application of artificial intelligence systems in the industry, and should require, for example, strong knowledge and skills in (transient) simulation and optimization. This should also require an ability to critically evaluate the results provided by such systems.

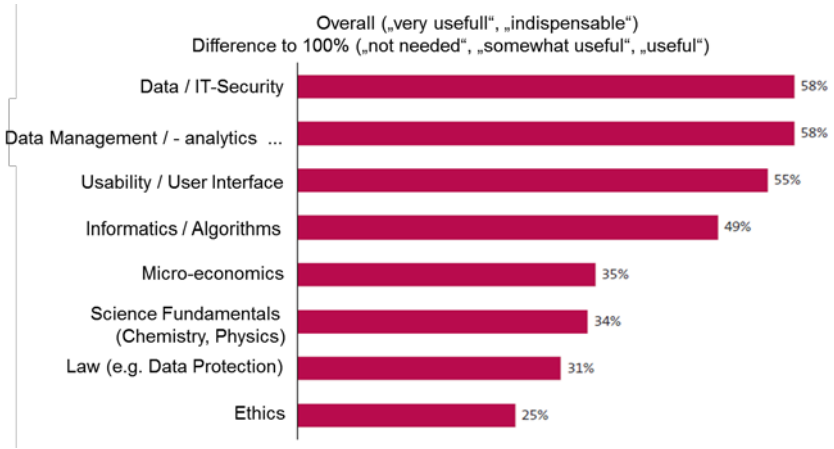

Figure 1. Industry 4.0 engineering knowledge outside the core [1]

4. Conclusions

The future chemical engineers will still have to demonstrate technical and management skills, taking into account ethics (global warming, resources depletion, well-being…) and economic aspects. The digital transformation should be seen as an opportunity, both for teaching and learning (use of virtual, augmented reality, contributions of artificial intelligence on acquisition of skills and knowledge…), as for the engineering practices, allowing to focus on innovation, interdisciplinarity and optimization.

The way to a truly digitally transformed plant is still very long, so far only logistics and maintenance have digitalized. Engineering competencies needed for digitized Chemical Engineering are necessarily unknown, because of the fast-changing digital environment. However, it will at least require: statistics, data models, data combination (vocabulary). Data analytics tools will become standard engineering tools like CAD, FEM. For the next decade we will still rely on data engineering experts, however.

Some new teaching topics should so be added in the curriculum, but as the first law of thermodynamics imposes, if the teaching duration remains unchanged, some other topics should then be removed. It is our responsibility, and interest to remain competitive and innovative, but also to meet social expectations, to think and anticipate these deep changes in the training of future chemical engineers.

Using supplementary screencasts in teaching computational tools to undergraduate chemical engineering students

Mazaher Molaei Chalchooghi*

Department of Chemical Engineering, University College London,
Torrington Place, London WC1E 7JE, United Kingdom
**m.chalchooghi@ucl.ac.uk*

Highlights

- Computational Tools in Chemical Engineering.
- Supplementary screencast videos.
- e-learning material.

1. Introduction

The application of screencast videos in teaching chemical engineering courses and their advantages have been reported [1], [2]. Screencasts are mainly used to enhance students' learning by giving them extra support through explaining certain topics or solving examples in short videos with narrations. One of the main advantages of using screencasts is that students with mixed abilities can benefit from these videos and replay them as many times as they need which will also increases student confidence [3]. This is also very useful for students with English as their second language, with hearing problem and dyslexic students.

Screencasts can either be used for flipping teaching approach [4], [5] or supplementary [6] to conventional teaching methods. In the latter, the videos are short (under 10 min) and are topic based to keep the attention of students. Also, short videos are more encouraging for students to go through this material. In this paper we will be reviewing the use of short screencast videos (~ 3 min each) as additional supplementary resources in teaching computational tools in chemical engineering.

2. Methods

In the Department of Chemical Engineering at University College London (UCL), we have already established using e-learning material to enhance students' learning in computational tools, and we have received very positive feedback from our students that it helped them to improve their learning [7]. Our undergraduate students receive some in–class lectures on use of computational tools (gPROMS, GAMS, MATLAB and Aspen Plus) followed by some computer lab tutorials. They also benefit from online-resources, which are particularly designed as supplementary material to give them extra support towards their learning, more specifically the details which cannot be covered during the in-class lectures due to the time restrictions.

After successfully implementing the use of e-learning material mainly in the form of self-learning lecture slides, the department has decided to also incorporate video learning materials in how we teach computational tools (gPROMS) in undergraduate core modules. The use of gPROMS in solving mathematical models, and in particular differential equations, of chemical process

engineering is integral to our undergraduate programmes, from Year 1 through to Year 4, during which they learn the main concepts and programming principles in gPROMS. The tool is introduced in an in-class lecture followed by two tutorials in Year 1. In Years 2 & 3 they experience advanced material only through the online resources. Yet more advanced topics are covered in Year 4 through a combination of in-class lectures and tutorials. This initial provision is now augmented by videos that have been developed by Process Systems Enterprise Ltd [8] and which are incorporated into, initially our Year 1, but will also be used for Years 2-4 going forward.

3. Results and discussion

The screencast material have very recently been introduced to our first year students and although we have received some positive feedback from those who have used this material, but we will receive more comprehensive feedback by end of the term. At the meantime, the main challenge could be encouraging students to go through this material as these are optional material and some students may not bother to approach the material. Details of students' feedback will be available to be presented in the congress. We will be reviewing students' performance through their in-class quiz (of gPROMS) and a coursework in a module known as Computational Modelling and Analysis. We will be comparing their performances to previous years which student did not have these screencast resources. We will also be tracking students' feedback and comments to Computational Modelling and Analysis, which usually happens at end of the term, and includes the use of gPROSM in solving model equations in this module.

4. Conclusions

The use of supplementary screencast material has been incorporated into teaching one of the computational tools for first year students in chemical engineering programme. So far, we have received positive feedback from students, but the details of the impact of these additional learning resources will be available by end of the term through their assessment results and also through the regular end of the term student survey.

Education 4.0: Which changes can be foreseen regarding students, higher education institutions and industry?

Michael Wilk[1], Steve Rommel[2], Marcel Liauw[3], Willi Meier[4], Hans-Ulrich Moritz[5], Bernd Schinke[6], Horst-Werner Zanthoff[7]

1 Merck KGaA, Darmstadt, Germany; 2 Konica Minolta Business Solutions GmbH, Darmstadt, Germany; 3 RWTH Aachen, Aachen, Germany; 4 Dechema e.V., Frankfurt, Germany; 5 Universität Hamburg, Hamburg, Germany; 6 Hochschule Mannheim, Mannheim, Germany; 7 Evonik Technology & Infrastructure GmbH, Marl, Germany*

**Corresponding author: michael.wilk@merckgroup.com*

Highlights

- Need for change in education matters due to digital transformation / Industry4.0 highlighted.
- Changes in student learning behavior and expectations discussed.
- Changing role of HEI considered.
- Increasing significance of life-long-learning for industry reviewed.

1. Introduction

The impact of the 4th Industrial Revolution on our future working environment is supposed to be highly significant, which already triggered a broad social discourse. Apart from many more or less speculative assumptions around the magnitude of potential job losses or which job profiles will become obsolete, an intensified discussion on the essential change requirements in educational terms is observed.

Regarding process engineers (and similar education profiles), these change requirements have been discussed within the late 2017 “Educations Days” organized by the German ProcessNet section “Education and Innovation” and hosted by Dechema e.V. in Frankfurt.

2. Methods

A highly interactive discussion in World Café and Design Thinking formats was structured following three dimensions introduced by key notes:
a) HEI 4.0: what needs to be done to make higher education institutions more agile and adaptive?
b) Student 4.0: how can we describe the learning behavior of digital natives? What is the impact?
c) Industry 4.0: what is the need for change regarding life-long-learning during professional life?

3. Results and discussion

Results have been summarized in form of theses and a White Paper is under development.
Main theses will be presented in the conference.

4. Conclusions

Three theses may serve as examples of the outcome:

A) Mastering the engineering fundamentals will remain a core competency requirement for graduates from HEIs and must be addressed appropriately. Moving towards the “VUCA world” (volatile, uncertain, complex, ambiguous), this mastery will be key to assess and solve highly complex problems or those with very limited known facts.

B) “Digital Natives” have outstanding capabilities in using and learning from digital media and benefit strongly from collaborative learning environments. Therefore, certain modern teaching and learning formats are especially well suited to improve knowledge dissemination and maximize learning outcomes.

C) To maintain employability in times with ever increasing speed of knowledge development and changing job profile requirements, the life-long-learning framework needs to be fostered. HEIs are invited to develop educational programs and offers for professionals and need to be mandated for this purpose.

An effective approach to embedded learning of professional skills contextualized in engineering practice.

Justin Siefker[1], Eva Sorensen[2]

1 Department of Chemical Engineering and Centre for Nature Inspired Engineering, University College London, London, United Kingdom;

2 Department of Chemical Engineering, University College London, London, United Kingdom

**Corresponding author: Justin.Siefker@ucl.ac.uk*

1. Introduction

Professional skills are an essential element of the modern engineering curriculum, and are required to provide graduates with the ability to competently approach the challenges of tomorrow. Even though professional skills are incorporated into engineering programs, employers still struggle to recruit graduates with sufficiently developed abilities. With industrial positions evolving in scope, do traditionally based educations adequately prepare students for the professional practice of engineering post-graduation? Unfortunately, even when professional skills are incorporated into engineering programs, this question persists as professional skills are often not embedded as integrated curricular themes facilitating continual, incremental development. While professional skills focused modules are essential for introducing new concepts, these modules are often non-technical in nature, and time-limited to a specific term. This approach routinely leads to a disjointed student experience, where professional skills are not applied within a real-world context and are disconnected from the broader curriculum, while constraining student development to a single term. On the other hand, directly embedding professional skills within core modules also leads to challenges, such as inconsistency of assessment format and evaluation criteria, tacit discouragement of incremental development, and application of professional skills in a manner not directly relevant to engineering in-practice. In particular, both approaches encourage the development of professional skills outside of a practical engineering or industrial context, and limit incremental development, as professional skills are practiced in unrelated contexts lacking a unified theme woven throughout the program. As a result, it is difficult to develop practical professional skills beyond a superficial level following these approaches.

In notable contrast to the above approaches, capstone design courses often foster significant development of practical professional skills. This often stems from the practical, integrated nature of engineering design. The quintessential design project incorporates and links core engineering theory, experimental results, process modelling, safety analyses, further impacts, and consideration of the broader context. The integration and delivery of such projects actively develops professional skills in a practical, professional context. Unfortunately, by this point of their studies, many students have already adopted poor habits, and must unlearn, acquire, and build professional skill competency within the duration of a single project. While capstone projects

enable effective development, due to their time-bound nature, they are not singularly adequate for preparing students to enter the engineering community.

2. Methods and discussion

Aside from industrial placements, design projects are often the closest to real-world practice students experience throughout their education. Acknowledgment of this reality provides the opportunity to develop an effective approach to embedding professional skills into an engineering curriculum from the onset of study. By embedding a coherent through-line of practical design, unified by a common theme and structure, the disadvantages of the classical approaches can be mitigated, and synergistic advantages arise. The elements to this approach include both professional skills focused modules and design projects embedded in core modules. Although, unlike the classical approach, the professional skill modules and embedded design projects serve only as part of a unified professional skills thread that builds rigor through the course of the program. In this manner, profession skills are holistically co-developed as essential elements of applied engineering in-practice.

3. Results and conclusions

An implementation of the discussed approach has become the favored method for professional skills development within the Department of Chemical Engineering at University College London (UCL). This approach has been enabled by the integration of a core through-line of practical design incorporate during each academic term. Multiple design projects are embedded in core modules each term and are facilitated as independent design sprints, with sequentially increasing rigor. The design projects are directly complimented by corresponding Design and Professional Skills modules, providing the requisite continuity for incremental development. The direct link between design projects and professional skills modules provides immediate context for taught professional skills, including engineering specific skills (e.g. safety evaluation, sustainability assessment, applied ethics). The success of this implementation is resultant of not only program structure, but also the structure of the design project sprints. Design projects are framed as a program nexus, with links throughout the program, and are perceived by students as independent milestones of the university experience. Herein, program structure and design project case studies will be critically discussed, focusing on both the successes and limitations of this approach.

Systematizing experimental work by a template for electronic laboratory notebooks

Patrick M. Piccione[1,*]

[1] Syngenta, 4333 Münchwilen, Switzerland;

*Corresponding author: patrick.piccione@syngenta.com

Highlights

- The general structure of scientific experimental work was abstracted, and the necessary steps highlighted.
- A structured framework to facilitate planning and execution of laboratory work by supporting the scientific thought process was developed in an ELN environment.
- The resulting template is shared to enable further use and adaptation, together with a commented example.

1. Introduction

Science relies on "quality"[1] for the essential qualities that have led to its success: reproducibility, predictability, falsifiability. Careful experimentation can be very time-consuming. In today's team-based working environment, it is therefore valuable to share work approaches openly and consistently to maximize effectiveness and minimize misunderstandings.

Electronic laboratory notebooks (ELNs) have recently soared in popularity.[2] Prior contributions in this area have focused on procedural, hardware and information technology aspects.[3,4] In addition to practical benefits (storage, sharability, and integration), ELNs offer an opportunity to structure thought. Accordingly, a systematic framework was created and embedded in Syngenta's ELN. This article shares the methodology and template so as to enable adaptations and improvements.

2. Methods

The framework was developed with the assumptions of Table 1 in mind.

Philosophical considerations	The most general science is hypothesis driven. Scientific abstraction requires interpretation to be useful. A clear purpose optimizes the benefit of work.
Practical considerations	The framework must encourage discussion between several parties - by explicitly listing assumptions and approach is beneficial. A highly structured approach induces clarity of thought. Efficiency is a key driver, leading to advance planning

Table 1. Assumptions for template development.

These principles led to the general framework in Figure 1. Syngenta uses the "Electronic Laboratory Notebook" from Dassault Systèmes. A special tab was added, which by procedure must be discussed at least with the individual's manager before formal sign-off, and experimental work.

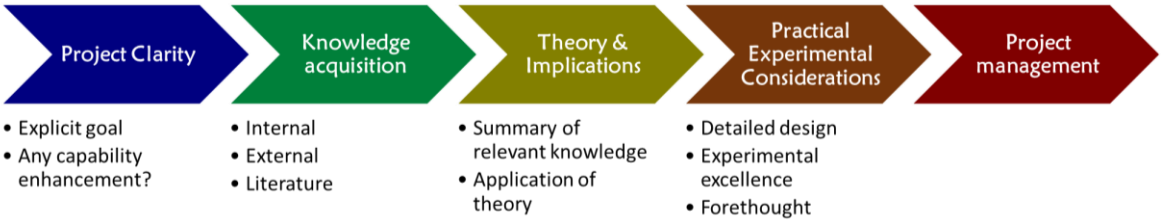

Figure 1. Successive steps in the ELN template.

3. Results and discussion

Actual experience, exemplified for mixing of a non-Newtonian fluid, showed that a compact document can be assembled with a moderate amount of effort. The compilation of relevant prior art and its implications enabled debate as well as the preparation of the later experimental work.

Strong managerial engagement to use and review the template during project discussions brought the approach alive. The best outcomes were obtained in "peer review"-type meetings. A mixed audience of both experimentalists and non-laboratory-based colleagues led to the best results. The ELN embedding allowed the framework to profit from the advantages thereof: sharability and formal validation steps; archival saving of additional insights and suggestions.

Some challenges in implementation also merit commentary. First, compiling and interpreting information takes time. Examples helped balance exhaustiveness and timeliness. Second, adoption was enhanced by writing the template steps in the natural order for performing the work.

The system has proven its value through use in many projects. By assisting scientific due diligence early on, it has ensured best long term use of resources. Specific examples include: pointing out the need for a more in-depth literature review; identifying additional measurements to be done; avoiding trials that were unlikely to lead to information; and emphasizing the calculations through which the information would ultimately be used.

Future opportunities include: the auto-generation of work reports; and modification for mathematical modeling. Different types of workflows, such as purely analytical work and academic exploratory work performed in the absence of theory, will also require adaptation.

4. Conclusions

A template has been devised to help systematize scientific work by clearly documenting: objectives; knowledge acquisition; relevant theory and its applications and expectations; and the resulting experimental considerations and plan. This framework, and its ELN implementation, enables systematic planning, as well as discussion and co-creation between researchers. The author invites others to adopt and adapt this new framework to systematize their own science workflows.

Are TRIZ and Mind Maps Two Sides of the Same Coin? Insights from a Chemical Product and Process Design Course

João Silva[1], Isabel João[2]

1 ISEL – Instituto Superior de Engenharia de Lisboa, Instituto Politécnico de Lisboa, CATHPRO/CQE, Instituto Superior Técnico, Universidade de Lisboa, Portugal; 2 ISEL – Instituto Superior de Engenharia de Lisboa, Instituto Politécnico de Lisboa, CEG-IST, Instituto Superior Técnico, Universidade de Lisboa, Portugal

Highlights

- TRIZ and Mind Maps (MM) for creative problem solving
- Creative product and process design teaching and learning with examples
- TRIZ and MM examples in Chemical Product and Process Design
- TRIZ and MM feature comparison to explore creativity development as a thinking skill

1. Introduction

In the last decades chemical engineering has undergone great changes due to the evolution of the so-called commodities for high value-added chemical products where the main issues are centered on its performance and quality [1]. Since many of the chemical products currently have little to do with the products developed a few decades ago, the portfolio of skills and technical knowledge required by the new chemical engineers has also been changing in recent years. Nowadays, chemical engineers work with a wide range of products not only commodity chemicals but mainly specialty chemicals, devices for chemical change and formulated products, this last classically classified to cover a large body of industrial sectors (e.g. paints, cosmetics, inks, pharmaceutical, personal care, household, food) [2]. It is central to prepare students for the more flexible, diverse and creative role that they are expected to perform in Chemical Product and Process Design (CPPD) activity, mainly because engineering students do not see their training as requiring much creativity [3].This work compares and contrasts TRIZ and Mind Maps to explore creativity development in ideas generation, a very important step in CPPD procedure.

2. Mind Maps and TRIZ in Chemical Product and Process Design

The TRIZ theory is based on the premise that creativity means finding a standard solution based on the premise that somebody somewhere has already solved the problem or one like it and adapting it to the current problem [4]. Genrich Altshuller developed TRIZ which is also known as TIPS and acronym of Theory of Inventive Problem Solving and known as Systematic Innovation because inventive solutions share common patterns, making TRIZ a problem-solving philosophy based on logic, data and research rather than on intuition. On the other hand, other types of creativity tools based mainly on intuition are widely used. Some of the methods usually applied for creativity enhancement are brainwriting and brainstorming that are used to develop creativity based on the assumption that a quantitative increase of ideas will bring a qualitative improvement and one

effective format to brainstorm generate ideas and get creativity development is the mind map [5] [6]. Looking at what is systematic innovation and for the intuitive processes of creativity it seems that these are at opposite poles with TRIZ suggesting a step by step excluding the intuitive approach and can be seen opposite to brainstorm and mind map techniques with try and error thinking. In this work we present examples from chemical product and process design course and we will use TRIZ and Mind Maps to explore creativity development and explore from the thinking skill perspective. Illustrative examples of mind maps are presented within the CPPD teaching and learning activities [7]. The potential of the maps to disclose students´ thinking about a topic of interest and to reveal connections and inter relationships between topics is highlighted as well as its role to develop student's creativity and thinking skills. Illustrative example of TRIZ in chemical Process Industry is presented with focus on the major challenges experienced by Chemical Process Industries to develop more sustainable processes [8]. Through a TRIZ illustration on how to deal with operational problems that can reduce energy efficiency of a distillation process the systematic innovation approach is explained (i.e. the contradiction matrix and the inventive principles).

Based on the examples developed within the DPP course, both creativity approaches (i.e. TRIZ and Mind Maps) are compared to identify the main differences and the linking issues. The main characteristics of each approach are described and the advantages of each are highlighted.

3. Conclusions

Despite the differences that exist between the systematic innovation of TRIZ and the intuitive processes of innovation where brainstorming and mind maps take place it can be concluded through the advantages identified in each method that the approaches are complementary and are the two sides of the same coin in creative problem solving and the combination can likely lead to creativity among students and development of higher order thinking skills.

Development of academics educating future generations of chemical engineers

Jarka Glassey[1], Fernando Russo Abegao[1], Sue Gill[2]

[1]School of Engineering, [2]Learning and Teaching Development Service,

Newcastle University, UK

*Corresponding author: Jarka.glassey@ncl.ac.uk

Highlights

- Benefits of a structured programme to assist engineering educators in their practice are highlighted.
- Overview of training activities is provided.
- Experiences of graduates of the programme demonstrate the added value of this training provision.

1. Introduction

Advances in learning technologies and the educational history and preferences of current generations of chemical engineering students increase the demands on the educators to develop their skills in new pedagogical methodologies, not just in technical aspects of their profession. In order to address current and future societal challenges, the future engineering professionals must be educated do develop into autonomous learners, capable of continuously acquiring new technical knowledge and essential professional competencies. Chemical engineering profession is particularly dependent on these characteristics to be fully developed in the graduates as soon as possible (preferably before graduation), although pedagogical literature clearly indicates the significant challenges in achieving these goals (e.g. [1]). Innovative pedagogical interventions, such as 'flipping' the classroom delivery and concentrating on the higher cognitive skills of the students have been identified as an effective method of deeper learning ([2], [3]). However, in order to achieve effective learning experience for the students, it is essential that the academics are confident not only in the technical aspects, but also pedagogical methodologies they need to implement. It is particularly pertinent with the move towards more technology enabled learning, when a range of tools and approaches is available to support the educators and the learners.

Newcastle University has been operating a structured programme of support and development of new-to-teaching academics for a number of decades now. This contribution will describe the structure of this training programme and highlight the experiences of the academics undertaking this course, both through the results of a survey of programme benefits and impact on the participants and through personal reflections of chemical engineering educators, who have completed the programme in recent years.

2. Programme structure

Certificate in Advanced Studies in Academic Practice (CASAP) programme aims to provide participants with the opportunity to critically reflect upon, evaluate, and develop their professional

practice as academics or support staff at Newcastle University in the light of relevant scholarship and research, responding positively to the institutional mission, the external context and the diversity of the student population. It also supports participants in developing appropriate knowledge and understanding, skills and professional values for academic practice; and the development of these, in alignment with the UK Professional Standards Framework [4]. In addition, it provides a fertile environment for participants to learn from and work effectively with colleagues from diverse academic backgrounds on matters of academic practice.

The programme brings together academics from all disciplines within the University, who undertake a series of modules including formal instruction of the latest pedagogical research developments in University-level education, technology enabled learning and assessment and practice these in active delivery of teaching. Participants are supported by experienced mentors (Faculty Programme Liaison Officers, FPLOs) – academics with long-standing experience and excellence in teaching. The assessment of the programme consists of a range of activities requiring reflection on personal practice that will be detailed during the presentation

3. Results and discussion

The effectiveness of the programme is regularly evaluated through the feedback questionnaires administered to the participants. In addition, a longitudinal evaluation of the programme was recently carried out to evaluate the long-term impact of this initiate upon the personal pedagogical practice of participants. These evaluations highlight that being observed and getting the feedback, meeting others from different backgrounds, having time to think about teaching and learning and having a professional standards adviser to talk with are highly valued by those that undertake this programme. In addition, the hands on delivery and 1:1 feedback from an observation, seeing others deliver in an engaging way, feedback on a video-recorded teaching activity, discussion and debate and working through ideas and issues with fellow teachers who do similar styles of teaching was seen a highly valuable practical support for future academic practice. In terms of pedagogical scholarship, learning about the range of learning theories and teaching methods that could extend my practice, talking to a range of teaching staff from other academic disciplines and having a teaching observation and the associated conversations and developing pedagogical vocabulary and familiarity with some teaching theories; sharing experiences; learning about new techniques; and being able to complete a project was highly valued. Detailed results and personal experiences of a chemical engineering participant will be shared during the presentation.

4. Conclusions

The importance of a structured training programme for new-to-teaching academics is highlighted through this contribution and supported by evidence from the participants. Details of the programme and the experiences of chemical engineering academics undertaking the training will be discussed in detail in the presentation.

From Jamming to Fast Compaction Dynamics in Granular Binary Mixtures.

Salvatore Pillitteri[1,*], Geoffroy Lumay[1], Eric Opsomer[1], Nicolas Vandewalle[1]

1 GRASP, Institute of Physics, Building B5a, University of Liège, 4000 Liège, Belgium.

**Corresponding author: s.pillitteri@uliege.be*

Highlights

- The maximal compacity can be optimized with the relative mass fraction of the components.
- The compaction is highly dependent on the size ratio of the beads.
- A jamming transition is observed close to the percolation threshold.

1. Introduction

The compaction of granular materials under vibrations is a popular method for powder characterization [1]. The final compacity and the typical time of compaction of a powder can be correlated to its flowability [1,2]. While the compaction dynamics is often studied with identical spheres as model particles, the polydisperse case has been poorly investigated at our knowledge. In our study, we focused on binary mixtures of spherical glass beads. We analyzed the dynamics of those systems by measuring compaction, considering both the mass fraction of small beads f and the size ratio $\alpha = d_L/d_S$, d_L and d_S respectively the diameter of large and small beads.

2. Methods

In our study, we use the automated device GranuPack from GranuTools [1,3], illustrated on the left of the Figure 1. This instrument performs free falls of Δz and measures after each tap the height *h* of the granular column. The compacity η is obtained by dividing the bulk density $\rho_{bulk} = \frac{4m}{\pi h D^2}$ by the true density of the material, $\rho_{true} = 2500\ kg/m^3$ in our case. The compaction curve is then fitted with the logarithmic law (1), as seen on the right of the Figure 1, to obtain the final compacity η_∞ and the typical time of compaction τ.

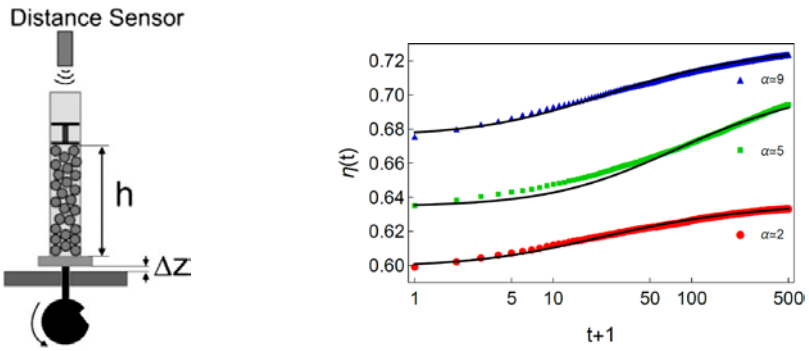

Figure 1. (left) Sketch of the experimental setup. (right) Exemples of three typical compaction curves for *f* = 0.2.

$$\eta(t) = \eta_\infty - \frac{\eta_\infty - \eta_0}{1 + \ln(1 + t/\tau)} \qquad (1)$$

3. Results and discussion

As many studies have shown, we observe that binary granular mixtures increase their maximal compacity with the size ratio of the beads. The evolution of η_∞ with f can be estimated by geometrical arguments [4,5], as seen on the left of Figure 2. Moreover, we observe experimentally a diverging typical time of compaction close to a critical size ratio $\alpha^* \approx 5.5$, as shown on the right of the Figure 2. This divergence appears in the vicinity of the percolation threshold $\alpha_c = 3 + 2\sqrt{3}$, when small particles can pass through the voids left by the large ones [6].

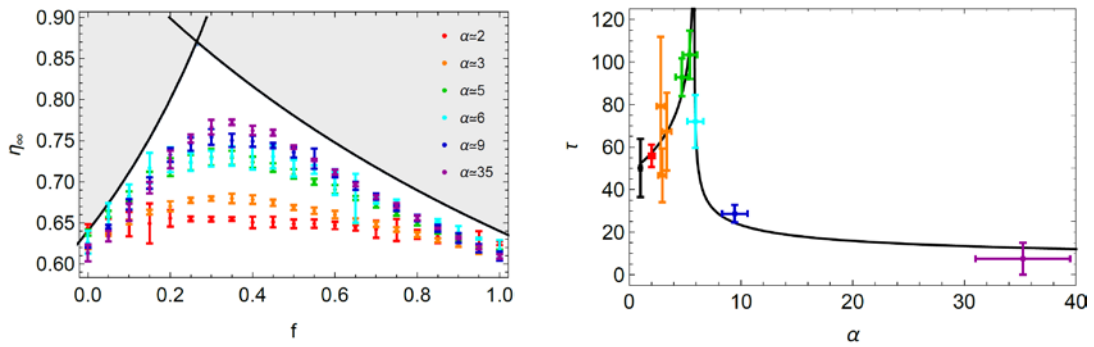

Figure 2. (left) Final compacity η_∞ depending on the fraction of small beads f for different size ratios α. (right) Typical time of compaction τ depending on the size ratio α for a fixed $f = 0.2$. The color code is the same for both graphics.

4. Conclusions

We studied the dynamics of compaction for various binary mixtures and evidenced a divergence of the typical time of compaction τ. This divergence seems to occur close to the percolation threshold and suggests that the jamming of the packing is maximum at this point.

Sustainable Performance and skills in Chemical Engineering 4.0

By Jean-Claude ANDRE and Eric SCHAER
LRGP-UMR7274 CNRS-UL, 1, rue Grandville – F54000 Nancy – France

When we enter in a process engineering classroom, what do we see? Is it in 2019 as in 2000 or 1960, close to the introduction of chemical engineering courses in France? The teacher stands at the front of the room, copying part of his/her notes, less and less often on the board, and more and more often using Power Point presentations, more or less personal, repeating aloud what he/she writes or presents on a screen.... Students sit, often passively, play with their mobile phones, a little less during the supervised exercises, which are essentially deductive, read more rarely, work on the homework of another class, or dream...

Understanding the learning environment invites us to consider the activity of today's learner in its intentional, instrumental and social components. This activity, in a formal or non-formal context, involves questioning the engineering of training systems, how to formalize processes, learning products and their evaluation. It is a complex set of approaches, not only because of the diversity of teaching methods on the one hand, but also because of the theoretical and epistemological frameworks used to describe and understand learning on the other. In Process Engineering, "teacher-researchers" are confronted with the lack of a framework for building their methods, both in terms of data production and analysis. What methods can be proposed? What criteria should be identified and defined to ensure their scientificity?

Today, the main axis of development of higher education institutions (and French Schools of Engineers) logically concerns the disciplines and contents of training. Graduates' professions are changing, sectors of activity are changing, and learners can no longer have the same skills and/or culture relative to the recent past. Among the current incremental trends, we retain the following aspects: occupation, sectors of activity, learners' cultures, the effects of spontaneous and stimulated pedagogical conservatism, etc. New knowledge is only placed on old knowledge without much change. Teaching is only partially successful: as soon as the conditions for learning are changed, common knowledge reappears. In other words, the student's mental representations are probably the main obstacle to teaching science subjects....

At the same time, our universe, which is globalized, but also weakened by different types of crises and trade wars, requires differentiated development of proactive, creative and supportive personalities: trained, through appropriate and varied accompaniments, to "juggle" variously with incessant new (artificial intelligence (AI)) or old topics, cognitive and methodological (complexity) objects, as well as material ones, without weighing down or bothering them, within a liberal and open civilization. Paradoxical tasks! Teachers and trainers can no longer be limited to mere masterful inculcations or binding and marginless imitations. They need a range of pragmatic modalities, gathered and certified cooperatively, following a progressive scientific research, in order to constitute a reasoned set of Methods and Instruments, Techniques and Values, Combinatorics and robust Modelling: that is, a varied, plural range of Engineering Sciences of training and education.

A forecasting analysis highlights various major trends (depletion of reserves, various types of pollution, clean processes, renewable energies, changes in trade, recycling, information inflation,

exploration of complexity, interdisciplinary projects, etc.). However, in the field of matter and energy transformation processes, we can observe the simultaneous presence of century-old processes (Sodium carbonate production, for example) at the same as recent activities in full development (additive manufacturing, some biotechnologies, etc.). How to manage such diverse temporalities and technological issues?

On this “simple” basis, the volume of information, which engineers are collectively called upon to know, is increasing considerably, faster than the ability of current curricula to take it into account.

This observation for an engineering domain that is rather difficult to attract students (in France), but which does not currently have any difficulty in placing graduates, raises a number of questions today:

1- How can the system of evaluating engineering education and training be made to understand the radical need to change working methods?
2- How can we anticipate a future that will have to take into consideration the complexity of the socio-technical systems covered by process engineering (PE)? How then can we support emerging problem-solving skills? How will the students be able to become successful researchers in PE?
3- How to encourage risk-taking and creativity in current training courses based on traditional deductive methods? How can it be adapted to anticipate and manage change?
4- With the development of the concept of Industry 4.0 and Artificial Intelligence, is there not a need to take this important contribution to training, saving time on basic teachings?
5- How to think about the transition concerning innovation on new processes resulting from research towards training?
6- How to take into account the notion of social and environmental responsibility in training?
7- Can we take into consideration the contributions of digital technologies to participate in training on the one hand, and in industrial development on the other? How to take into account the students' appetite for these new technologies?
8- How can we obtain "sustainable" engineers who will be able to participate in technological progress in their field of competence based on the answers to these various questions?

The increase in the knowledge required in the current disciplinary educational system, limited in time to a 3+2 year schooling, is not possible. Artificial intelligence can fill certain gaps, even more and better; it can then participate in an emerging process in the training of managers and in decision support. The emergence of AI is therefore an opportunity to rethink and relocate, in time and space, the exchanges between teachers and students, especially individualized ones. It is a world under construction that is becoming closer, going beyond the current “MOOC's” (Massive Open Online Course).

To achieve this objective, facilitators will be sought to develop the company's competitive subsidiarity, taking into account its processes and constraints (safety, supply, waste management, environment, society, etc.) as well as communication methods, a good estimate of current societal and technological movements, etc. So these are open proposals for reorienting the mission of process engineers?

It seems important that a student discovers the complexity of the subject matter of a practical question when leaving the (indispensable) disciplines learned, that he or she “goes beyond” the limits of his or her basic teaching to try to see the question in a way other than through disciplinary

filters. This is why it might be useful to introduce into a compartmentalized system the idea of a virtuous “circle” over various openings in order to achieve an updated performance... But in a world in profound change, are the characteristic times of the different changes compatible? To do nothing is a mistake, to do nothing is a risk taking! Then, let us follow Henri Bergson, a French philosopher who wrote: “Man is the only animal whose action is poorly assured, who hesitates and gropes, who forms projects with the hope of success and the fear of failure”. Let's dare...

The purpose of the presentation will concern, on the one hand, the factual elements present and envisaged in the future, but also proposals that could be the subject of questioning and debate with the GP audience.

Analysis of Problem based learning (PBL) applied in heat transfer course for chemical engineering students.

Bustos-Gutiérrez Paola[1*], Saavedra Jorge[1], Reyes Laura[1]

1 Universidad del Bío-Bío, Departamento de Ingeniería en Maderas, Escuela de Ingeniería Química

Avenida Collao 1202, Casilla 5C, Concepción, Chile

**Corresponding author: pdbustos@ubiobio.cl*

Highlights

- PBL experience in heat exchanger design was successfully implemented.
- Third year students showed an important change in perception of acquired knowledge
- Leadership, autonomy and responsibility were determining aspects in collaborative work.
- Teams with good results were those with motivation and that saw their colleagues as source of knowledge.

1. Introduction

Today, Chemical process industries (CPI) have noticed that the difference between chemicals engineers they need and professionals who are being formed at universities is actually big [1]. CPI need people with skills like, team work, communication, creativity and critical think, among others. With this in mind, universities have gradually changed their educational models from "teacher centered" to "student centered". So, academics have been forced to change their classical lectures to the use of active methodologies.

Among many others, problem based learning (PBL) has shown be able to motivate students because PBL is based in real situations, so, students feel closer to professional world [2]. Also, specifically in engineering, it has been reported that PBL is an effective tool for significant learn and for acquire several soft skills needed in the current industry [3].

2. Methods

PBL intervention was done in heat transfer course for chemical engineering students who were in 3rd year (from 5,5 years). Teams with 4 o 5 students were formed and each one received a different practical problem. The main goal of all problems was the heat exchanger design. Students were characterized with Perry's inventory and a test of long learn skills [4]. PBL was performed in 8 sessions of 80 minutes each one. Teams analyzed problem, did brainstorming, defined learning objectives and thought about the best solutions that could be implemented. Evaluation was done in different ways and in different moments of PBL process, so, rubrics were constructed. Self and peer evaluations were considered too. At the end, students answered surveys that measured team work quality and their perception of acquired knowledge during the intervention.

3. Results and discussion

Perry's inventory shows the maturity of students in order to face PBL experience, in this work, they averaged a Perry´s level of 3,5±0,3, which is consistent with their academic level and implies they yet need some teacher accompaniment as guide learning [4]. Even this, it is important to mention that teams with the same Perry´s level did not always have the same performance.

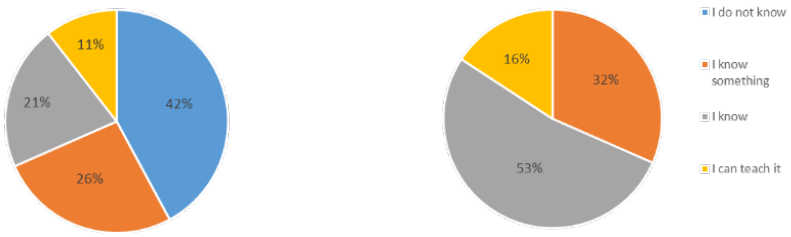

Figure 1. Percentage of responses to the statement "I know what overall heat transfer coefficient is"

Regarding the perception of knowledge, figure 1 shows the change produced in a particular conceptual aspect related to heat exchangers design. This behavior was repeated with other eight conceptual and proceeding aspects. There were no variations in attitudinal aspects, maybe because the time spent in this work was not so long. There were interesting changes in long learn skills, especially in seeing the peers as a reliable source of knowledge. Teams who improved in this aspect were who showed the best performance at the end of the experience. Concerning team work, leadership, was one of the important points associated to disagreement. Responsibility and autonomy in assigned tasks were an important source of conflict too. In spite of this, all teams finished the activity and 86% of students pointed PBL as a good methodology and strategy to do the connection between university courses theory and professional reality.

4. Conclusions

(i) In addition to Perry´s level, motivation and frustration management affected performance of the teams. (ii)The more conflictive aspects of collaborative work were: type of leadership, autonomy and responsibility. (iii) When students saw their peers as valid sources of knowledge, team work was improved. (iv) Most of students rated PBL experience as enriching, academic and personally.

Corresponding author: * romain.kapel@univ-lorraine.fr

Highlights

- Identification of models for proteolysis kinetics was realized
- Kinetic terms were correlated with operating conditions (T, pH and E/S)
- Pareto front were generated toward cost and time of reaction

1. Introduction

Enzymatic proteolysis is an effective process to improve protein properties (digestibility and functionalities). However, the enzyme cost often remains a killer for industrial proteolysis implementation. Proteolysis kinetics and performances depend on several operating conditions (pH, temperature (T), ratio Enzyme/Substrate (E/S)). To date, there is a lack of rationality in proteolysis process implementation. Several approaches were proposed to model proteolysis kinetics. At the best, these approaches were able to predict degree of hydrolysis (DH) kinetics as a function of T and protein initial concentration or E/S. But to our knowledge, no methodology for multi-objective optimization (enzymatic cost and reaction duration) has ever been proposed.

The aim of this communication is to present a new methodology for establishing Pareto front (reaction duration vs enzymatic cost) of proteolysis with a given protease / protein couple at chosen protein conversion rate (Xp) or DH values. The proposed methodology was applied to the enzymatic hydrolysis of rapeseed albumins using Alcalase 2.4L. Because of its balanced amino acid profile and good functional properties [1], this isolate can be of interest as an alternative to animal proteins for food applications. However, its digestibility is poor, requiring a comprehensive study of its proteolysis.

2. Methods

The first part of the method consisted in a simulation of DH and Xp kinetics as a function of pH, E/S and T. In order to describe this complex system 3 assumptions were made: (i) Xp and DH kinetics follow 2nd order reaction models [2], (ii) maximum hydrolysis terms (Xp_{max} and DH_{max}) only depend on pH, (iii) hydrolysis kinetic terms (k_{Xp} and k_{DH}) depend on T, pH and E/S**.** Xp_{max} and DH_{max} were determined experimentally. k_{Xp} and k_{DH} were modelled as a function of the operating conditions by an original methodology. A full factorial design of experiments (DoE) with 3 factors (T, pH and E/S) was implemented. Proteolysis kinetics (Xp and DH) were monitored during 3 h in the conditions of the DoE matrix. Kinetics were monitored by a recently published method [3] and regressed using second order model to get the corresponding kinetic terms. Then, correlation models between operating conditions (T, pH and E/S) and kinetic terms were obtained by non-linear regressions. The second part of the method consisted in implementing the obtained models with genetic-evolutionary algorithms to generate the Pareto front. These front presented the best compromises between enzymatic cost and time of reaction for desired DH or Xp value.

3. Results and discussion

First, mean peptide size *vs* DH was studied in the operating pH and T range of Alcalase at E/S between 1/15 and 1/150 for rapeseed albumin hydrolysis by Alcalase. The same trend was observed, suggesting that the same proteolysis mechanism (one-by-one type) occurred whatever the operating conditions. Then the methodology described above was applied. Xp_{max} and DH_{max} varied between 89% and 100% and 15% and 23% respectively for pH ranging from 7 to 10. DoE methodology enabled to establish correlations between pH, T and E/S and the kinetic terms (k(Xp) and k(DH)). The ANOVA showed that the 2 models were reliable. R^2 for k(Xp) and k(DH) correlations were 0.9 and 0.85 respectively. Furthermore, p-value was inferior to 0.05 and no significant lack of fit was observed.

The simulation methodology was validated with experimental kinetics in two set of operating conditions totally different from DoE matrix and with different initial protein concentration. Relative errors less than 15 % were founded between the predicted and observed values of Xp and DH for the validation conditions (Figure 1A). Then, Pareto fronts were successfully generated for different DH and Xp values.

Finally, the best DH trade-off in terms of functional properties (emulsifying and foaming properties) and *in vitro* digestibility for rapeseed albumin hydrolysis with Alcalase was searched and found at 18% DH. The Pareto front was established as explained above (Figure 1B). The figure shows that 16 mg protease /g substrate could be saved for a prolongation of 1 hour of reaction (6 instead of 5 hours of hydrolysis) in order to get the targeted DH value.

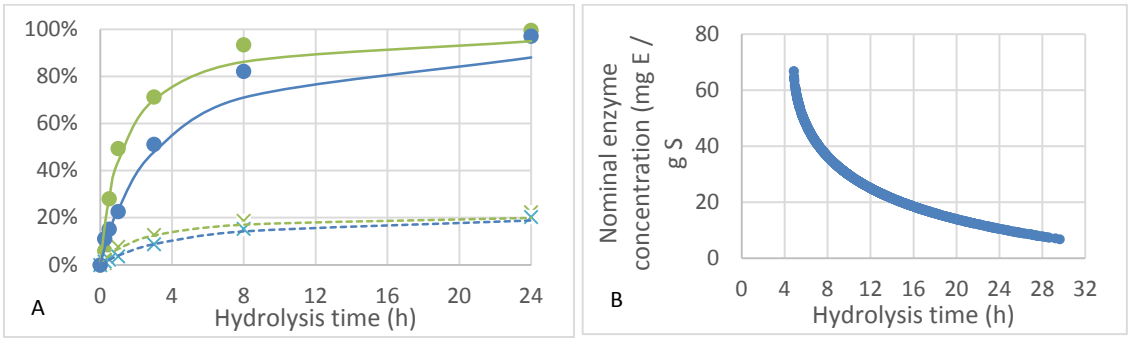

Figure 1. Experimental kinetics (cross type and round points) and predicted kinetics (dotted and solid lines) of Xp (round points; solid lines) and DH (cross type points; dotted lines) for validation points (S_0= 10 g/L in blue; S_0= 50 g/L in green) (A) and Pareto front generation (B) for DH value of the identified compromise digestibility/functionnalities.

4. Conclusions

The modelling study is a powerful tool to predict the Xp and DH values with defined operating conditions and for a given time in order to produce hydrolysates. That means significant time savings in order to characterize chosen hydrolysates toward functional properties or bioactivities (antimicrobial or antioxidant).

Hybrid modeling of bioprocesses: revisiting the direct identification method

José Pinto[1], Gerald Striedner[2], Rui Oliveira[1*]

1 REQUIMTE, FCT/Uni NOVA Lisboa, Portugal; 2 Dep. Biotechnology, BOKU University, Vienna, Austria

**Corresponding author: rmo@fct.unl.pt*

Highlights

- Modification of the direct identification method.
- Much faster and stable identification of hybrid models.
- Improved scalability of hybrid models to more complex biological systems.

1. Introduction

The general bioreactor hybrid model has been used many times to describe the dynamics of a bioprocess (e.g. Psichogios and Ungar, 1992, Oliveira, 2004). This model is primarily based on a set of material balance equations of the key substrates/products taking the form of a system of ODEs. The reaction kinetics such as the specific growth rate, m, substrate uptake, vs, and product synthesis rates, vp, are less defined parts of the model. They are the result of thousands of metabolic reactions regulated at different levels by genes, proteins and environmental factors. In hybrid models the rates are modeled by artificial neural networks (ANN) acknowledging the fact that they are too complex to be described mechanistically. The combination of ODEs with ANNs gives rise to so-called hybrid semiparametric models with particular identification challenges. Training the ANN linked with ODEs is not the same as a standalone ANN. There are two main methods to train the ANN: the direct (e.g. Tholudur & Ramirez, 1996) and the indirect method (e.g. Psichogios and Ungar, 1992). The indirect method is much more complex, slower and less flexible than the direct method but it typically produces more accurate and above all more stable results. For this reason it has been preferred in the literature.

2. Modified direct identification method

The direct identification is a two-steps method where the material balances and ANN are decoupled. In a first step the the biologic kinetic rates are calculated from the experimentally measured concentrations by solving the material balance equations (e.g. Tholudur & Ramirez, 1996). In the second step the calculated rates are used as target outputs for the training of the ANN. The training can proceed with standard techniques such as error backpropagation. In this study we propose the time integral of weighted least squares of volumetric reaction rates as cost function for ANN training in the second identification step.

3. Results and discussion

A synthetic data set was generated by simulation of a simple fed-batch bioprocess whereby biomass, X, grows on substrate, S, and produces product, P, over time, t. Gaussian noise was

added with a standard deviation of 0.3 g/L for all variables. These data are represented by the symbols in the upper panel plots of Fig. 1. The biologic kinetic rates were calculated from the concentrations by differentiation. Smoothing splines were applied to the concentrations X, S and P over time, followed by analytical differentiation of the splines function to obtain estimates of derivatives dX/dt, dS/dt and dP/dt at given time points. A Monte Carlo approach was adopted whereby the calculation of rates is repeated 100 times by adding Gaussian noise with s.d. of 0.3 g/L to the concentrations. This procedure resulted in the "experimental" reaction rates represented in the lower panel plots of Fig. 1. These data were set as target outputs of a 3-layered ANN with 1 input (substrate concentration, S) and 3 outputs (the specific rates). The results of the modified direct identification method are shown in the lower panel for the rates (full line is true property; dashed line is ANN prediction). Finally, the integration of ODEs coupled with the trained ANN resulted in the predicted concentrations shown in the upper panel plots (full line is true property; dashed line is ANN prediction)

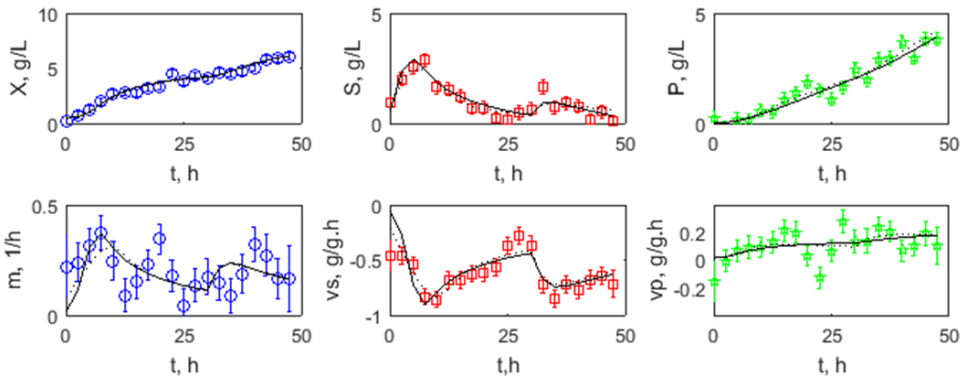

Figure 1. Hybrid modeling results using the direct identification approach. Symbols are measurements, full line is true property and dashed line is the respective hybrid model prediction. Upper panels from left to right represent concentrations of biomass (blue), substrate (red), product (green) over time. Lower panels represent from left to right the specific growth rates of biomass (blue), substrate (red) and product (green).

4. Conclusions

As seen in the results the modified indirect identification method enabled an almost perfect identification of the specific reaction rates (comparison between the full and dashed lines). Equivalent results are however also obtained with the classical direct approach. The most remarkable result is the fact that the integration of ODEs+ANN (i.e. the full hybrid model) resulted in almost perfect identification results in terms of concentrations. Opposed to this, the traditional direct identification method typically fails in the prediction of concentrations. Thus we conclude that the modified direct method has similar performance to the currently preferred indirect methods. This is very significant as the scale and complexity of hybrid models can be largely augmented by applying a much faster and much more flexible direct identification methods.

Highlights

- Highest energetic performances of bead milling are for inlet cell concentration ≥ 50 g/L
- Separation and purification steps are negatively affected by the optimal BM parameters
- Integrated optimization is required as well as techno-economic analysis.

1. Introduction

In the last years microalgae production attracted rising interest and a peak of governmental and industrial investment mainly aimed at green and sustainable food/feed and pharmaceutics production. Large segment of the current market involves the production of raw and entire biomass and only few high-value products extractions. One of the issues limiting the use of algae feedstock for several industrial fields (food, beverages, bio-plastics and bio-materials, cosmetics) is the lack of optimized downstream technology for microalgae components fractionation at industrial scale [1]. In this study, the fractionation of soluble and not soluble product is investigated for the widely recognized microalga *Chlorella vulgaris*. In particular, bead milling is used as cell disruption technology then, centrifugation and membrane filtration are applied for water soluble product separation and purification.

2. Methods

Microalgal strain

The microalgal strain used in this study was *Chlorella vulgaris*. The biomass was gently provided by MIAL (Germany) in the form of paste 20% dry matter.

Bead milling cell disruption

Disruption experiments were performed by bead milling (*Dyno-mill multi lab*) operated in pendulum mode, at temperature of 20°C, flow rate of 200 mL min^{-1} and filling ratio of 80%. Beads density, beads diameters, the rotation speed and initial biomass concentration were varied in order to test different stress intensities. Specific energy requirement for the 90% of cell disruption was calculated according to Montalescot et al. [2]:

$$E_m \propto \frac{SN_{0.9} \cdot SI}{m}$$

Centrifugation

Centrifugation parameters (speed, g and time, min) were chosen in order to meet the availability in the existing large-scale facility of GEPEA (Algosolis): 8000 g for 20 min.

Membrane filtration

The filtration process was conducted with a pilot scale filtration plant. All membranes used (0.22 µm and 3 kDa) were made of ceramic to minimize interactions between the compounds and the membrane. The transmembrane pressure (TMP) was arbitrary fixed at 2 bar for 0.22 µm membrane and 5 bar for 3 kDa which corresponds to classical transmembrane pressures for such operation. The recirculation flow rate was fixed at 250 L h^{-1}.

Biochemical analysis

The entire biomass, the solid and liquid fractions obtained from the different downstream steps were analysed for proteins, pigments, sugars and lipids content according to AOAC methods.

Technoeconomic analysis

A complete biorefinery model was proposed for the adopted strain. The techno-economic feasibility of the process was tested using the software SuperPro Designer (Intelligen Inc.).

3. Results and discussion

The combination of bead milling/centrifugation/membrane filtration was analyzed for *Chlorella vulgaris*. Optimal bead milling parameters (0.5 mm glass beads, filling ratio 80%, rotational speed of 8 m/s) and biomass concentration (150 g/L) were identified for soluble proteins release in the water fraction and for low energy consumption related to disruption step. Theoretical and experimental studies showed the impossibility of processing the lysate obtained if the optimization is solely done on bead milling. Indeed, the following centrifugation at large scale produced a liquid fraction characterized by intense green colour, high viscosity, presence of numerous small particles. The nature of the liquid fraction also prevented the exploitation of membrane filtration as solvent-free purification technology. A new refining model was proposed and validated by techno-economic analysis.

4. Conclusions

The optimal yield and energetic performances of a single downstream step (bead milling) rarely produce the optimal raw material for the following purification or transformation steps. Different solutions have been proposed and the techno-economic feasibility of the new bio-refinery process was proved.

**Corresponding author: michail.koutinas@cut.ac.cy*

Highlights

- Isolation of microorganisms adapted to drilling fluids.
- Microbial consortium characterization using next-generation sequencing.
- Monitoring of microbial consortium dynamics using quantitative polymerase chain reaction.

1. Introduction

The entire eastern Mediterranean is swimming in huge untapped oil and gas (O&G) reserves. Thus, drilling operations have recently increased considerably in Cyprus necessitating the safe disposal of drill cuttings (DC) currently posing important waste management and environmental problems mainly due to the vast quantities generated and the high content in contaminants. IESC Ltd and Cyprus University of Technology currently aim to develop an enhanced hybrid ozone oxidation-bioremediation system at pilot-scale for DC treatment producing added-value compost as well as a consortium of microorganisms with applicability in bioremediation of similar waste.

The study of population dynamics through qPCR may quantify the expression of specific metabolic routes involved in the biodegradation of different pollutants [1]. Furthermore, metagenomic methods, such as Next Generation Sequencing (NGS), employed for assessing the composition of entire environmental communities in a variety of microbial habitats have resulted in discovering new genes and gene products from uncultivated microorganisms, assembling whole genomes [2]. Recent NGS studies applied in hydrocarbon bioremediation processes have shown the crucial effect of these techniques in identifying, monitoring and estimating the proportions of degrading populations during soil bioremediation providing information for novel biocatalysts and enzymes involved [3].

The proposed waste management technology is expected to significantly reduce current thermal processing costs, while the company aims in eventually moving the novel technology for DC management to full scale and to increase its competitiveness through production of added-value commodities. The work is part of the OzoneBioPro project, which is funded from the Research Promotion foundation of Cyprus.

2. Methods

Operation of the pilot system: DC treatment involved ozonation in a 0.3 m^3 reactor followed by bioremediation (1 m^3 each installation) through composting with the addition of green waste and activated sludge. Various process parameters in ozonation and bioremediation were evaluated.

Molecular biology techniques: Total RNA isolation, cDNA synthesis and Quantitative Real-Time Polymerase Chain Reaction (Q-RT-PCR) was conducted as previously described [4].
Isolation of microbial degraders: Samples of untreated DC including oil contaminated soil and activated sludge, respectively, were used. The isolation procedure was conducted using minimal medium (M9) supplemented with drill cutting fluid following the procedure applied in [1]. The microbial isolates were identified through DNA extraction followed by PCR amplification, while the PCR products were sequenced using Next-Generation sequencing (Macrogen, the Netherlands). Analysis of obtained sequences was performed using the BLAST NCBI database.

3. Results and discussion

The objectives of the development of the hybrid ozone oxidation-bioremediation technology are explained in Fig. 1. Currently, the isolation of microbial degraders adapted to DC is finalized and the hybrid pilot unit has been designed and constructed at the premises of IESC Ltd in Limassol (Cyprus). The presentation will include evaluation of the performance of the ozonation-bioremediation system for DC treatment, evaluation of the microbial dynamics in the bioprocess using NGS and qPCR as well as characterization of the microbial consortium constructed for enhancement of DC bioremediation.

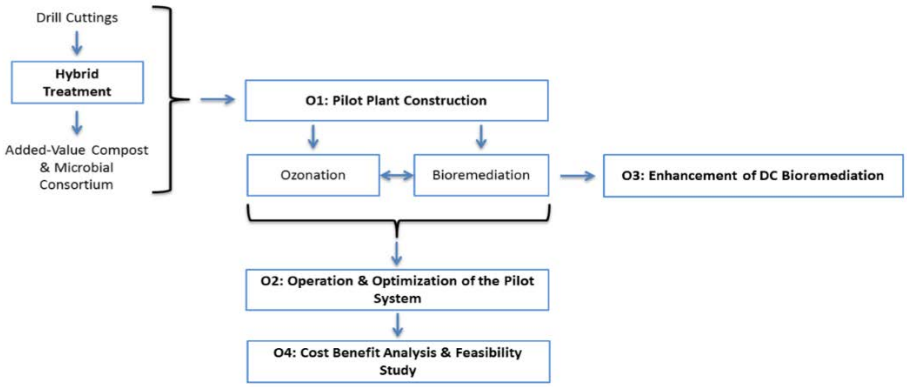

Figure 1. Outline of project objectives.

4. Conclusions

Application of NGS and qPCR for monitoring the microbial diversity, the genomes of all microorganisms incorporated and expression from specific metabolic routes in DC bioremediation will progress research beyond the current state-of-the-art through correlation of microbial diversity with the efficiency of bioremediation under different process conditions.

Aerosol Photobioreactors: a New Possibility for Cultivation of Phototrophic Biofilms.

Judith Stiefelmaier[1], Dorina Strieth[1], Björn Wrabl[1], Roland Ulber[1]*

1 Chair of Bioprocess Engineering, TU Kaiserslautern, Gottlieb-Daimler-Str. 49, 67663 Kaiserslautern, Germany

**Corresponding author: ulber@mv.uni-kl.de*

Highlights

- Terrestrial cyanobacteria are versatile organisms but only sparsely investigated.
- Aerosol photobioreactors for surface-associated cultivation of terrestrial biofilms.
- Investigation of biofilm growth under varied cultivation conditions possible.
- Investigation of surface-adhesion of biofilms on different substrates.

1. Introduction

Cyanobacteria, belonging to the oldest known microorganisms, are a diverse group of phototrophic bacteria with a wide product spectrum. For instance, cyanobacterial biomass is already used as food additive and pigments can be used as natural stains in foods, cosmetics or clothing, which fits costumer preferences. Several antimicrobial substances have already been discovered in different cyanobacterial strains and in their extracellular polymeric substances (EPS). In addition, EPS amongst others contain various polysaccharides. A subcategory of cyanobacteria represent the so-called terrestrial cyanobacteria. Those generally grow in biofilms embedded in EPS and are attached to air-exposed surfaces such as stone, soil or bark. However, due to a lack of suitable cultivation systems, terrestrial cyanobacteria have only been sparsely investigated. The emerse photobioreactors (ePBR) developed at the Chair of Bioprocess Engineering (TU Kaiserslautern, Germany) provide a possibility for the surface-associated cultivation of terrestrial cyanobacteria with media-supply via an aerosol [1]. This enables the more detailed investigation of terrestrial cyanobacteria with the prospect of finding new products.

2. Methods

The hexagonal emerse photobioreactor (hePBR) (see Figure 1 A) consists of a hexagonal glass vessel with a plastic lid, a holding for three variable cultivation surfaces and several connections. Due to the reactor geometry the biofilm on the cultivations surfaces can be lighted uniformly with LEDs. The aerosol for media-supply is generated in an extra vessel by an ultrasonic transducer based on a patent by Schmidt and Just [2] and subsequently transferred into the reactor vessel. After cultivation in the hePBR the cyanobacterial biomass was analyzed concerning EPS and pigment content. To evaluate biofilm adhesion to the cultivation surface, grown biofilms were overflown with liquid medium at different flow speeds. Biofilm deformation and peel off were documented by optical coherence tomography (OCT).

3. Results and discussion

Cultivations in the hePBR were conducted successfully at different temperatures, on different substrates and with different wavelengths of light. Hereby, the effect on biomass and EPS formation and pigment composition was investigated. Variations of cultivation conditions revealed a differing impact on biomass productivity as well as on EPS content (Figure 1 B). Furthermore, by varying light wavelengths pigment composition and content could be influenced (data not shown). Increasing adhesion of the biofilm to the cultivation surface during emerse cultivation could be shown by OCT while applying different flow velocities. This set-up allows the comparison of adhesion to different substrates and of different cyanobacterial strains.

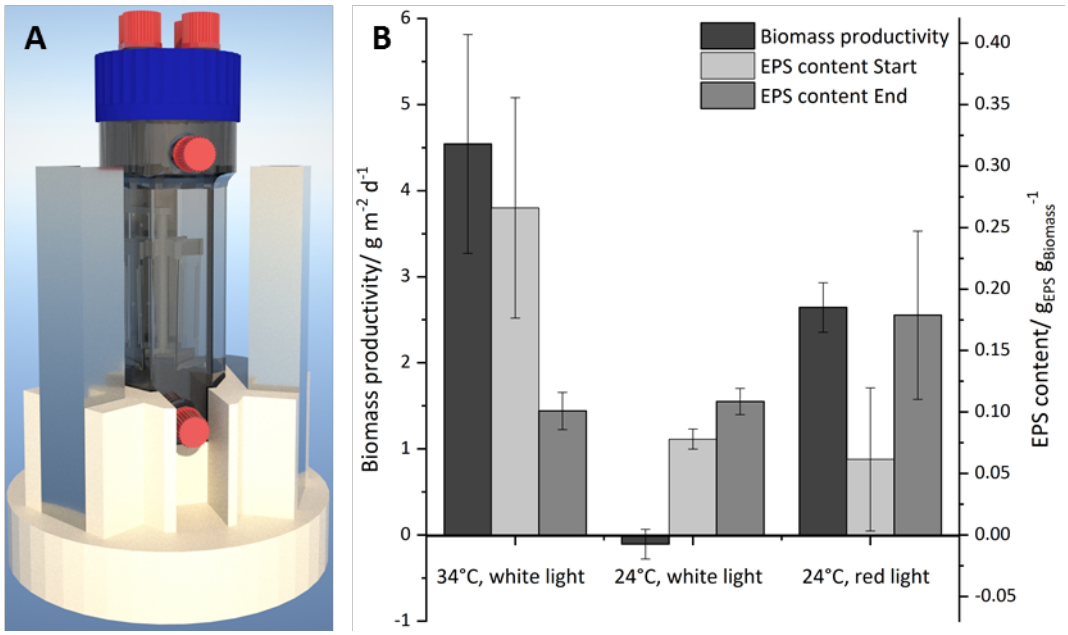

Figure 1. A: CAD model of the hePBR; B: Effect of different temperatures and light colors on biomass productivity and EPS content of *Coleofasciculus chthonoplastes*

4. Conclusions

The hePBR offers a possibility for surface-associated cultivation of terrestrial cyanobacteria. This allows the enhanced research of these microorganisms under conditions mimicking their natural habitat, which can help discovering further potential products.

Highlights

- L-lactic acid of optical purity >99% is produced from lignocellulosic biomass.
- Time of inoculation has influence on the overall yield of the SSF process.
- Using the SSF-process enables to decrease process durations <24 h.

1. Introduction

Lignocellulosic biomass is an abundant and inexpensive renewable material which does not compete with the production of food. Several lignocellulosic waste streams of agro-industrial processes yet bear the possibility to be valorized. In this study, lignocellulosic biomass was utilized as an alternative sugar source for the fermentative production of high optical pure L(+)-lactic acid (L-LA). The recalcitrant nature of the lignocellulose was overcome by the patented LX-pretreatment [1]. Mild process conditions reduce the formation of furfural or hydroxy-methylfurfural (HMF) which enhances the subsequent fermentation. Simultaneous saccharification and fermentation (SSF) is performed, employing the thermophilic bacterium *Bacillus coagulans*. Low pH and high temperature regime of the SSF allow the process to be operated under non-sterile conditions.

In classical SSF, enzymes and inoculum are added simultaneously to the vessel [2]. Additionally, fed-batch studies developed effective feeding schemes using various time points for supplement of enzyme or inoculum [3]. Nevertheless, a systematic approach is needed to understand the influence of delayed inoculum supplement to the enzyme reaction. This study aims to contribute to the development of optimized feeding schemes for SSF of lignocellulosic substrates.

2. Methods

The lignocellulosic feedstock that was used in our experiments was the fibrous effluent of an anaerobic digestion plant fed with corn silage. Pretreatment was done by the LXP Group GmbH at a dry matter content of approx. 80% employing the patented LX-method [1]. The lignocellulosic biomass was dissolved in 75 - 80% phosphoric acid at 60 to 75 °C at a ratio of approx. 1:3 (w/w) for 15 - 45 min at ambient pressure. After the dissolution was complete the carbohydrates were precipitated leading to a process stream referred to as LX-cellulose.

With this LX-cellulose, SSFs were carried out at ATB in 1 L-scale using the enzyme CellicCTec2® (Novozymes A/S, Denmark) and the thermophilic bacterium *B. coagulans* isolate A166 at 50 °C and pH 5 adding 10 g L^{-1} yeast extract as nutrient and 20% (w/w) NaOH for pH regulation. In contrast to classical SSF in which enzymes and inoculum are added at once, we also performed "delayed SSF" experiments by adding inoculum subsequently to the enzymes at different time points (0, 6 and 12 h).

3. Results and discussion

The "delayed SSF" strategy yielded in L-LA with 99.5% optical purity. Our experimental results showed that by delaying the addition of the inoculum an improvement on the overall yield of the process was achieved. Figure 1.A shows that a delay of 6 h can enhance overall yield to 10% (t = 12 h). The overall yield is given as produced lactic acid divided by the total sugars that could potentially be released from the substrate (in g_{LA} g_{Sug}^{-1}). Furthermore, from Figure 1.B it can be stated that with *B. coagulans* A166 SSF process durations of <24 h are possible. This is also due to the fact that the mild conditions of the LX-method reduce the formation of growth inhibitors during pretreatment.

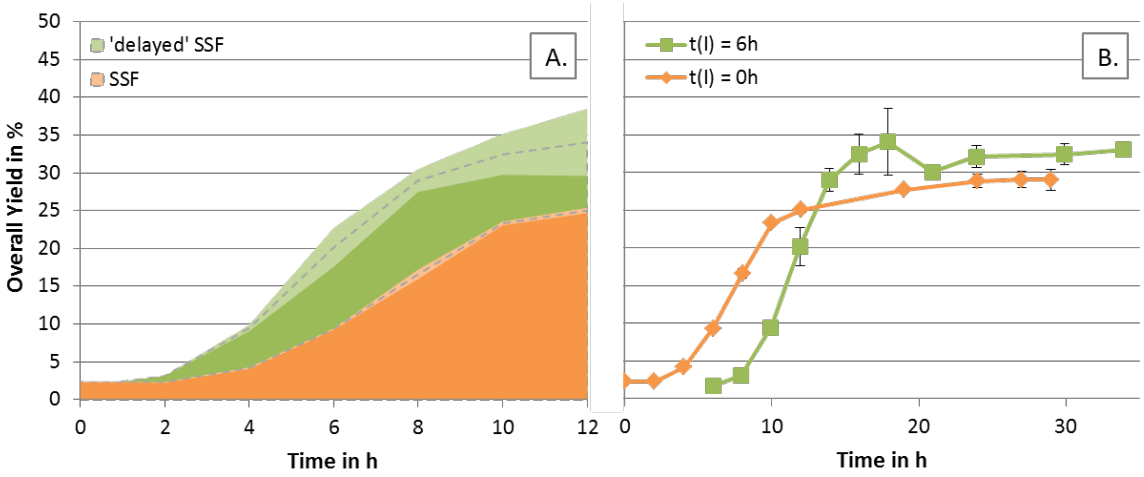

Figure 1. SSF of LX-pretreated corn silage digestate employing *B. coagulans* A166; comparison of inoculation at t(I) = 0 h and t(I) = 6 h ('delayed' SSF): A. yield over time of fermentation; B. yield over time of whole SSF process.

4. Conclusions

Our study aimed at producing high optical pure L-LA from corn silage digestate which was pretreated by the LX-method. The *B. coagulans* isolate A166 effectively fermented glucose and xylose to L-LA, reaching high productivity. The SSF experiments indicated that time of inoculation is crucial for the development of an optimal process. Final titers of around 20 g L^{-1} were obtained, with an optical purity of 99.5%.

Highlights

- *B.succiniciproducens* produced 37 g/L of succinic acid on *A. donax* hydrolysate.
- *A fermentation efficiency of about 75% was demonstrated on pilot scale FB experiments*.
- *Effective and theoretical optimized process performance was assessed via material flow analysis.*

1. Introduction

Due to its wide range of applications in the food, pharmaceutical and chemical fields, microbial synthesis of succinic acid is receiving growing attention, generating already relevant industrial results, as well as fueling constant research for improvements. In order to develop a sustainable process, a special focus is now set on the exploitation and conversion of lignocellulosic biomasses into platform chemicals.

2. Methods

Fermentation experiments were performed on a Biostat C (150 L total volume) with a working volume of 70-80 L (Sartorius Stedim; Melsungen, Germany). All fermentations were carried out at 37°C on MH medium supplemented with *A. donax* hydrolysate. The culture was sparged with CO_2 at 0.1 vvm and agitation speed was set to 100-200 rpm and a constant pH of 6.5 was maintained. For the fed-batch phase a concentrated feeding solution containing sugars and yeast extract, was added to the broth in order to prolong growth. The feeding profiles provided addition of about 33-55 g/L of total sugars either pure or diluted in *A. donax* with a rate ranging from 0.2 to 1.2 g/L·h. The global evaluation of process efficiency considering the conversion of cellulose and hemicellulose to monosaccharides and their fermentation to succinic acid was performed [2].We carried out material flow analysis (MFA) by using the STAN software (published by TU Wien, Institute for Water Quality, Resource and Waste Management) that is a freeware that follows the Austrian standard ÖNorm S 2096 (Material flow analysis – Application in waste management).Shake flask experiments were conducted in 0.1 L bottles filled with 0.1 L of medium at 37°C and 140 rpm, in a rotary shaker incubator (model Minitron, Infors, Bottmingen, Switzerland). Bottles were sealed with stainless steel headpiece caps and sterile venting filters to insufflate CO_2, before starting the

experiment and during growth. Experiments were conducted on standard MH medium supplemented with lignocellulosic hydrolysates as C source.

3. Results and discussion

In the present work we used *Basfia succiniciproducens* BPP7 in separated hydrolysis and fermentation experiments with *Arundo donax* as starting material. We developed batch and fed-batch strategies, the latter showing a maximal production of about 37 g/L of succinic acid a productivity of 0.9 g/L·h on the pilot scale. Global mass balance calculations demonstrated a hydrolysis and fermentation efficiency of about 75%.

	SA (g/L)	LA+FA/SA (g/g)	AA/SA (g/g)	SA/TA (g/g)	TA/SA (g/g)	Fermentation efficiency (%)
FB1	26.5	0.30	0.18	2.06	0.48	46.9
FB2	21.0	0.36	0.22	1.77	0.56	67.0
FB3	24.0	0.22	0.20	2.37	0.42	49.2
FB4	37.0	0.29	0.17	2.16	0.46	75.4

Table 1-Fed-batch fermentations on pilot scale. SA, succinic acid; LA, lactic acid; FA, formic acid; AA, acetic acid; TA, LA+FA+AA.

A Material Flow Analysis was applied showing that, in the identified conditions 88.5 % of succinic acid per Kg of virgin biomass used, and 52% of product on the total generated output, were obtained. Considering an optimized process that uses *A. donax* as only C source, data indicated a potential yield of about 30% of product, and an unconverted residue of 31% mainly composed of lignin, a potentially valuable feedstock for bioenergy and biochemicals production.

4. Conclusions

The use of fed-batch strategies for the growth of *B. succiniciproducens* on *A. donax* improved the titer and productivity of succinic acid on a scale that is close to industrial application. Best experimental results were analysed by material flow analysis to evaluate another aspect of industrial development and assess the performance of the entire production process.
Currently, investigations on the possibility of using other lignocellulosic biomasses and microorganisms are in progress.

Highlights

- Biochip architecture including nanowire FETs, dielectrophoresis' electrodes is developed.
- Dielectrophoresis allows to concentrate antigens in the vicinity of nanowire sensor.
- Concentrating of antigens potentiates the biochip sensitivity.

1. Introduction

Real time detection of viruses in atmospheric bioaerosol samples may be done using devices based on nanowire FET [1], [2]. Viruses' concentration in aerosol is very low in some cases. It may lead to missing the viruses in the sample due to insufficient sensor's sensitivity. Viruses in the measuring chamber volume are distributed randomly. The vicinity of nanowire has a small part of the whole chamber volume and viruses predominantly from this volume easily interact with antibodies on the nanowire. It is proposed to use dielectrophretic forces [3] for viruses' concentration near nanowire for increasing the nanowire FET biochip sensitivity.

2. Methods

Preliminary experiments were conducted using vaccinia virus (LIVP strain was obtained from the FBRI SRC VB "Vector"'s Governmental Collection of viruses) stained with FITC dye (Thermo Fisher, USA) at room temperature. A droplet (volume of about 1 µL) of suspension with low virus concentration was placed between electrodes and luminescent particles behavior was observed using dark field microscope Stemi 2000 (Zeiss, Germany). Vaccinia virus is one of the largest viruses (its dimension is about 400 nm), so its movement may be readily seen under optical dark field microscope.

3. Results

Biochip architecture including as 12 nanowire FETs as electrodes for dielectrophoresis at each nanowire FET is developed, Figure 1. Preliminary experiments showed that viruses can be

effectively concentrated by dielectrophoresis near the electrodes, Figure 2. One of these electrodes is nanowire itself.

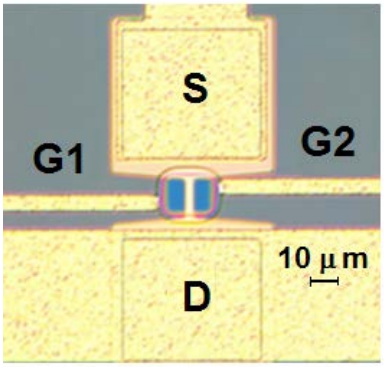

Figure 1. Top view of biochip's fragment. S – FET's source, D - FET's drain and nanowire between them; G1 and G2 - electrodes for dielectrophoresis.

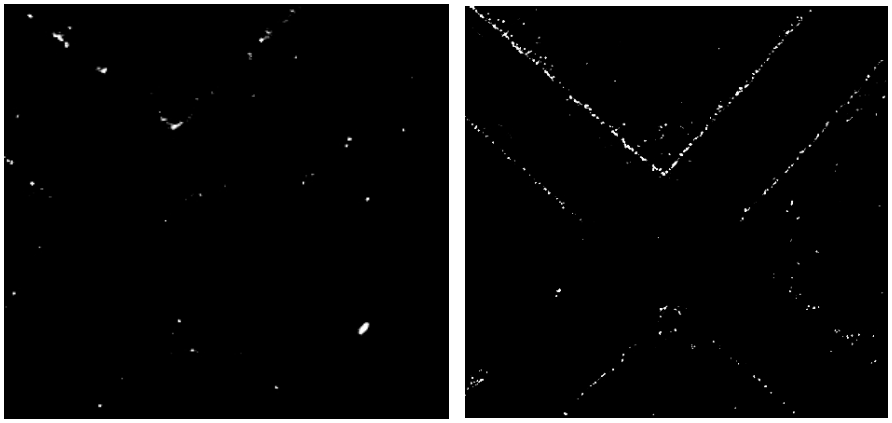

Figure 2. Distribution of vaccinia viruses (bright white dots) between perpendicular electrodes Left – no electric field applied. Right – electric field applied with frequency 200 kHz, voltage amplitude 5 V.

4. Conclusions

The results obtained visually demonstrates the possibility of viruses in bioaerosol samples to be concentrated near nanowire sensor. So the sensitivity of biochip may be increased using dielectrophoresis.

Feasibility Study of Glycolysis Using New Thermodynamic Standard Data.

Thorsten Greinert[1], Christoph Held[1]

1 Laboratory of Thermodynamics, TU Dortmund University, 44227 Dortmund, Germany

**Corresponding author: christoph.held@tu-dortmund.de*

Highlights

- Thermodynamic approach to describe reaction equilibria.
- New consistent standard Gibbs energy of reaction for glycolytic reactions.
- Thermodynamic explanation of the feasibility of the glycolysis pathway.

1. Introduction

Thermodynamics has successfully been applied to many areas of biological systems. However, application of thermodynamics to examine entire metabolic networks remains a challenging task. A prominent example for such a network is the enzymatic reaction cascade of the glycolysis pathway. The feasibility of a pathway can be explained by means of second law of thermodynamics, i.e. by the rule that Gibbs energy of reaction $\Delta^R g$ has to be negative for each single reaction. Applying this to glycolysis leads to positive $\Delta^R g$ values for some reactions, i.e. thermodynamic analyses using literature standard data predict that glycolysis is not feasible [1]. We found [2] that reasons for this phenomenon are inconsistent published data on reaction equilibria of the single reaction steps.

2. Methods

The Gibbs energy of reaction $\Delta^R g$ is determined using standard Gibbs energy of reaction $\Delta^R g^0$ and the cellular metabolite activities (expressed as ratio of products and reactants Q) and solving $\Delta^R g = \Delta^R g^0 + RT\ln Q$. In recent works it was found that published $\Delta^R g^0$ values were not determined under standard conditions (hypothetically ideal solution) [2,3]. This causes inconsistent values for $\Delta^R g^0$ and thus also unreliable $\Delta^R g$ values. $\Delta^R g$ might even be positive though the reaction has been found to be feasible under the given conditions, which leads to wrong conclusions when examining metabolic networks. Thus, the main goal of this work was to understand the thermodynamics of each single reaction step within glycolysis. Therefore, reaction equilibria were measured in-vitro and influences of the reaction medium on reaction equilibria were determined experimentally. In order to bring these experimental conditions to standard state, activity coefficients of the metabolites were measured and modeled with the electrolyte Perturbed-Chain Statistical Associating Fluid Theory (ePC-SAFT) [4].

3. Results and discussion

Combination of experimental equilibrium concentrations and activity coefficients allowed establishing an activity-based approach to describe reaction equilibria while simultaneously providing consistent standard data $\Delta^R g^0$ for the single reactions of glycolysis. Based on the new $\Delta^R g^0$ values and the activity coefficients of the metabolites, the feasibility of glycolysis could be proven in this work. This is shown in Figure 1, in which $\Delta^R g$ values calculated from literature and from new $\Delta^R g^0$ values are compared. The comparison shows, that there is a significant difference between the literature and the new data. Using new data from the introduced approach does even result in negative $\Delta^R g$ values, where using literature data resulted in positive values, which shows the relevance of new high precision standard data. Additionally, applying the new $\Delta^R g^0$ values and the activity-based approach allows predicting the influence of the reaction medium (concentrations of the metabolites, salts, pH value, temperature and cosolutes) on reaction equilibria.

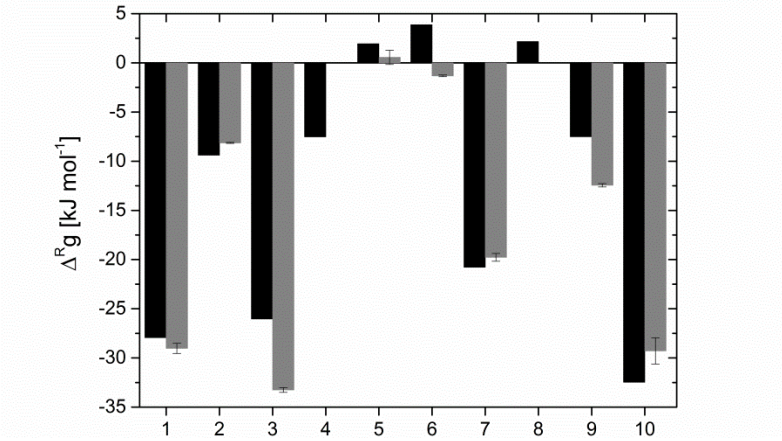

Figure 1. Gibbs energy of reaction calculated from literature (black) and new (grey) standard Gibbs energy of reaction for the ten single reaction steps of glycolysis pathway.

4. Conclusions

Inconsistent published data on reaction equilibria and standard Gibbs energy of reaction $\Delta^R g^0$ have been identified to be the reason why thermodynamic analyses failed to explain the feasibility of glycolysis. Thus, an activity-based approach has been developed which uses concentration-based equilibrium measurements and activity coefficients from modeling with ePC-SAFT in order to provide new consistent $\Delta^R g^0$ values. Based on this approach, the feasibility of glycolysis could be proven in this work. Additionally, applying the new $\Delta^R g^0$ values and the activity-based approach allows predicting the influence of the reaction medium on reaction equilibria.

Process Analytical Technology Implementation for Protein Refolding: GCSF as a Case Study

Vishwanath Hebbi, Garima Thakur, and Anurag S. Rathore*

Department of Chemical Engineering, Indian Institute of Technology, 110016, Hauz Khas, India
**Corresponding author: asrathore@biotechcmz.com*

Highlights

- Implementation of Doe and PAT is demonstrated in refolding operation
- Real-time data of redox, temperature and pH was used to build SPC charts
- MVDA based statistical charts were used to monitor and control refolding of GCSF

1. Introduction

Process analytical technology is gaining interest in the biopharmaceutical industry as a means to enable consistency in processing and thereby in product quality via process control. Protein refolding is known to be significantly impacted by critical process parameters and feed material attributes including composition and pH of the solubilization and refolding buffers. Hence, in order to achieve robust process control and product quality, these attributes and parameters need to be monitored[1]. This paper presents an approach towards statistical process control and monitoring of protein refolding utilizing the measurements of online redox potential, temperature, and pH for development of a statistical model. The model has then been integrated with LabView to permit real time monitoring of the refolding process.

2. Methods

Refolding operations were conducted at lab scale in 50 mL and 500 mL glass beakers for solubilisation and refolding, respectively. Real-time data was collected using online probes of redox, ph and temperature. Critical variables were varied in design space and operating space and their implications on critical quality attributes were analysed using HPLC. Real-time data were used to build statistical control charts using multivariate data. The model was tested for operation in design space, operating space and potential deviations.

3. Results and discussion

Continuous measurements of ORP, pH, and temperature were performed during buffer preparation and protein addition steps. The ORP signal was found to be highly sensitive to each subsequent addition, as is evident from the changes to its profile as a function of time. Temperature and pH signals provide complementary measures of process changes. Simultaneous use of multiple sensors makes the PAT tool more robust as it effectively deals with issues that otherwise arise during commercial installation including signal-to-noise variability, drifting, and unexpected failure.

Characterization of time profiles of process variables within design space

The authors defined the design space for refolding to deliver refolding yield greater than 70%, oxidized impurities below 15%, and protein concentration above 0.18 mg/mL [2]. In the present study these

findings have been utilized for design of a suitable PAT application . Eight control runs were conducted around design space and were validated through HPLC analysis.

Detection and identification and implementation of deviations with SPC charts

Figure 1 shows the Hotelling's T2 plots of the deviation batches plotted using the training model. For the solubilisation buffer, the urea deviation appears at zero minutes and the DTT deviation appears at 46 minutes. In the refolding buffer, pH deviation appears at 37 minutes, and deviations caused due to the addition of improperly solubilized IBs (due to low urea or DTT) appear when the SIB is added at 40 minutes. Once a deviation is present in the system, errors in the SPC charts persist for future time intervals, as the changes in the online measured variables of ORP, pH and temperature persist in future stages of the batch. The overlay of analytical RP-HPLC profiles corresponding to the deviations has been shown in Figure 1(c).

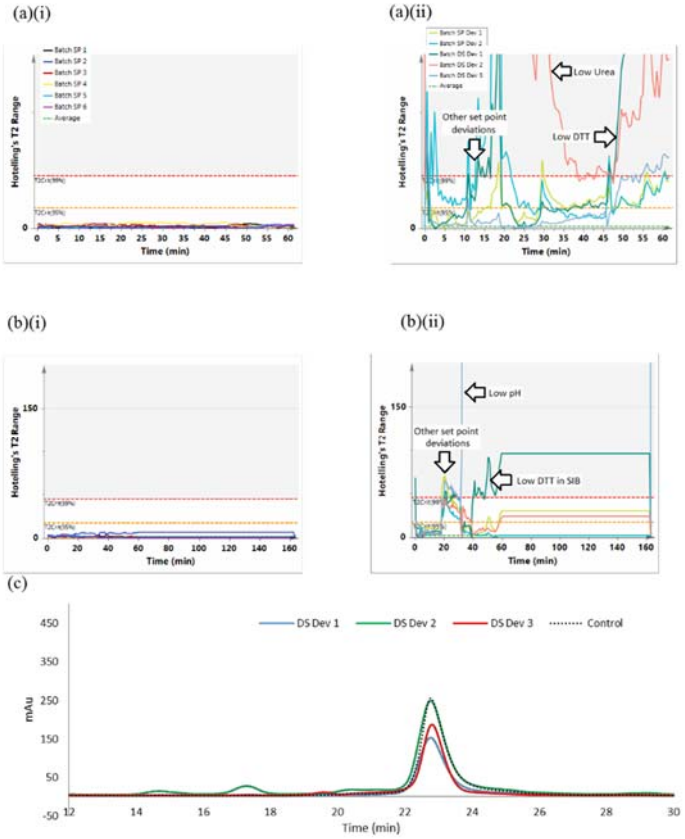

Figure 1 Hotelling's T2 charts for (a) solubilisation and (b) refolding for (i) control batches and (ii) deviation batches, (c) overlay RP-HPLC chromatograms of deviation runs and control run.

4. Conclusions

This study describes a PAT tool to monitor a complete refolding unit operation, from preparation of the solubilisation and refolding buffers to quenching of the refold. Data from online ORP, pH, and temperature probes are used to create a fingerprint of a typical refolding batch within the pre-defined design and operating spaces. A database of successful runs about a set-point is then created and used to develop statistical process control charts to monitor the evolution of the batch with respect to the addition of each subsequent component and are used in real-time monitoring for process deviations.

Syngas Mass Transfer in a Membrane Bioreactor.

Marina Elisiário[1,2], Heleen De Wever[2], Wouter van Hecke[2], Henk Noorman[1,3], Adrie Straathof[1]

1 Department of Biotechnology, Delft University of Technology, van der Maasweg 9, 2629 HZ Delft, the Netherlands; 2 Flemish Institute for Technological Research (VITO), Boeretang 200, 2400 Mol, Belgium; 3 DSM Biotechnology Center, PO Box 1, 2600 MA Delft, The Netherlands

**Corresponding author: m.perdigaoelisiario@tudelft.nl*

Highlights

- Syngas fermentation is a promising route for bio-based production of commodity chemicals
- Syngas fermentation mass transfer limitations can be overcome in a membrane bioreactor
- Mathematical models can describe mass transfer and conversions in a membrane bioreactor

1. Introduction

Syngas can be obtained from sustainable and renewable processes such as biomass and municipal waste streams gasification, water and carbon dioxide electrolysis or directly from gaseous waste streams of heavy industry (e.g. steel industry) [1]. Syngas fermentation to commodity and fine chemicals is an emergent technology in biobased economy and it is foreseen to have an important contribution against climate change, by the reduction of greenhouse gas emissions and simultaneous valorization of waste streams. Syngas fermentation for ethanol production is a process currently being established at commercial scale. Novel microbial processes are developed to drive syngas biotechnological applications towards the production of more valuable multi-carbon compounds.

At the process side, the mass transfer limitation is the major resistance for gaseous substrate diffusion, due to the low aqueous solubilities of the gaseous substrates and reduced mass transfer coefficients. This is one of the urgent challenges to be tackled in syngas fermentation to building blocks, so that sufficient productivity and product titers can be achieved [2].

Membrane bioreactors are a promising configuration for overcoming gas to liquid mass transfer limitations in syngas fermentation [3]. High gas-liquid interfacial areas can be achieved in hollow fiber membrane modules given their geometry and higher driving force can be obtained by increased transmembrane pressure. However, so far the potential of membrane bioreactors has not been systematically explored for syngas fermentation.

2. Methods

Syngas fermentation in suitable membrane bioreactors is mathematically modeled using Comsol Multiphysics, using chemostat data and literature data. This allows computational fluid dynamics calculations. Model-based optimization incorporates syngas feed rate and composition, nitrogen

source feed rate, pressure, cell concentration, product concentration, and liquid flow rate. Additionally, the model optimization results will be used for design of experiments of the membrane bioreactor at lab scale and further validation of the model.

3. Results and Discussion

The syngas substrates are fed in hollow fiber lumens and the microorganisms are maintained on the shell surface, that is, on the liquid contacting side of the membrane fibers. At many conditions, the microorganisms can form biofilms. The gaseous substrates permeate across the hollow fiber wall toward a biofilm, where the microorganisms convert the gaseous substrates into the product, which then diffuses to the liquid phase.

4. Conclusions

At sufficiently high membrane area, mass transfer kinetics does not remain limiting. Therefore, other relevant phenomena need to be taken into account as well, such as fluid dynamics, fermentation stoichiometry and kinetics, and biofilm formation kinetics.

Highlights

- The presence of exopolysaccharide improves significantly the support colonization
- The surfactin productivity of immobilized cells is higher in a continuous process mode
- A high dilution rate enhances biofilm formation on the reactor support

1. Introduction

Biofilm bioreactors have shown to be efficient cultivation systems for the production of bacterial biosurfactants [1]-[3]. They provide improved productivity and process stability through cell immobilization while avoiding foam formation. The widely known Gram-positive bacterium *B. subtilis* 168 is a potential producer of a very powerful biosurfactant, surfactin, with many applications in different industrial sectors [4]. The genome of *B. subtilis* 168 is completely sequenced and the strain can easily be genetically modified [5]. However, as a result of its domestication process, this laboratory strain is not able to produce surfactin anymore due to genetic mutations in the *sfp* gene coding for a co-factor required for the synthesis [6]. Furthermore, *B. subtilis* 168 possesses only poor biofilm formation capacities. This is mostly due to a deficiency in exopolysaccharide production [7]. In this work, different surfactin producing mutants of *B. subtilis 168* with increased adhesion and biofilm formation capacities have been investigated for the cultivation in a trickle-bed biofilm reactor [2].

2. Methods

The used *B. subtilis* 168 mutants contained all a functional *sfp* gene necessary for surfactin production. Firstly, a mutant with restored exopolysaccharide production (*epsC+*) has been selected to optimize the natural immobilization of the bacterial cells on the bioreactor support. Secondly, cell filamentation has been additionally provoked through the deletion of the *sepF* gene which is involved in the cell division process [8]. The idea was to promote further the initial cell adhesion step as well as the support colonization through this change of cell shape. The surfactin productivity and biofilm formation capacity of these mutant strains have been studied under batch and continuous process conditions in a trickle-bed biofilm reactor containing a structured metal packing with a high specific surface area for the cell colonization [1], [2]. Moreover, the effect of the dilution rate on biofilm formation has been examined.

3. Results and discussion

As expected, the *epsC+* mutants showed significant improved attachment capacities on the biofilm bioreactor support resulting in an increased surfactin productivity compared to the control strain. The restoration of the exopolysaccharides permitted the cells to produce a biofilm matrix which helps to stick the cells together for their immobilization on the reactor support. The surfactin productivity could be further increased through the transition from a batch to a continuous production mode. An increased dilution rate (D=0.5 h^{-1}) permitted to enhance the biofilm formation and thus higher cell densities on the reactor support could be achieved. By choosing a dilution rate higher than the maximum specific growth rate, the number of suspended cells could be reduced by washing out the cells. Microscope images of biofilm samples of the *epsC+ ΔsepF* mutant revealed strongly filamentous cells. The deletion of *sepF* did not affect the cell metabolism and had a minor impact on the support colonization in comparison to the presence of exopolysaccharides.

4. Conclusions

A continuous production mode is more favorable for surfactin production than the production in a batch reactor. A dilution rate that is higher than the maximum specific growth rate permits to reduce suspended cells and increase the biofilm formation in the trickle-bed biofilm reactor and thus improve the surfactin productivity. Exopolysaccharide production is important for an increased support colonization by *B. subtilis 168* whereas induced morphological changes seem to have a lower impact on the final biofilm formation but may facilitates initial adhesion on the reactor support.

Designing scale down fermentations: strategies and challenges

Amit Deshmukh[1], Cees Haringa[1], Wouter van Winden[1], Boris Zacchetti[2], Maria Metheniti[3]
Luis Portela[3], Frank Delvigne[2], Henk Noorman[1]

Corresponding author: Amit.Deshmukh@dsm.com

Highlights

- Scale down simulator design based on CFD-CRD model
- Following life lines of organism, seeing through microorganism view
- Microfluidics techniques studying single cell and population heterogeneity

1. Introduction

In microbial fermentations, it is frequently observed that upon scaling up of processes there is a loss in performance (yields/productivity/titers) due to lack of homogeneity in industrial fermentors. It is now generally recognized that a good scale down (SD) protocol is necessary to capture the inhomogeneities (for C-source, oxygen, precursors, pH, temperature, or shear stress) due to realistic mixing times at production scale. Depending on the characteristic times, one or more of these gradients may have impact on the performance of strain/process in fermentation. Developing a scale down protocol for lab-scale environment that reflects industrial heterogeneities is challenging due limited knowledge of said heterogeneity. Traditionally, a scale down protocol mimicking the heterogeneity based on characteristic times alone is insufficient as this method lacks spatial resolution.

2. SD simulator design approach

An alternative solution that was proposed was a scale down approach using a novel methodology integrating computational fluid (CFD) and reaction dynamics (CRD) modelling of industrial fermentors [1]. In these simulations, the multiphase flow and transport phenomena taking place inside the bioreactor are simulated and integrated with the microbial reaction kinetics (e.g. substrate uptake) [2]. The microorganisms inside the reactor are followed along their trajectories, where they experience a changing environment. This approach resulted in metabolic response from the microorganism point of view and provided input for experimental design of scale down simulators.

3. Strategies and Challenges

This CFD-CRD coupling is an improvement over the traditional approach for designing scale down experiments, though it brings its own challenges that need to be addressed [2]. On the CFD side, the bioreactor hydrodynamics such as macro-mixing, gas–liquid interaction, and microbial reactions are often considered dominant. However, for specific cases it may be necessary to consider to look

into meso-mixing, eddy micro mixing, film diffusion for viscous processes, including non-Newtonian rheology. On the CRD side, currently, the models coupled with CFD are limited to metabolic models but that can be extended to a broader spectrum of cellular responses (eg. transcription and translation dynamics, protein formation, cell cycles), provided the resolved timescales are sufficient to capture such dynamics. Furthermore, the CRD models should be designed by keeping its coupling with CFD in mind such as to avoid instabilities eg. noisy rates or non-zero rates at zero pool size. Computational advances are required to enable full fermentation duration, and real-time simulations.

Actual design of SD simulators is guided by the lifeline structure (smooth changes versus discrete jumps) and practical considerations. In a single vessel SD-simulator, which is straightforward to operate and analyse, all organisms see the same extracellular environment and the effect of extreme fluctuations cannot be captured. On the other hand, a multi-vessel simulator accounts for a distribution of the exposure time to the various conditions by design, but not for the distribution of the amplitude. Additionally, the operational challenges will remain such as pumping issues for shear-sensitive and complex rheology systems. While current SD simulators operating at industrial biomass concentration may capture dynamics at the average level, more rapid dynamics at the individual cell level are unattainable. Some of these challenges cannot be overcome in single system and the selection of the SD simulator will depend on the case study at hand. It was shown that single and multiple compartments do not show similar microbial response for identical extracellular disturbances [4].

The challenges still remain for the SD simulators such as to decouple rate-of-change from consumption, to impose the full range of amplitudes and (stochastic) durations, and that each cell undergoes a different experience similar to the industrial scenario. Some of these can further be tackled using advancements in microfluidic devices, using fluorescent techniques.

4. Conclusions

Integrating computational fluid (CFD) and reaction dynamics (CRD) modelling of industrial fermentors allows improved design of SD simulators. Some of the challenges remain such as improving the simulation of bioreactor hydrodynamics, coupling of CFD-CRD models, and lack of industrial scale data for model validation. Some of the issues can be solved by increasing computational power, efficient CFD-CRD models, and scaling down further to microfluidics level.

Continuous manufacturing

DESIGN OF A CONTINUOUS SEMI-PARTITION BIOREACTOR FOR *IN-SITU* (EXTRACTIVE FERMENTATION) PRODUCT REMOVAL

George .M. Teke [1], Robert .W. Pott[1]

Department of Process Engineering, University of Stellenbosch, South Africa

**Corresponding author: rpott@sun.ac.za*

Highlights

- A novel adapted bioreactor for *in-situ* product recovery (ISPR) was design and demonstrated.
- Separation profile, mixing and settling studies were conducted and evaluated.
- Mathematical model was demonstrated for mass transfer and flowrate characterization.

1. Introduction

Fermentation technology involves the use microorganism to convert simple substrates to valuable products, which find use in a variety of industries, from pharmaceuticals to fine chemicals. While fermentation technologies are commonly used, and represent a mature technology, there are nonetheless still challenges, particularly with regards low product yield and productivity caused by product inhibition, high energy consumption, mass transfer and selective metabolic issues [1], [2]. Extractive fermentation was introduced in the 1960's, as a mechanism to combat several of these issues. The technique is based on product removal while it is been formed (*in-situ*). This technology has developed over years, with usage of different separation techniques such as gas stripping, pervaporation, adsorption and liquid-liquid extraction. For the most part, many of these systems have been developed to run on batch mode operation. While development of fed-batch or continuous production systems has not received as much attention. Continuous systems, in particular, can be attractive, since yield, productivity and economies of scale can be improved over batch operation (although other operational challenges remain) [3], [4].
To give biotechnologists another operational mode from which to select from, more research needs to be focused on a robust *in-situ* design on the continuous systems of production, to be implemented for industrial use. This project presents the design and evaluation of adapted bioreactors for usage during *in situ* liquid-liquid extractive fermentation.

2. Methods

Reactor operation

The designed bioreactor is shown in Figure 1 below, this design permitted the continuous mixing and settling of two immiscible liquids. The mixing region used a Continuous stirred tank bioreactor (CSTR) while the settling region was an insert. As an exemplary two-phase system, 10 wt% of polyethylene glycol (PEG-8000) and 10wt% potassium phosphate solutions where added to the system of deionized water and stirred continuously. The addition of New Coccine dye to the mixture permits the recording of the separation profile of the liquids which was based on settling heights of the top and the bottom phases with respect to time.
Tracer solutions of 0.1M NaCl salt was used that permitted the validation and parameter fitting of a mathematical model derived to obtain the mass transfer and inter-compartmental flux values. Also, a mixing time studies was done using this tracer solution to understand the homogeneity of the systems. All experiments were done in triplicates for errors minimization.

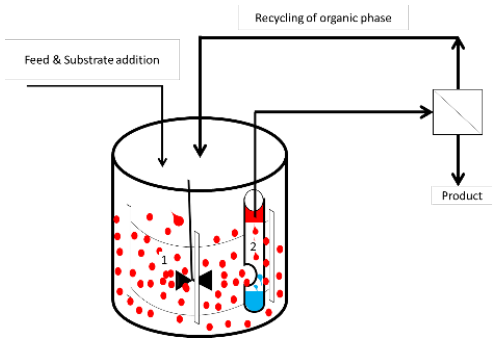

Figure 1: A Semi-Partitioning Bioreactor Diagram, 1- CSTR (Mixer) and 2- Inserted tube (settler)

3. Results and discussion

In Figure 2 below, 2(A) demonstrate a mixing and settling capacity of the designed bioreactor which is in line with other works on phase separation [5]–[7]. These previous studies demonstrate a phase boundary after settling which is not our case because the driving force of the impellers into the settler still permits some mixing as demonstrated by S (figure 2A). This indicates the possibility of a continual mixing, settling, potential substrate addition, cell or organic phase recycling, and a possibility of product/ by-product removal from the top organic phase there by reducing production cost. 2(B) demonstrated a perfectly fitted model that generates a 0.005 $l(\text{sec})^{-1}$ and 1.53 $lm^{-2}(\text{sec})^{-1}$ of flowrate and mass transfer (K_L) values respectively of the system (Semi-partitioning bioreactor) after triplicate runs. This high rate of exchange of materials is evident as there is a rapid homogeneity of the system as shown in the mixing time (t_m) curves in 2(C) with t_m being 112 seconds and 9 seconds of the settler and mixer sections respectively.

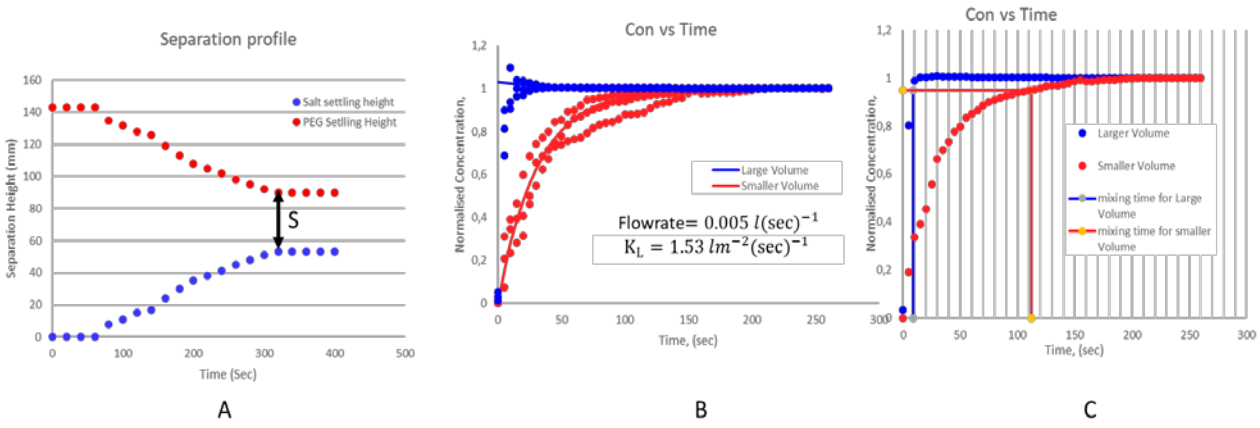

Figure 2:A Brief result summary (A)-Separation Profile, (B)- Mathematical model for Flowrate and Mass Transfer obtained (C)- Extent of mixing (Mixing time). Large volumes - mixer section while smaller volume - settler section.

4. Conclusions

The results above have demonstrated the possibility of designing a mixer-settler bioreactor which would be applicable for *in-situ* product removal. This implies there would be a continuous addition of substrate in the mixer section with a spontaneous removal of the product through settling section of the bioreactor. A mathematical model was generated for the system which made us better understand the extent of mixing or the fast rate of homogeneity in the system.

Highlights

- It shows three formulations containing dispersed phase mass fractions of 10, 20 and 30% respectively.
- Summarizes the stability presented by the microemulsions at pH changes
- Provides detailedde accelerated stability profiles

1. Introduction

The fruit of ACK presents a high content of total phenolic compounds, mainly anthocyanins; These compounds have functional properties as antioxidant activity and with potential for their use as natural dyes. However, due to their high reactivity they are highly susceptible to degradation against environmental factors such as light, temperature, pH, among others. In this way, the incorporation of these compounds in encapsulation systems allows not only provide a means of transport, but also protection and release. EM´s are translucent, optically isotropic and thermodynamically stable dispersions, which have a small droplet size (5-50 nm) and low surface tension, which can result in better permeation and high absorption of compounds. Scientifically, ME is a dispersion of oil, surfactant and water [1] and are found in such concentrations that they form spontaneously, and whose formation depends on the thermodynamic equilibrium between the aqueous, oily phases, and the surfactant. The ME can be a good liquid membrane carrier for the transport of hydrophilic substances through the lipoidal media and for transporting the hydrophobic substances through the aqueous medium [2]. In this sense, the pH of the aqueous phase has a significant effect both on the type of the emulsion and on its stability and functionality. So the objective of this research is to evaluate the kinetic stability of $ME_{W/O}$ when subjected to pH changes by determining the change in D_{hd} and its stability against sedimentation phenomena.

2. Methods

Ethanolic extracts of ACK (5 g of ACK in 50 mL of EtOH 75% v / v) were obtained. $ME_{W/O}$ were obtained by means of a low energy method, where the ethanolic extract of ACK [10-30%] was dripped in the oil phase constituted by rosemary essential oil (due to its functional properties; AER) [40-80%], and Tween 80 (T80) and Span 80 (S80) [50:50, 10-30%] as surfactants. The obtained emulsions were adjusted in their initial pH (5.0) and characterized according to their D_{hd} in a

dynamic light scattering size analyzer (NanoSizer ZS) and accelerated stability in a Lumisizer dispersion analyzer, operated at 2000 rpm with 250 measurements every 30 s [3]. From these data the sedimentation velocities were obtained for each emulsion.

3. Results and discussion

The fresh $ME_{W/O}$ presented an initial pH of 5, with purple colorations. The D_{hd} ranged from 1.82 to 3.36 nm, where at a higher concentration of aqueous phase and surfactant showed a significant reduction in droplet size ($P < 0.05$). When carrying out the pH modification it was observed that in acidic conditions the D_{hd} presented changes in all emulsions, observing significant difference for 10 and 20% concentrations of extract and surfactant. For the pH of 7 there was a significant increase in D_{hd}, of ME2, followed by ME1 (Figure 1). It is worth mentioning that ME3 was the system with the lowest pH effect. This may be due to the fact that the presence of the different counterions (OH -, H +) present in the medium, can induce the destabilization of the equilibrium reached during the formation of the ME and that, under a certain level of concentration of both extract and of surfactant, this effect is minimized. Table 1 shows the values obtained for the sedimentation rate as an accelerated stability evaluation method derived from the transmission profiles of the ME, for the ME3 it was stable, while for the ME2 it increased in the two pHs (3 and 7).

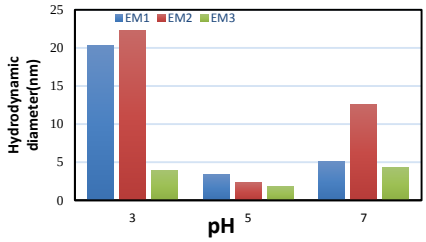

Figure 1. Effect of pH on the D_{hd} of the $ME_{O/W}$.

Tabla 1. Sedimentation rate of the $ME_{O/W}$

	Sedimentation rate (s^{-1})		
	pH 3	pH 5	pH 7
ME1	-0.1536 ±0.09	0.1156±0.04	-0.0731±0.06
ME2	0.3212±0.10	0.1707±0.02	0.3142±0.08
ME3	0.1148±0.01	0.1651±0.02	0.1497±0.09

4. Conclusions

The ME containing 30% ACK extract and 30% surfactant showed the best physical and kinetic stability with respect to pH change, while ME2 showed the highest change in its D_{hd} and higher sedimentation rates followed by ME1. The above can be attributed to the fact that the stability of these dispersed systems depends on the equilibrium achieved between the different phases involved, so that the modification of the ionic strength in the medium promotes the generation of new equilibriums that impact stability and potentially functionality of these systems. The above opens the guideline to the evaluation of the chemical stability of the materials trapped in the ME´s.

1. Introduction

Phenotypic diversification has been the focus of intensive researches during the last decade that have led to a coherent mathematical and experimental framework of molecular stochasticity in prokaryotic and eukaryotic systems. This framework has been notably used in order to decipher the impact of regulatory network structure on possible metabolic specialization in clonal population of bacteria upon diauxic shift [1][2], but we are still far from applying these knowledges to more specific case studies, e.g. bioprocess optimization where control of phenotypic diversification is desired [3]. This is partly due to the fact that most of these researches have been conducted at low spatio-temporal resolution, i.e. either on a limited numbers of cells, or focused on given time point.

2. Methods

Phenotypic diversification dynamics of E. coli strains displaying different glycolytic fluxes (i.e., either wild-type strain E. coli W3110, mutant strains ΔptsG and ΔptsGΔmanX displaying reduced glycolytic flux or mutant strain ΔompC exhibiting increased glycolytic flux) have been investigated based on automated flow cytometry [4]

.3. Results and discussion

ΔompC strain, exhibited considerably increased diversification rate in chemostat cultivation. By comparison with the other strains, a correlation between the intensity of the glycolytic flux and the phenotypic diversification rate has been established. Interestingly, this effect was increased when strains were exposed to a succession of diauxic shifts in continuous culture, suggesting the occurence of a cell-decision making process in front of environmental fluctuations.

4. Conclusions

Phenotypic diversification rate is correlated to glycolytic flux in E.coli population. This study suggest. a step forward for managing the heterogeneity of microbial systems.

Highlights

- Isopropanol-butanol-ethanol fermentation joined to gas stripping-pervaporation system
- *C. beijerinckii* DSM6423 fermented successfully industrial sugarcane-sweet sorghum juices
- 559 g/L of butanol were obtained in an IBE fermentation with gas striping-pervaporation

1. Introduction

n-Butanol is a four-carbon alcohol used as an advanced biofuel as well as a commodity chemical. It can be produced through the acetone-butanol-ethanol (ABE) or isopropanol-butanol-ethanol (IBE) fermentation by various *Clostridium* spp. in which a solvent mixture is produced. The production of isopropanol instead of acetone, which is corrosive, makes the produced mixture of solvents (IBE) to be used as fuel [1]. The raw material used for biobutanol production and the energy consumption are the major costs in an ABE [2] or IBE fermentation. Both sugarcane and sweet sorghum are crops which have high amount of soluble fermentable sugars. The low product concentrations reached in the fermentation broth, which is probably a consequence of cell toxicity by butanol, cause an intensive energy consumption. In order to overcome this problem gas stripping and pervaporation are the main recovery techniques studied for *in situ* butanol recovery process. Pervaporation coupled directly to the fermentation can present fouling in the membrane. The aim of this work was to evaluate a hybrid *in situ* gas stripping-pervaporation process to recover butanol of a batch fermentation of sugarcane and sweet sorghum juices using *C. beijerinckii* DSM 6423. Gas stripping was used to continuously remove butanol from fermentation broth, followed with pervaporation to further condense butanol.

2. Methods

Batch fermentation from the industrial medium of sugarcane and sweet sorghum juices was performed in a 2.5-L bioreactor using *Clostridium beijerinckii* DSM 6423. Fermentation conditions were: 35 ºC, initial pH 6.0 and 150 rpm. Gas stripping started at 23 h at a gas flowrate of 0.7 vvm and condenser temperature 0 ºC. Sugars were determined by HPLC using a Shodex SUGAR KS-801 column at 55 ºC and 0.7 mL/min. Organic acids and solvents were determined by GC equipped with a flame ionization detector and a fused silica column. Pervaporation assays were done with a

polydimethylsiloxane (PDMS) membrane. Pervaporation conditions were: flow rate 50 mL/min, vacuum 20 mbar, feed and condensation temperature 70 and -6 °C, respectively. An IBE aqueous solution with the same condensate composition as that obtained from the fermentation coupled with *in situ* gas stripping (I-B-E: 46-36-6 g/L) was used as the feed solution. Isopropanol, butanol and ethanol were determined by HPLC using an Aminex 87-H column at 30°C and 0.6 mL/min. To evaluate the pervaporation performance, partial permeation flux and selectivity were calculated.

3. Results and discussion

Sugar and solvent profiles are shown in Fig. 1. A sugar conversion of 98% was obtained in 158 h which demonstrated that the gas stripping system successfully mitigated butanol inhibition. As expected, sugar conversion was reflected in higher solvent concentration. Butanol and isopropanol concentrations reached were 7.8 and 10.9 g/L, respectively (total solvent as IBE 19.6 g/L). The average solvent concentration in the condensate was 47.5 g/L isopropanol, 33.1 g/L butanol, 4.9 g/L ethanol. Neither acetic nor butyric acids were detected in the condensate.

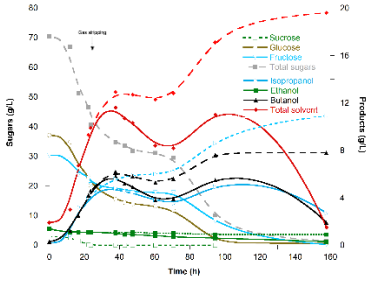

Figure 1. Fermentation batch profiles with *in situ* gas stripping from sugarcane-sweet sorghum juices. Dashed lines indicate the total production including products collected in the gas stripping condensate and those remained in the fermentation broth. The arrow indicates when the gas stripping started.

The condensate was then submitted to pervaporation for further butanol dehydration. At the beginning of the pervaporation butanol and IBE fluxes were 100 and 134 g/hm^2 respectively, which declined to 39 and 52 g/hm^2 after 38 h because of the decrease in their retentate concentrations. Isopropanol and ethanol fluxes were lower (9-32 and 1-2 g/hm^2, respectively). Butanol selectivity varied between 50-78, while for isopropanol and ethanol were stable at less than 6. The hydrophobic characteristic of the PDMS contributed to the high selectivity for butanol and low selectivity for isopropanol and ethanol. The separation efficiencies and concentration in the condensate during 38 h were: 16, 83 and 8 % and 140, 559 and 10 g/L for isopropanol, butanol and ethanol, respectively. Results showed that the membrane was effective to recover butanol from feed with high butanol concentration.

4. Conclusions

The strategy used allows alleviating butanol inhibition and to recuperate a condensate containing high butanol concentration (559 g/L), which could reduce energy consumption in the final product recovery.

Economic evaluation of sugarcane industry integrated to cogeneration system and bio-oil hydrotreatment for diesel and gasoline production.

Edvan Gonçalves[1], Lucas Rocha[1], Mara Scaliante[1], Marcelino Gimenes[1], Sérgio Faria[1], Marcos Souza[1]

1 State Universit of Maringá, Paraná, Brazil

**Corresponding author: eq.evgoncalves@gmail.com*

Highlights

- There are some technical obstacles that must be overcomed in order to become pyrolysis of biomass financially viable in front of cogeneration in the sugarcane industry.
- Advances in the area of catalysis may allow the production of diesel and gasoline through catalytic hydrotreatment of bio-oil.
- A new integrated plant concept estimates the production of diesel and gasoline from renewable sources at a very competitive price in the Brazilian market.

1. Introduction

Considering its potential for products generation, the pyrolysis of biomass has been shown to be a field of research that arouses and deserves great attention of scientific community. Such process consists of thermochemical decomposition of biomass under reduced atmosphere and results in the synthesis of three main fractions: pyrolysis liquid, biochar and gases (carbon oxides, hydrogen and hydrocarbons) [1, 2].

The chemical composition of bio-oil delimits its physical properties and its quality in the steps of storage, handling and combustion. Thus, to be used as a liquid fuel, bio-oil needs to satisfy several technical and market barriers, complying with constraints and standards of quality, and safety related to their properties (pH, viscosity, homogeneity, water content, calorific potential, acidity, among others) [3]. Therefore, several researches are being developed with proposes of improving deficiencies found in bio-oil, calling attention the process of deoxygenation by hydrogenation and catalytic hydrogenation for hydrocarbons production, which meet the composition range of diesel and gasoline [4, 5].

Nsaful et al. [6] investigated the integration of the cogeneration power system to a rapid pyrolysis process with the possibility of convert biomass energy into bio-oil or electricity. Furthermore, the results showed that it is preferable, from the economic point of view, to allocate all excess of bagasse to the generation of electricity in cogeneration systems. In constrast, it is possible to observe that the research of Dutta et al. [5] show promising results of the economic feasibility of integrating lignocellulosic pyrolysis processes with hydrotreatment and bio-oil catalytic hydrocracking for production of biofuels. Overall, considering what has been exposed, and taking account that in Brazil the sugar and ethanol plants jointly offer more than 186 million tonnes of sugarcane bagasse on the market annualy and the effects of inflation and reduction of non-

renewable fuels, this work has been proposed to study the technical and economic viability of integrating systems of energy cogeneration of sugarcane industry to the processes of rapid pyrolysis in fluidized bed coupled to hydrotreatment of bio-oil, aiming the production of diesel and gasoline.

2. Methods

The synthesis, simulation and economic evaluation of integration of energy cogeneration system of a sugar and alcohol production plant to the processes of pyrolysis of sugarcane bagasse, hydrotreatment and catalytic hydrocracking of bio-oil for the production of diesel and gasoline, product separation and vapor reforming of non-condensable gases for hydrogen production were performed using Aspen Plus™ software. The effect on financial indicators results was investigated considering the variation of biomass feed division for energy cogeneration and pyrolysis systems. The sensitivity analysis for the results of bagasse split by 50% for cogeneration and 50% for pyrolysis was developed considering variation of financial and operational parameters.

3. Results and discussion

In general, the results show that the internal rate of return on capital investment is greater for production of diesel and gasoline than for energy cogeneration. The cogeneration system shows internal rate of return of 6.9% a year while pyrolysis and hydrotreatment transformation demonstrated 12.4%. For the net sales revenues prices of fuels produced, it was possible to estimate $0.64/L (maximum of $0.70/L in sensitivity analysis), while the value practiced in the Brazilian market, in September 2018, was estimated in the range of $0.72/L and $0.88/L.

4. Conclusions

The implementation of the new concept of integration requires the commitment of greater financial resources than the current used cogeneration system. Despite this, in view of all the proposals investigated, the highest values of economic viability have been estimated for the production of diesel and gasoline through pyrolysis and catalytic hydrotreatment. The results showed that it is possible to supply these products to the Brazilian market with very competitive prices.

Techno-Economical Evaluation of the Rotating Packed Bed Technology for the Recovery of Natural Aromas from Fermentation Broth .

Ilya Lukin[1], Gerhard Schembecker[1]*

1Laboratory of Plant and Process Design TU Dortmund University, Emil-Figge-Strasse 70, D-44227 Dortmund/Germany

Dortmund/Germany

**Corresponding author: gerhard.schembecker@tu-dortmund.de*

Highlights

- RPB showed larger investment and operation costs for small-scale processes
- The cost analysis revealed the limitations of the novel technology
- The flexibility analysis covers the recovery of differently volatile aroma mixtures

1. Introduction

An increasing supplementation of products with aromas leads to an enhanced interest in biochemical production as an alternative to natural feedstock extraction[1]. Although advantageous, the economic success of aroma fermentation is still often limited by the challenging downstream process. An in-situ stripp-absorption using a Rotating Packed Bed (RPB) presents a novel approach for the recovery of natural aromas from crude biochemical broth. Our recent research shows that the mass transfer limitation of the absorption of volatile aromas can be overcome in a centrifugal field of the RPB increasing the process productivity. However, the rotation of the packing causes additional cost compared to the conventional techniques. Moreover, the lack of experience in operational boundaries and scale up parameters is yet a hurdle on the way to broad industrial application. Thus, the competitiveness of this novel technology needs to be evaluated in terms of its flexibility and costs.

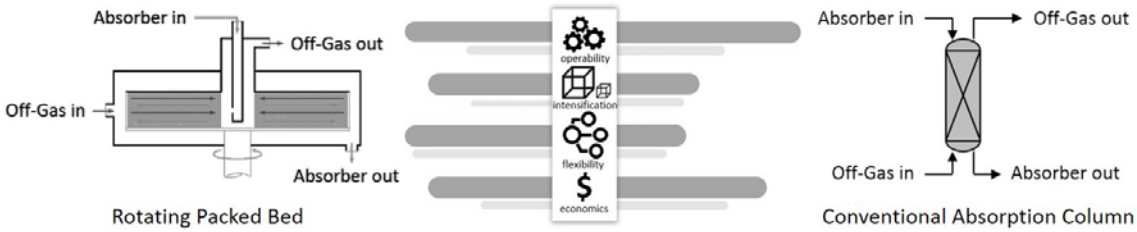

Figure 1. Techno-Economical comparison of a Rotating Packed Bed and conventional recovery techniques

2. Methods

The profitability is evaluated in terms of investment and operational costs, which are calculated in dependence of the separation task scale and difficulty. Experimental results support the analysis of the influence of the production stage parameters as well as of the physico-chemical properties of the target compound. The operational boundaries of the RPB absorption are analyzed using flexibility maps[2].

3. Results and discussion

At the conditions for the absorption of a model aroma compound from an exemplary fermentation process investigated in this study, the small scale RPB showed larger costs than a simple bubble column (Fig 2).

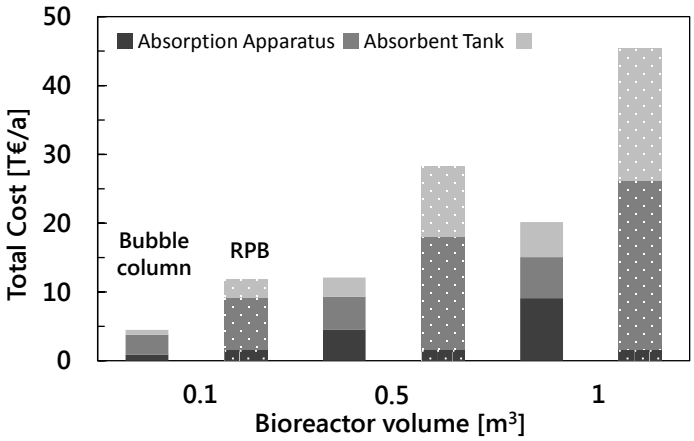

Figure 2. Total costs for the recovery of model aroma from the bioreactor off-gas for the Rotating Packed Bed and conventional Bubble Column (based on an exemplary fermentation process (100 h, 1 vvm aeration, constant aroma release, 95 % recovery) after the scale-up form laboratory experiments).

The analysis revealed that the costs of the RPB process were mainly driven by the large volume of water used as absorbent. Although low, the energy costs of RPB were three times higher than that of a bubble column. Obviously, the RPB could not fully display its advantages at operation with water. In order to reduce the absorbent consumption, the more hydrophobic liquids like plant oil were used. On the one hand, the enormous recovery increase is expected due to the rotation assisted mass transfer enhancement. On the other hand, only minor increase of operational costs is expected due to moderate pressure drop increase. Especially when dealing with highly viscous liquids like plant oil the RPB should be superior to other recovery techniques.

Further expansion to the broad range of aroma compounds of different volatility classes as well as to aroma mixtures will lead to more elaborated understanding of the technological potentials and limitations for the recovery of different products.

4. Conclusions

The stripp-absorption with Rotating Packed Bed presents a novel approach to the recovery of biochemically produced aromas. The results of the techno-economical evaluation of this potent technique will be presented. The flexibility analysis will reveal the potential and limitations of the RPB use for different classes of biotechnological aromas in comparison to classical downstream techniques.

Anaerobic digestion of model food waste at high and low concentration for the production of chemicals

Davide Dionisi,* Claudia Fernandez Martin, Serena Simonetti

University of Aberdeen, School of Engineering, Chemical and Materials Group, Aberdeen AB24 3UE, Aberdeen, Scotland, UK

**Corresponding author: davidedionisi@abdn.ac.uk*

Highlights

- Anaerobic digestion of model food waste was investigated with waste concentration in the range 25-400 gCOD/l
- The total product yield at the end of the experiments was in the range 10-13 % (COD basis), unaffected by the feed concentration
- Lactic acid and acetic acids were the main products in experiments at high and low feed concentration, respectively.

1. Introduction

Short-chain organic acids (e.g. acetic, propionic, butyric, lactic) and alcohols are usually commercially produced from fossil fuels (e.g. natural gas) or food crops (e.g. bioethanol production from corn). The production of these chemicals from the anaerobic digestion of organic waste would be in principle a more attractive and sustainable process [1, 2]. So far research on the production of these chemicals using anaerobic digestion has been mainly carried out at relatively low feed concentration, with, correspondingly, low concentration of the products, low process productivity and high separation costs. This study aims to investigate the effect of feed concentration on the anaerobic fermentation of model food waste, with the aim at achieving the highest possible product concentration and yield and process productivity.

2. Methods

The model food waste was prepared based on the estimated composition of unavoidable food waste in the UK [3]. The composition of the most concentrated waste (feed A) included the following: yeast extract 80 g/l; wheat grass powder 72.1 g/l; sucrose 66.6 g/l; oleic acid 52.6 g/l; starch 45.7 g/l; peptone 26 g/l. Distilled water was used to prepare feed A (which had a concentration of 429 gCOD/l) and the diluted feeds B (1:2 dilution, 214 gCOD/l), C (1:4, 107 gCOD/l), D (1:8, 54 gCOD/l), E (1:16, 27 gCOD/l). The batch tests were carried out in agitated 300 ml glass vessels, operated at room temperature (24-26 ^{O}C), with uncontrolled pH and inoculated with the effluent of a completely-mixed commercial digester fed with organic and food waste. The batch tests lasted 42 days and were run in duplicate.

3. Results and discussion

Figure 1 shows the main results. The concentration of total products generally increased over time and reached 40 g/l with the most concentrated feed. Interestingly, the total product yield was

virtually unaffected by the feed concentration, being in the range 10-13 % COD/COD. The pH dropped rapidly and remained acidic for feed A-D, while it increased to approximately 6.5 in the reactor with the most diluted feed (feed E), indicating some conversion of the acids into methane. A strong effect of feed concentration was observed on product distribution. The reactors with the most concentrated feeds (A, B) produced mainly lactic acid (about 80 % of the total products). The most diluted feeds (C, D, E) produced a wider spectrum of products, acetic acid being the main product, with low lactic acid concentrations. COD removal (not shown) from the liquid phase was very low with the concentrated feeds (A, B) and was the highest for the most diluted feed (E) (30 % COD removal), confirming that for this feed concentration some of the COD was converted to methane.

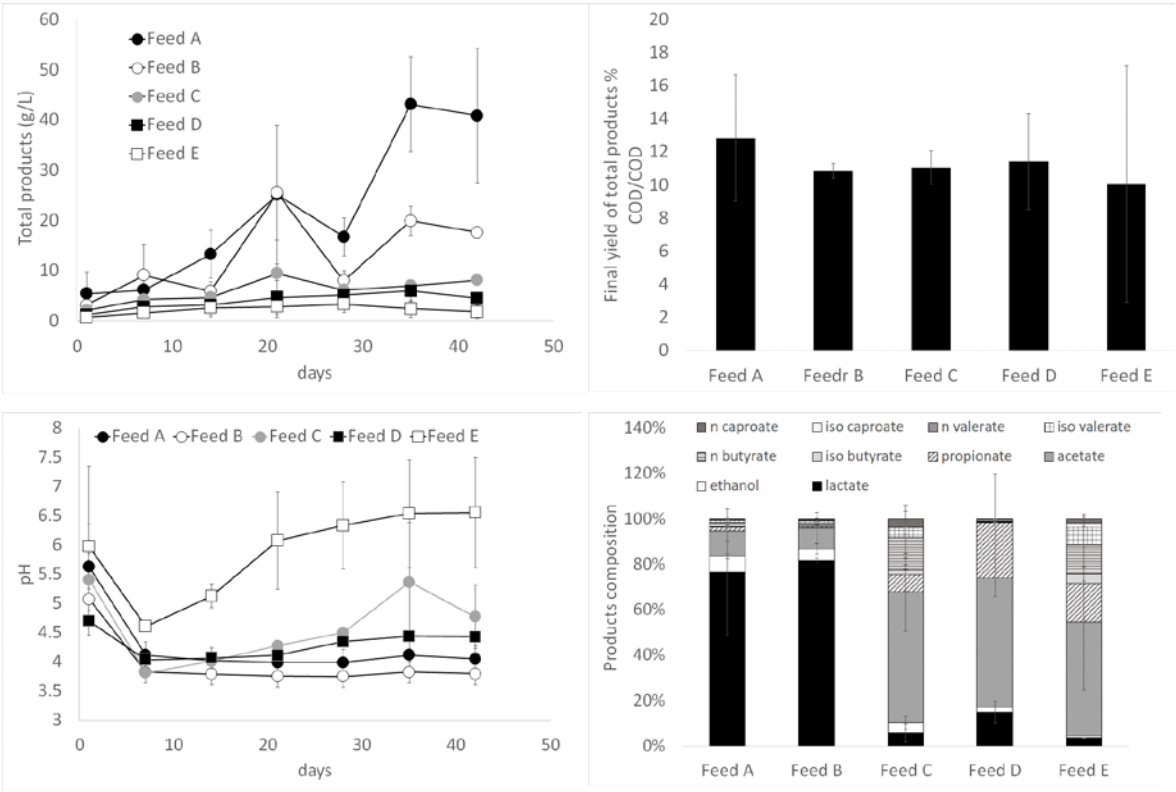

Figure 1. Main results of the batch tests

4. Conclusions

The results indicate that anaerobic digestion of food waste for the production of chemicals is feasible even with very high concentrations of the feed and with no pH correction, with no inhibition observed even a feed concentration of up to 429 gCOD/l. The research is ongoing with the aim to increase the product yield, concentration and productivity, using a combination of batch tests and SBR (Sequencing Batch Reactors) runs.

Reactive coupling: A novel approach for glycerol free biodiesel production.

Ibrahim A. Mohammed, Jonathan G.M. Lee, and Adam P. Harvey

School of Engineering, Newcastle University

**i.a.mohammed2@ncl.ac.uk*

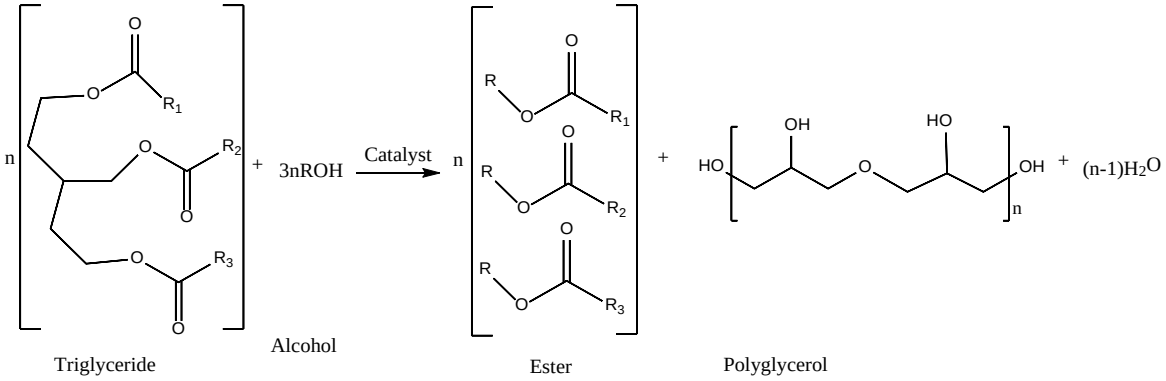
Highlights

- Simultaneous production of biodiesel and polyglycerol.
- Reduction in the use of methanol during biodiesel production.
- Conversion of the excess methanol to added value product.

1. Introduction

Using conventional processes, biodiesel production is necessarily accompanied by the production of a low value glycerol-rich co-product. There is currently a substantial worldwide surplus of this coproduct, and it is of low value due to its low quality (due to the high level s of impurity present) and oversupply. The aim of this project was to develop a process to convert the glycerol produced into polyglycerol, a higher value product, in situ. In principle, this could improve the economics of biodiesel production. The improvement would not only be via the increased coproduct value, but also by reducing the methanol requirement of the process, which would reduce the load on the distillation column (used to recycle the methanol).

The "reactive coupling" proposed is given below:



2. Methods

The coproduct will undergo step-growth polycondensation in the same pot to produce polyglycerol and water. The reaction was performed in a pressurized vessel at 130 – 160 °C with sulfuric acid as the catalyst. The effect of reaction temperature, catalyst concentration and molar ratio of triglyceride to methanol was studied. Both FAME, polyglycerols and gas sample produced were analyzed using gas chromatography. Methyl heptadecanoate (C17) was used as internal standard for the FAME and N,O Bis(trimethylsilyl)trifluoroacetamide with trimethylchlorosilane (BSTFA) was used to silylate the polyglycerol sample before analysing with the GC.

3. Results and discussion

Conversion of the triglyceride of approximately 100% was achieved. The glycerol were majorly converted to diglycerols. The glycerol conversion increased with increasing temperature and with decreasing mole ratio. The diglycerols peaks are similar to previous reports (Barros *et al.* 2017, Guerrero-Urbaneja *et al.* 2014, Ayoub and Abdullah 2013) with the α,α diglycerols isomer more predominant than the α,β diglycerols and the β,β diglycerols. A high signal around 6 minutes was observed, which was presumed to be the cyclic diglycerols with two hydroxyl groups while the glycerol and diglycerols have three and four hydroxyl group attached to them respectively.

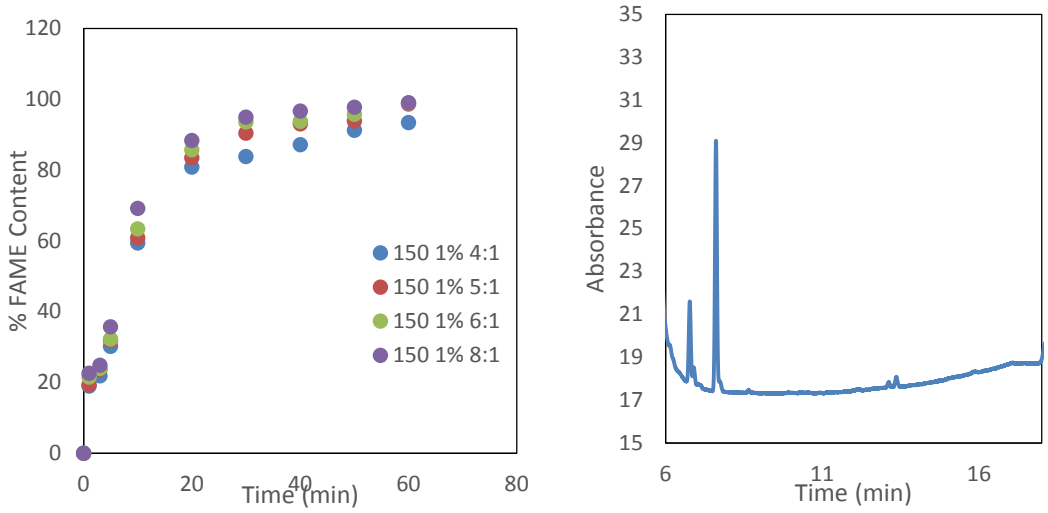


Figure 1. (a) Percentage FAME content after analysis with GC and (b) GC of the coupled glycerol during combined transesterification and reactive coupling showing the glycerol and isomers of diglycerols peaks.

The gas sample analysed were mostly methanol with few percentage of dimethyl ether (DME). This might be due to dehydration of the excess methanol in the reaction.

4. Conclusions

A proof-of-concept has been developed for this process to achieve high triglyceride conversion at low methanol-to-oil molar ratio and polyglycerols as the co-product of the reaction. The α,α diglycerols linear isomer was predominant among linear diglycerols which indicate the high selectivity of the homogeneous catalyst towards the etherification.

Enhancing the Biochemical Methanation Potential of Sugarcane Bagasse using VoDCa (Vortex based Devices for Cavitation) Pre-treatment

Sanjay Nagarajan and Vivek Vinayak Ranade*

Multiphase flows, reactors and process intensification group, School of Chemistry and Chemical Engineering, David Keir Building, Queen's University Belfast, Belfast – BT9 5AG, United Kingdom.

** Corresponding author: v.ranade@qub.ac.uk*

Highlights

- A patented Vortex based Device for Cavitation was used for bagasse pretreatment
- Effect of additives prior and during cavitation was quantified.
- Biochemical methanation potential (BMP) of untreated & pretreated bagasse were compared.
- 1st order kinetic model (with time delay) was used to describe BMP.

1. Introduction

Anaerobic digestion (AD) for biogas production is an established technology for the production of biofuels combined with waste minimisation. AD was firstly used for wastewater sludge treatment, its application was however extended to biogas production from food waste, organic fraction of municipal solid waste, agri residues, animal slurries and other lignocellulosic biomass (LCB) later. Especially, with the recent climate agreement, global interest in AD to intensify biogas production is on the rise. Although a mature technology, process instability is of concern deterring its expansion.

The predominant hindering factor is the recalcitrance of LCB feedstock. To overcome the recalcitrance and to improve its digestibility, a range of pre-treatments have been reported [1-2]. Amongst the methods available, a physico-chemical method known as cavitation was utilised in this work to pre-treat sugarcane bagasse (SCB) for enhanced biogas production. Acoustic or hydrodynamic cavitation (HC) have been reported in literature for the purpose of pre-treatment of a range of LCB's. HC is energetically favourable and relatively easier to scale up when compared to ultrasonication and hence preferred [3-5]. Conventional HC treatment were predominantly performed using orifice plates or venturi tubes as HC devices. However, these devices exhibit problems such as erosion and clogging. A recently patented device by Ranade *et al;* – vortex diode, could however be used as an alternative to conventional devices for this purpose [6]. These Vortex based Devices for Cavitation (VoDCa) have been reported to be superior than the conventional devices for simulated waste water treatment [7], and now its application has been extended for LCB pre-treatment.

In this work, we report the use of VoDCa for the pre-treatment of SCB. SCB was selected as the feedstock due to its availability, for instance, Indian sugar industries generate ~80 million tonnes annually. Additional HC investigations were performed with additives prior or during bagasse cavitation to achieve enhanced pre-treatment. Biochemical methanation potential (BMP) of the samples were then compared and the optimal pre-treatment combination was identified.

2. Methods

HC experiments were conducted in a rig with a configuration shown in Figure 1 with SCB as feedstock. Additional experiments with additives such as alkalis and H_2O_2 prior or during the HC pre-treatment were performed. Solids were characterised using a range of techniques before and after treatment. Liquid phase was analysed using a HPLC. The solids were then subjected to 1 week BMP tests to quantify the enhanced BMP due to pre-treatment. A 1st order kinetic model (with time delay) was developed and used to describe the BMP data.

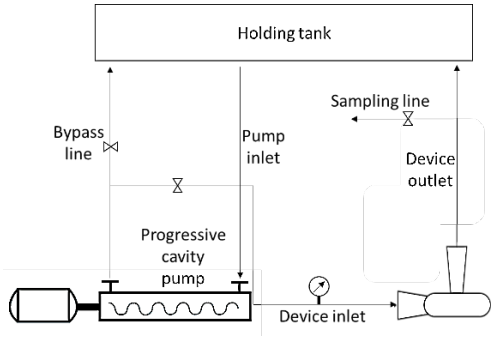

Figure 1. Experimental rig of VoDCa for bagasse pre-treatment

3. Results and discussion

There have been reports in literature that have presented results on LCB delignification using alkali (or H_2O_2)-conventional device HC combined pre-treatment of a variety of LCB for bioethanol or biogas production. Delignification is required, as the lignin, when present and broken down to phenolics, have the capability to inhibit methanogensis. It is expected that the combined pre-treatment in this case using novel VoDCa would be efficient in delignifying bagasse as well as hydrolyse a part of the polysaccharides enhancing its biodigestibility. It was shown that the model parameters obtained from 7 days of BMP data were able to simulate BMP data for longer durations. The model was then used to quantitatively understand the influence of pre-treatment combinations on delay time as well as maximum BMP. The approach and results will be useful to develop optimal pre-treatment for bagasse and other LCB valorization.

4. Conclusions

VoDCa based pre-treatment was found to enhance BMP of bagasse. The approach and results presented here are useful for developing an effective pre-treatment method for bagasse which can be easily scaled-up.

Highlights

- Biological methane production (BMP).
- Simultaneous bioreactor system (SBRS).
- CO_2-hydrogenotrophic methanogenic strains.

1. Introduction

The biological methane production (BMP) is a promising technology for CO_2 neutral energy production and storage. Usually methanogens, an archaeal group of microorganisms, are applied in biotechnological process to produce methane (CH_4), water and biomass from hydrogen (H_2) and carbon dioxide (CO_2) according to (1). There are two ways to perform the process, either in continuous or discontinuous mode. A further possibility is to use pure or industrial emission waste gas for the biomethanation [1-4].

$$CO_2 + 4\ H_2 \rightarrow CH_4 + 2\ H_2O \quad (1)$$

Primarily the bioprocess is limited by the gas-liquid mass transfer step [4-5]. This is also influenced by different factors like the geometry and velocity of the stirrer, the sparger system or gas flow rates. The prevailing partial pressure in the system is an additional coefficient. Therefore, we developed the simultaneous bioreactor system (SBRS), which operates at elevated pressure to increase the dissolved concentration of H_2 and CO_2 during the reaction. Different CO_2-hydrogenotrophic methanogenic strains were cultivated in the SBRS at a pressure of 10 and 50 bar relative.

2. Methods

The SBRS has four identical reactors. Each of them has a total volume of 160 mL, which can be used for screening of methanogens in closed batch cultivation mode at pressure up to 50 bar relative. Five different methanogenic strains are tested in the SBRS at 10 and 50 bars.

- *Methanothermobacter marburgensis* DSM 2133
- *Methanobacterium thermaggregans* DSM 3266
- *Methanobacterium palustre* DSM 3108

- *Methanobacterium subterraneum* DSM 11074
- *Methanocaldococcus villosus* DSM 22612

The microorganisms are obtained from “Deutsche Stammsammlung für Mikroorganismen und Zellkulturen”. In addition, five hyperthermophilic strains will be tested. The following key aspect were used for the experiments: they were performed with a H_2:CO_2 (4:1) substrate gas mixture, a simplified medium composition for each strain (60 mL) was used, a $Na_2S \cdot 9\ H_2O$ solution (1 v/v%) was injected and the SBRS is mounted on a laboratory shaker instead of using a stirrer.

At the end of each experiment, gas- and liquid samples were taken through the respective valves. The obtained gas samples were measured with a gas chromatograph to determine the methane off-gas concentration, while the liquid samples get reconditioned for scanning electron microscope (SEM) pictures. In addition, the biomass samples were taken, after releasing the overpressure from the SBRS. The biomass is washed by centrifugation with water and finally dried over night (105°C) to determine the dry weight.

3. Results and discussion

To describe the CO_2-BMP process different parameters like the turnover rate, the methane evolution rate (MER) and the maximum conversion rate, were selected. Calculating the turnover rate is an alternative way to determine the CH_4 productivity indirectly [6]. *M. villosus* showed an increased conversion rate, turnover rate, and MER results at 50 bar compared to 10 bar.

Through the online measurement of the pressure, it can be shown that the methanogenic CH_4 production leads to a pressure drop. The production of CH_4 was also checked by GC measurements for each experiment.

4. Conclusions

Our developed SBRS is a suitable high throughput bioreactor system for fast characterization of methanogens and gas converting microorganisms at 10 and 50 bar. All strains were successfully cultivated at 10 bar and until now also the two strains *M. Marburgensis* and *M. Villosus* were successfully cultivated at 50 bar. Further experiments with the remaining strains are planned. It has been demonstrated that gas conversion and biomethane production can be achieved in each experiment.

Optimization of batch aqueous two-phase extraction and centrifugal partition chromatography in purification of monoclonal antibodies

Wojciech Marek, Wojciech Piątkowski, Dorota Antos

Rzeszow University of Technology, Faculty of Chemistry, Department of Chemical and Process Engineering, Powstańców Warszawy Ave. 6, Rzeszów

**wmarek@prz.edu.pl*

Highlights

- Aqueous Two-Phase extraction (ATPE) was applied for purification of a monoclonal antibody.
- ATPS containing PEG and ammonium sulfate was used.
- The efficiency of a batch single-stage and multi-stage ATPE (CPC) was compared.

1. Introduction

The most expensive step in downstream processing of monoclonal antibodies is protein A chromatography. Therefore, to reduce the cost of the chromatographic step, an alternative prepurification method can be used. In this work, a method based on coupling aqueous two-phase extraction (ATPE) and centrifugal partition chromatography (CPC), which is a multistage-extraction process, was developed. The subject of the study was a CHO cell-culture supernatant (Harvest), which contained a monoclonal antibody IgG1. ATPE was used for clarification, concentration and capture of the target product and partial separation of impurities in one or two stages.

Alternatively, CPC, comprising several hundreds of extraction stages, was applied. The bottom phase (BP-1) produced in the first ATPE-stage (Fig. 1) was further processed in a CPC system (Fig. 2). Fractions collected from the ATPE (BP-1 and BP-2) and CPC (F-CPC) stages were analyzed by protein A chromatography (AC) and size exclusion chromatography (SEC) for the antibody concentration and purity.

An optimization of the process was performed subject to purity of the target product, the residence time (or flow rate of the mobile phase) and possibility of recycling of the ATPS-phases.

2. Methods

ATPE and CPC were performed in systems containing polyethylene glycol (PEG, 3350 Da) and ammonium sulfate dissolved in water. The CPC mobile phase was the bottom phase from ATPE, whereas the CPC stationary phase was the ATPE-upper phase, the rotor speed was 1800 rpm, the rotor volume was 100 mL.

The *SEC purity* was calculated as the ratio of the peak area recorded for the IgG monomer and the sum of the area of IgG peak and peaks of all impurities.

The *level of impurities* in the factions was determined from the AC analysis as the area of the flow-through peak (FT) divided by the area of the FT-peak received for BP-1.

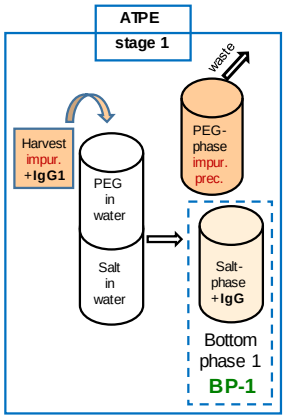

Figure 1. Single-stage batch extraction for antibody capture and precipitation of impurities

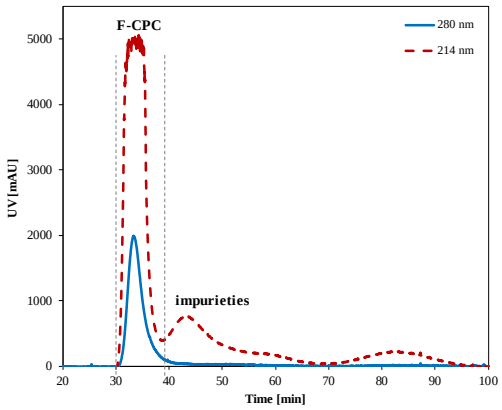

Figure 2. Example of a chromatogram from CPC purification of the ATPE-bottom phase BP-1. F-CPC – fraction of the target protein

3. Results and discussion

Impurities with low solubility were precipitated and removed in the first ATPE-stage, in which extraction was accompanied with precipitation of impurities (Fig.1). The bottom phase (BP-1), contained the target product (IgG1), and a high amount of impurities. That amount was reduced by ca. 40% after purification in the second ATPE-stage (see BP-2 in Table 1). Processing of BP-1 by CPC allowed us to further reduce the level of impurities by more than 80%. The fractions of the target product collected after two ATPE-stages and after CPC were analyzed by SEC. They contained low molecular weight impurities and very low amount of IgG-aggregates (<1%).

The CPC stationary and mobile phases (without the target product) were reused in the first ATPE-stage preceding CPC. In case of batch ATPE-extraction stages only the upper phase (e.g. BP-2) was recycled. The recycling conditions were optimized to reduce the solvent consumption.

Table 1. Purity of the target product fractions. The level of impurities was referred to BP-1 (assigned as 100%), BP-2 is the bottom phase fraction after the second ATPE-stage, F-CPC is the fraction collected after CPC.

Fractions	BP-1	BP-2	F-CPC
Level of impurities	100%	58%	12%
SEC purity	29%	42%	78%
IgG recovery	99%	99%	82%

4. Conclusions

- High recovery of the antibody was achieved due to selective extraction of the target product into the ATPE-bottom phase
- Significant reduction of impurities in CPC step was observed in comparison to two-stage ATPE.
- Recycling of phases in both ATPE and CPC operations allows reducing solvent consumption and the total cost of the operation.
- ATPE and CPC fractions can be further directly processed by HIC process due to high kosmotropic salt concentration in post-extraction solutions. Such sequential operations have a potential to substitute protein A chromatography.

We would like to acknowledge Polpharma Biologics for providing the biological material.

Thermodynamics Based Design Method of Aqueous Two-Phase Systems for Extractive Purification of Biomolecules

Maximilian Wessner[1], Mike Nowaczyk[1], Christoph Brandenbusch[1]

1 Laboratory of Thermodynamics, TU Dortmund University, 44227 Dortmund, Germany

**Corresponding author: christoph.brandenbusch@tu-dortmund.de*

Highlights

- Thermodynamics based design method for aqueous two-phase systems
- Prediction of biomolecule partitioning in aqueous two-phase systems
- Process tailored purification systems for selective extraction of biomolecules

1. Introduction

The downstream processing of biotechnological products such as therapeutic proteins is a challenging task. It has been shown recently, that Aqueous Two-Phase Systems (ATPS) offer mild processing conditions and a biocompatible environment for the purification of biomolecules due to their high water content of 70-90 wt% [1]. ATPS consist of two hydrophilic components, termed phase formers, (most likely either polymer – polymer or polymer – salt) dissolved in water above a critical concentration, forming two immiscible liquid phases. State of the art identification of ATPS is based on trial-and-error screening methods. In order to circumvent these cost intensive methods, a novel target-oriented method has to be available. This presentation will introduce a thermodynamics based design method [2] dramatically minimizing the experimental effort for ATPS design, and giving rise to a predictive description of the intermolecular interactions between low-molecular components and biomolecules. Based on the knowledge of the interactions of the molecules in solution, the critical concentration of the phase formers, aggregation propensity of the biomolecules, and the partition coefficients of the biomolecules are estimated.

2. Methods

In a first step phase equilibria data, either determined experimentally or modeled applying the ePC-SAFT equation of state [3], is used to determine the minimal concentration of phase formers that allow for the formation of an ATPS. This provides an access to the interactions between the low-molecular components. In order to take the interactions of the biomolecules in the ATPS into account, the osmotic virial coefficients B_{22} (biomolecule - biomolecule interactions) and B_{23} (biomolecule - solute interactions) are measured using composition gradient multi-angle light scattering (CG-MALS) for different concentrations of phase formers (polymers, salts) and displacement agents (e.g. neutral salts). Osmotic virial coefficients lower than zero indicate attractive interactions, values higher than zero indicate repulsive interactions. CG-MALS setup comprises of a Calypso II mixing unit, an Optilab T-rEX refractive index and a DAWN HELEOS 8^+ light scattering detector from Wyatt Technology (Santa Barbara, CA). Subsequently an in-house model [2] is used to predict the partition coefficient of the biomolecules in the ATPS.

3. Results and discussion

In order to identify an optimal ATPS for a given target component, investigations were performed for five phase formers. However, only the results for tri-sodium citrate (Na_3Cit), sodium glutamate (NaGlu) and polyethylene glycol 2000 (PEG2000) are briefly discussed in this abstract. At first, phase equilibria data were measured experimentally (figure 1 left side) and evaluated with respect to the critical concentration of phase formers required to form an ATPS. Furthermore, a model was used to characterize the interactions between the low-molecular components in the ATPS. The measurements show that the critical concentration of phase formers needed is comparable for all combinations investigated. Afterwards B_{22} values of Immunoglobulin G (IgG) in presence of the respective phase former were measured using CG-MALS to determine the interactions between the biomolecules (figure 1 right side). It is shown that B_{22} values of IgG in presence of NaGlu are dramatically higher compared the values for Na_3Cit. Based on these results the attractive interactions between IgG molecules in presence of NaGlu are significantly lower and as a consequence, the aggregation propensity of IgG is reduced. Thus, by choosing the NaGlu-PEG2000-ATPS at the respective concentrations indicated in Figure 1 the thermodynamics based design method was successfully applied to identify a process tailored purification of IgG.

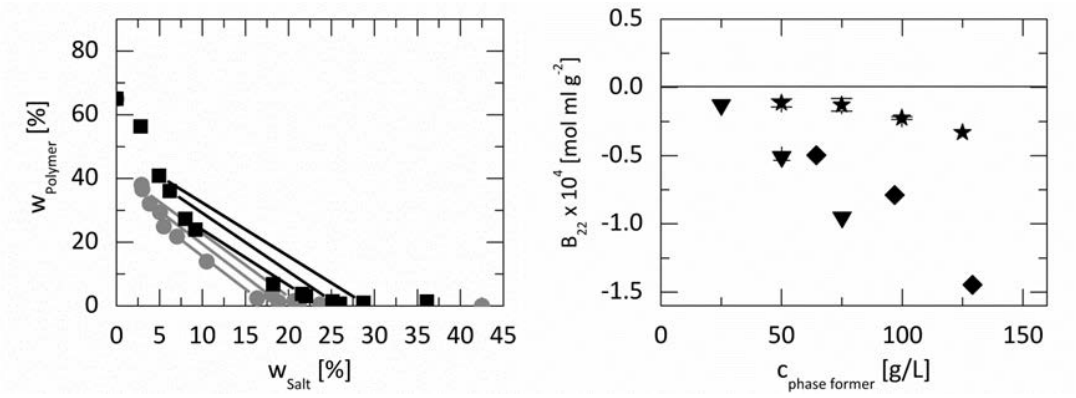

Figure 1. Left: Phase equilibria and binodal curve of ATPS containing sodium glutamate / polyethylene glycol 2000 (■) and tri-sodium citrate / polyethylene glycol 2000 (●) at pH of 7 and 298.15 K. Right: B_{22} values of Immunoglobulin G in presence of the phase former tri-sodium citrate (◆) [4], sodium glutamate (★) and polyethylene glycol 2000 (▼) in an aqueous 50 mM K_2HPO_4-NaH_2PO_4 solution with pH of 7 and 298.15 K.

4. Conclusions

Within this work, we present a thermodynamics based design method selecting suitable phase former for the extractive purification of IgG. Conventional design approaches fail, due to the fact that knowledge on the interactions between the molecules in an extraction process is limited. It was shown that the description of these interactions is the key factor for establishing a process tailored design of a suitable ATPS. The new method allows for an estimation of the aggregation propensity as well as the partitioning of the biomolecule in the ATPS. It has been proven that the method is a powerful tool and can be used for variety of biomolecular components.

1. Introduction

Novel modifiable solvents can play a key role in obtaining the maximum value from biomass, increasing sustainability of current biorefinery processes, and avoiding regulatory issues. Switchable solvents ability to reversibly change their nature (hydrophobic-hydrophilic, and/or polar-non polar) can be used to improve existing liquid-solid extraction unit operations thanks to pretreatments simplification and reduction of their energy requirement. Natural Deep Eutectic Solvents (NaDESs) feature an assignable (by proper choice of their components) and in some cases tunable hydrophilicity. Most commonly, NaDES are hydrophilic, but hydrophobic NaDES have been discovered and a NaDES-based SHS has been introduced. Novel SHS- and NaDES-based biorefining concepts and techniques have been developed targeting two major current and forthcoming biomass resources: lignocellulosic materials (LCM) and microalgal biomass. Here we give account of two promising green approaches exploring paradigmatic shifts in biorefinery.

2. Methods

So far, SHS have only been used in their hydrophobic form to extract hydrophobic solutes. During the hydrophobic-to-hydrophilic switch, dissolved hydrophobic solutes separate as a second (hydrophobic) phase which is easily collected. However, the treated biomass might also contain hydrophilic solutes that can be easily removed by treating the residue of the hydrophobic extraction with the hydrophilic form of the very same SHS. Subsequent back-switch to the hydrophobic form leaves a hydrophilic phase constituted by water and water-loving solutes behind, whereby the cyclic extraction can restart. The biomass extraction can begin with either the hydrophobic or the hydrophilic form of the solvent and may continue with the other form. The operation sequence starting with a hydrophobic extraction was denoted by the inventors as Forward-Mode extraction (FME) and the opposite sequence (hydrophilic extraction first, then hydrophobic) was called Backward-Mode Extraction (BME) [1] (Figure 1A). This dual use of SHS, denoted as “Circular Extraction”, has been touted to increase the utility of the extraction process and of the solvent itself. Recently, the first NaDES-based switchable system was developed (“NaDES-Y”) [2] to address the toxicity issues of other SHS (such as DMCHA) in the food and other regulated domains. The present paper compares its performance in microalgae extraction to that of DMCHA (DimethylCycloHexylAmine) under said “Circular Extraction” approach. Choline chloride-based NaDES are of hydrophilic nature and exhibit polarity higher than water that can be tuned by adjusting water content in the NaDES formulation. Choline chloride-based NaDES are able to solubilise lignocellulose. However, a recent quantum leap forward in NaDES-based processing has demonstrated [3] revolutionary closed-cycle fractionation of LCM into cellulose, hemicellulose and lignin.

3. Results and discussion

As far as microalgal biomass biorefining is concerned, Sed at al. (2018) used the "Circular Extraction" protocol to assess NaDES-Y potential in extracting useful biological fractions compared to DMCHA, a well-known SHS. Results are shown in Table 1.

FME Extraction stage	Metabolite extraction in FME			BME Extraction stage	Metabolite extraction in BME		
	Proteins	Carbo-hydrates	Lipids		Proteins	Carbo-hydrates	Lipids
I - Hydrophobic	4 (7)	8 (42)	88(96)	I - Hydrophilic	4 (7)	8 (42)	88(96)
II - Hydrophilic	32 (34)	25 (9)	0 (0)	II - Hydrophobic	32 (34)	25 (9)	0 (0)
Total	36 (41)	33 (51)	88 (96)	Total	36 (41)	33 (51)	88 (96)

Table 1. Extraction efficiency in FME with NaDES-Y compared to (DMCHA)

LCM biorefining by NaDES can be carried out in closed-cycle [3] based on a first extraction, which dissolves lignin and hemicellulose, followed by two selective precipitations, the former obtained by tuning NaDES polarity by adding water (lignin precipitates), and the latter obtained by adding acetonitrile as an antisolvent (xylan precipitates) (Figure 1B). Although acetonitrile still taints the "intrinsically bio-safe" concept, researchers will hopefully find a bio-safe antisolvent alternative.

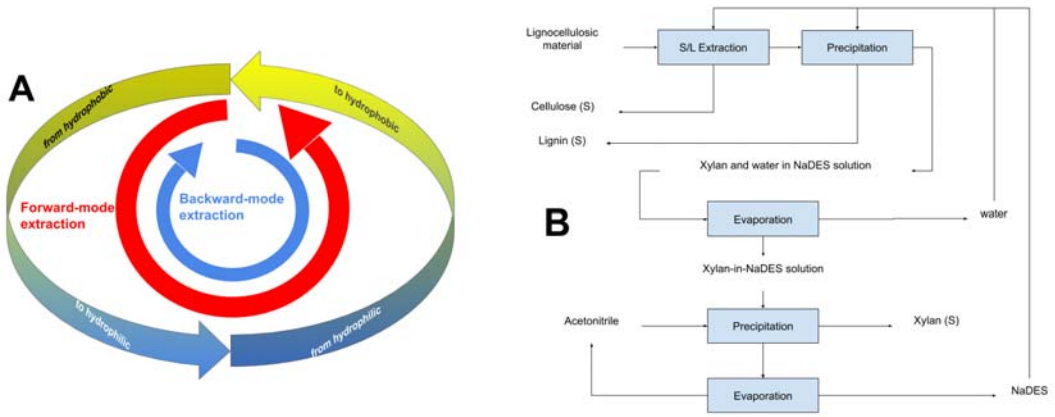

Figure 1. FME and BME approaches (A) and NaDES-based LCM biorefining (B).

4. Conclusions

Solvent extraction of a complex biomass containing an array of compounds should be treated with an array of solvents. With the aid of novel solvents which may change intrinsic features at the user's will the "one-solvents-fits-all" target might come into the biorefinery range.

Highlights

- A solvent selection strategy including extraction performance and biocompatibility is proposed.
- Flow cytometry results are used as a quick assessment of solvents' biocompatibility.
- The effects of active and inert diluent on extraction and biocompatibility are studied.

1. Introduction

3-Hydroxypropionic acid (3-HP) is an attractive platform molecule that can be converted into several compounds such as acrylic acid and biodegradable polymers. Thanks to the increasing interest in the use of renewable resources in order to develop more sustainable processes, research on its production by bioconversion with microorganisms has made remarkable advances [1]. However, its industrial commercialization is still limited by low yields caused by product inhibition. Previous studies have shown that *in situ* reactive extraction assisted by a hollow fiber membrane contactor (HFMC) is a promising strategy to intensify glycerol bioconversion to 3-HP by a selected strain of *Lactobacillus reuteri* and simplify its recovery and purification [2-4]. However, there are some process limitations that need to be better understood in order to develop a system that allows continuous and *in situ* extractive bioconversion. Notably, the biocompatibility of the extraction system together with a good extraction performance are key factors. The objective of this work is to study a selection strategy to choose an adequate organic phase composition.

2. Methods

A screening of solvents was performed using trioctylamine (TOA) as the extractant compound. This tertiary amine is able to react with the organic acid in the aqueous media. It was mixed with different fatty alcohols with chain lengths from 8 to 18 carbons (active diluents) and alcanes (decane and dodecane, as inert diluents) at different proportions. Each mixture was evaluated in terms of 3-HP extraction performance and biocompatibility with respect to *Lactobacillus reuteri*. Extraction performance was determined by the extraction yield of a 3-HP solution at 5 g/L and 25°C, and the viscosity of the organic phase. A good extraction performance requires a high extraction yield and a low viscosity, which is related to a faster mass transfer in HFMC. In addition, biocompatibility with a selected strain of *Lactobacillus reuteri* [5] was evaluated by flow cytometry using two fluorescence probes simultaneously, carboxyfluorescein diacetate (cFDA) and propidium iodide (PI), that are able to assess respectively the enzymatic activity and the membrane integrity

of the cells put in contact with different organic mixtures. Bioconversions of 5 g/L of glycerol in contact with the organic phase molecules were also performed in order to compare substrate consumption and metabolites production. Substrate and metabolites' concentrations were determined by HPLC.

3. Results and discussion

Extraction yield and viscosity of the mixtures were used to select the type of inert diluent to use and its concentration. It was determined that there was no significant difference between the extraction yield using decane and dodecane at the same concentration. Moreover, although the viscosity of mixtures with decane were slightly lower, dodecane was selected, since it was expected to be more biocompatible in a HFMC because it is less soluble in water. The proportion of 20% TOA, 40% decanol and 40% dodecane was selected for comparison of the different active diluents maintaining the same molar proportion between TOA and the active diluent. Figure 1 shows that between the most biocompatible mixtures, the one with dodecanol 47% (2.1 mol/L) is the most interesting for *in situ* extraction since it has a lower viscosity than oleyl alcohol 80% (2.5 mol/L) and a higher extraction yield than 2-hexyl-1-decanol 61% (2.1 mol/L). The interest of dodecanol was corroborated by flow cytometry and 3-HP production results.

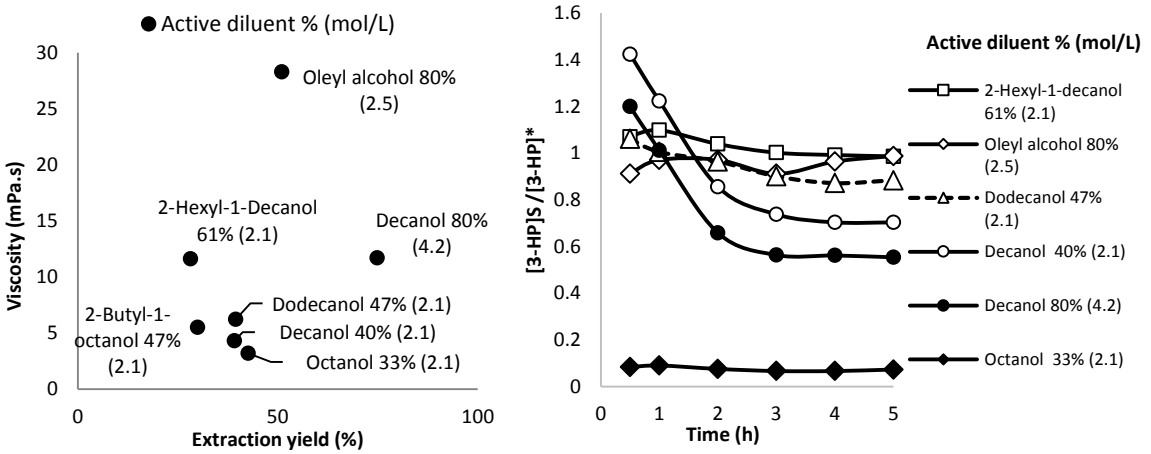

Figure 1. Extraction performance (yield and viscosity) and biocompatibility (3-HP production ratio) of the evaluated organic solvent mixtures. [3-HP]s = 3-HP produced in contact with solvents molecules. [3-HP]* = 3-HP produced in control (without contact with solvents molecules).

4. Conclusions

The selection methodology developed in this study is a useful tool for process optimization, because it compares solvent properties important for reactive extraction that are relatively easy to evaluate. After this preliminary screening, the number of organic phases to be tested in bioconversion coupled to HFMC *in situ* extraction system is considerably reduced, saving experimental effort.

Hierarchical and non-hierarchical HZSM5 based catalysts for selective alkylation and hydrogenation of guaiacols in Kraft lignin derived bio-oil.

Ashutosh Agarwal[1], Masud Rana[1], Seong-Jae Park[1], Jeong-Hun Park[1]*

1 Department of Environment and Energy Engineering, Chonnam National University, Gwangju 61186, Republic of Korea

**Corresponding author: parkjeo1@jnu.ac.kr*

Highlights

- Ni and/or Zn impregnated HZSM5 significantly enhanced the formation of alkylated guaiacols
- Hydrogenation was favored over hierarchical catalysts
- Deoxygenation was favored over non-hierarchical catalysts

1. Introduction

Diminishing fossil fuels and increasing energy demand have sparked immense interest in the utilization of biomass as renewable resource for biofuel production [1]. Partly replacing fossil fuels with upgraded bio-oil would be an alternative approach to accomplish reduction in massive consumption of fossil fuels. Lignin is often preferred as renewable feedstock for the production of bio-oil due to its low cost and ease of availability [2]. Among various types of lignin, Kraft lignin is essentially used for the production of bio-oil via thermochemical conversion. Due to low heating value and high instability derived from oxygenated compounds, upgrading of bio-oil becomes inevitable [3].

Bio-oil upgrading normally occurs via three main mechanisms, which involves hydrogenation, hydrodeoxygenation and alkylation. Catalyst employed during bio-oil upgrading chiefly governs the quality and cost of upgraded bio-oil [4]. Noble metal catalysts such as Pd/C, Pt/C and Ru/C which holds high potential for hydrodeoxygenation activates towards bio-oil upgrading remains unpreferred for industrial applications due to high cost and scarcity [5, 6]. Besides this, traditional sulfur based catalysts are also not employed for bio-oil upgrading as they tend to deactivate the catalyst leading to the formation of coke [7]. Non-noble metal catalysts such as Ni and Zn have recently been attracting great attention for hydrodeoxygenation of bio-oil due to their high activity and low cost [8]. Ni metal catalyst activates hydrogen and drastically prohibits the polymerization of unsaturated hydrocarbons while Zn enhances catalytic performance of zeolites during bio-oil upgrading process. Metal catalysts are often incorporated in support material such as zeolite in order to avoid agglomeration of metal catalysts that helps in enhancing their catalytic activity. HZSM5 has been widely used as support material for incorporation of metal catalysts due to its high thermal stability, porous structure, controllable acidity and ability to accomplish hydrodeoxygenation and alkylation [9, 10]. Besides this, HZSM5 zeolite have been known for its ability to convert heavier components of bio-crude into smaller fuel range fractions [11]. Mesoporosity in zeolites enhances production of aromatic compounds enriched biofuel by

promoting easy diffusion of hydrocarbons to acid sites [12]. Further, incorporation of active metal species onto zeolite support improves catalytic activity by promoting hydrogenation of oxygenated compounds [13].

Generally, the size, dimensionality of zeolite channels and its acidity plays vital role in governing the activity and selectivity of HZSM5 for organic reactions. Incorporation of secondary porosity at mesoscale in hierarchical HZSM5 acts as molecular sieves which favors fast mass transport [14]. In this research, we compared the catalytic performances of hierarchical and non-hierarchical Ni and/or Zn/HZSM5 catalyst at different Ni and/or Zn loading ratios for bio-oil upgrading. Several analytical techniques such as FE-SEM, EDS, XPS, ICP-OES, XRD and N_2 adsorption-desorption isotherms were used for catalyst characterization. The catalytic activity of synthesized catalysts was compared with Ru/C catalyst.

Kinetic study of fed-batch production of 3-hydroxypropanoic acid (3-HP) by *Acetobacter aceti* within an integrated process

Florence de Fouchécour[1], Anaïs Lemarchand[1], Claire Saulou-Bérion[1], Henry-Éric Spinnler[1]*

1 UMR 782 GMPA, AgroParisTech, INRA, Université Paris-Saclay, 1 av. Lucien Brétignières 78850 Thiverval-Grignon, France

Highlights

- *Acetobacter aceti* is an efficient 3-HP producer from 1,3-propanediol (1,3-PDO)
- 1,3-propanediol is quantitatively converted to 3-HP in a sequential fed-batch process
- *A. aceti*'s growth on glycerol allowed an efficient subsequent bioconversion
- 3-HP production was always accompanied by bacterial growth

1. Introduction

3-hydroxypropanoic acid (3-HP) has been identified by the US Department of Energy as one of the priority chemical targets that can be obtained from biomass, notably due to its variety of applications [1]. 3-HP production is primarily performed using biotechnological processes. However despite ever intensifying research effort on the matter, important hurdles still remain and commercial 3-HP production is not yet achieved [2]. Our work aims at developing an integrated approach for 3-HP production from glycerol. Glycerol is first converted to a mix of 1,3-propanediol (1,3-PDO) and 3-HP by *Lactobacillus reuteri*. Subsequently, 1,3-PDO is selectively oxidized into 3-HP by acetic acid bacterium *Acetobacter aceti*, in order to reach an overall yield from glycerol close to 100 %. To prevent substrate and product inhibition, 3-HP synthesis by *A. aceti* was tested in fed-batch mode in bench-scale bioreactors.

2. Methods

Fed-batch bioconversions of 1,3-PDO to 3-HP by *A. aceti* were carried out using a pH-based feeding strategy: pH was controlled by addition of an equimolar solution of base and 1,3-PDO, so that the substrate (1,3-PDO) was supplied as it was consumed. Both growth-coupled and –uncoupled bioconversion strategies were tested. In the latter case, *A. aceti* was first grown until late exponential phase on glycerol as growth substrate, before initiating the 1,3-PDO feeding. Such growth-uncoupled bioconversions were carried out at different pH: 4.0, 4.5 and 5.0. Bioconversion kinetics were then compared by fitting modified Gompertz to cell and product concentrations. These models could then be used to study the evolution of specific productivities over time.

3. Results and discussion

The pH-based feeding strategy could support simultaneously *A. aceti*'s growth and 1,3-PDO conversion into 3-HP. Yet, cell density remained low, around 0.26 g of cell dry weight (CDW) per

liter. Detrimental accumulation of the intermediary 3-hydroxypropanal (3-HPA) was also observed. In comparison, the sequential fed-batch strategy (*i.e.* growth on glycerol followed by 1,3-PDO feeding) could achieve more efficient 3-HP biosynthesis: maximal specific productivity $q_{3\text{-}HP,max}$, was higher (2.11 vs. 1.90 $g_{3\text{-}HP}$ g_{CDW} h^{-1}), and the final 3-HP titer was increased eight-fold. Moreover, for all tested pH conditions, this sequential strategy prevented *A. aceti* from accumulating 3-HPA: 1,3-PDO was thus quantitatively converted into 3-HP. The bioconversion was found the most efficient for pH = 5.0, in which case dioxygen availability appeared as a limiting factor. Interestingly, a second bacterial growth phase was observed when 1,3-PDO was supplied after a first growth step on glycerol, regardless of the pH at which the bioconversion was performed. Thus the bacterial cell density was further increased, reaching a maximum of 2 g_{CDW} L^{-1}.

4. Conclusions

Acetobacter aceti was found to be a promising biocatalyst for 1,3-PDO conversion into 3-HP. It was found to be the most efficient when first grown on glycerol, prior to 1,3-PDO being supplied to the medium which was controlled at pH = 5.0. Future work will include the implementation of a kinetic model as a tool to better understand the bioconversion and to help integrate this step into the whole integrated process.

Comparison of Lignin Yield from Sugarcane Bagasse Using Liquid Hot Water and Ionic Liquids and Ionic Liquids Only.

Nirmala Deenadayalu[1], Gueh Charles Gnana[1]

1 Department of Chemistry, Durban University of Technology, KwaZulu-Natal, South Africa

**Corresponding author: NirmalaD@dut.ac.za*

Highlights

- Liquid hot water and ionic liquid pretreatment yielded higher yields of lignin (68 m/v %).
- Microwave digestion was effective in isolating the lignin.
- Optimized pretreatment time for only ionic liquids was 20 minutes.
- Ionic liquid 1-ethyl-3-methylimidazolium acetate was more effective than 1-butyl-3-methylimidazolium hydrogen sulphate.

1. Introduction

Globally the high cost and diminishing reserves of crude oil coupled with global warming effects have resulted in research for alternate energy and chemical sources. Lignocellulosic material is one of the largest renewable resources containing hemicellulose, lignin and cellulose. Extraction of the different components of the lignocellulosic material can lead to the valorisation of the biomass and reduce dependence on crude oil.

There are many pretreatment methods for the separation of cellulose, lignin and hemicellulose, namely: acid hydrolysis, base hydrolysis, steam explosion, mechanical and biochemical methods. All of these methods are environmentally harmful due to the release of volatile organic compounds that contribute to global warming effects. A new class of solvents known as ionic liquids are suitable for pretreatment since they have properties such as: low vapour pressure, recyclability, solubility in a range of organic compounds and liquid at room temperature that make them attractive for biomass pretreatment.

Sugarcane bagasse (SCB) is a renewable lignocellulosic resource in South Africa obtained after the sugar milling process. The annual production of SCB is approximately 6 million tons per annum produced by 14 sugar mills that are located on the north coast of KwaZulu-Natal (Paterson – Jones, 1989).

In this work, lignin yields from sugarcane bagasse pellets was investigated using liquid hot water (LHW) and ionic liquids (ILs) and only ionic liquids. The LHW process was applied to sugarcane bagasse pellets at 200 °C, for 30 minutes in a high pressure reactor for removal of hemicelluloses. The complex cellulignin residue was treated with the ILs: 1-ethyl-3-methylimidazolium acetate ([Emim][OAc]) or 1-butyl-3-methylimidazolium hydrogen sulphate ([Bmim][HSO_4]), using microwave digestion at varying time intervals. Direct Ionic liquid treatment was done on sugarcane bagasse pellets with ILs: [Emim][OAc] or [Bmim][HSO_4] using microwave digestion.

2. Methods

The sugarcane bagasse was first ground to 3-5 mm, dried to 10-12 % moisture and pelletized using a pellet mill. 1.0 kg of pelletized bagasse was used for the LHW hydrolysis at a temperature of 200 ^{o}C in a 3.0 L high pressure fixed bed reactor for 30 minutes with a volume flow of 250 ml/min of water. Hemicellulose dissolved in the water and a solid residue (cellulignin) was collected from the reactor. Compositional analysis of the sugarcane bagasse pellets, cellulignin and the complex cellulignin after enzymatic hydrolysis was done using NREL procedures.

For the extraction of lignin, a ratio 1:10 of SBP (0.5 g) and ionic liquid (5 g) was weighed in duplicate and transferred into 65 mL Teflon vessels, transferred to a microwave oven with parameters: power (80 Watt); ramp time (10 minutes); temperature (180 ˚C) and different hold times of 3, 10, 15 and 20 minutes for each run. After each run the extracted lignin was transferred to a 100 mL beaker rinsed thoroughly with 10 mL solution of 1-4 dioxane-water 95:5 (v/v), transferred into a 50 mL volumetric flask and diluted with a mixture of 1-4 dioxane-water 50:50 (v/v) for UV analysis.

3. Results and discussion

The amounts of glucose released in g/L during enzymatic hydrolysis of cellulignin using enzyme Cellic CTec2 or Metaplus/Rapidas was 27.5 g/L and 3.8 g/L after 6 hours of hydrolysis. The effectiveness of the combined enzyme Metaplus/Rapidas was lower than the Cellic ® CTec2 enzyme.

The IL [Emim][OAc] gave the highest lignin yield (68 %) for the LHW and IL method at 10 min. For the sugarcane bagasse pellets the highest yield was 59 98% at a reaction time of 25 min. The IL: [Emim][OAc] was the better of the two ILs used.

4. Conclusions

Liquid hot water and IL extraction of lignin from sugarcane bagasse pellets was successfully used to extract lignin. Although the highest yield was obtained for the LHW and IL method, the preferred method would be IL treatment on the sugarcane bagasse pellets since it eliminates the use of high energy input.

Highlights

- Process models incorporating start-up, shut-down and normal operations
- Nelder-Mead algorithm for process optimization and SOP tuning
- OTS with capability to automatically re-parameterize SOPs
- Enables operators to take corrective action to quickly recover from upset events

1. Introduction

The increasing complexities in process configurations, starting raw material options, and the variety of product offerings in modern biorefineries present peculiar challenges for operators and plant process automation systems [1]. Existing operator training simulators (OTS) provide a safe simulated environment for developing the skills of operators, amongst other benefits. In this paper, the usefulness of the traditional OTS is extended by incorporating an algorithm that helps operators effectively manage process upsets and changes in feed properties through automatic tuning and adjustment of standard operating procedures (SOPs).

2. Methods

The C++ based modelling tool C-eStIM [2] was used to develop and parameterize process models for feed pre-treatment, fermentation and distillation. A commercial process control and automation software, WinErs [3], was used to integrate all unit operations into a single functioning biorefinery, with accompanying heat exchangers, pumps, and control valves. Biorefinery standard operating procedures (SOPs) were used to create sequential function charts in GRAFCET [4] for biorefinery operations. Furthermore, a parameterizable SOP for automatic adjustment of enzyme loading in response to fluctuations in inlet feed composition was also implemented using GRAFCET. The Nelder-Mead algorithm [5] for the minimization of multi-dimensional functions was developed for process optimization and automatic tuning of SOPs in response to upsets during fermentation and distillation unit operations.

3. Results and discussion

Modelling results for hydrolysis and fermentation were consistent with published data while the distillation model incorporates a cold start-up, normal batch, semi-batch and continuous

operations, and unit shutdown. The developed OTS can be used to train biorefinery operators for both normal and non-routine operations. Automatic SOP adjustment shows that hydrolysis enzyme dosage is automatically adjusted in response to fluctuations in solids loading concentration (Figure 1).

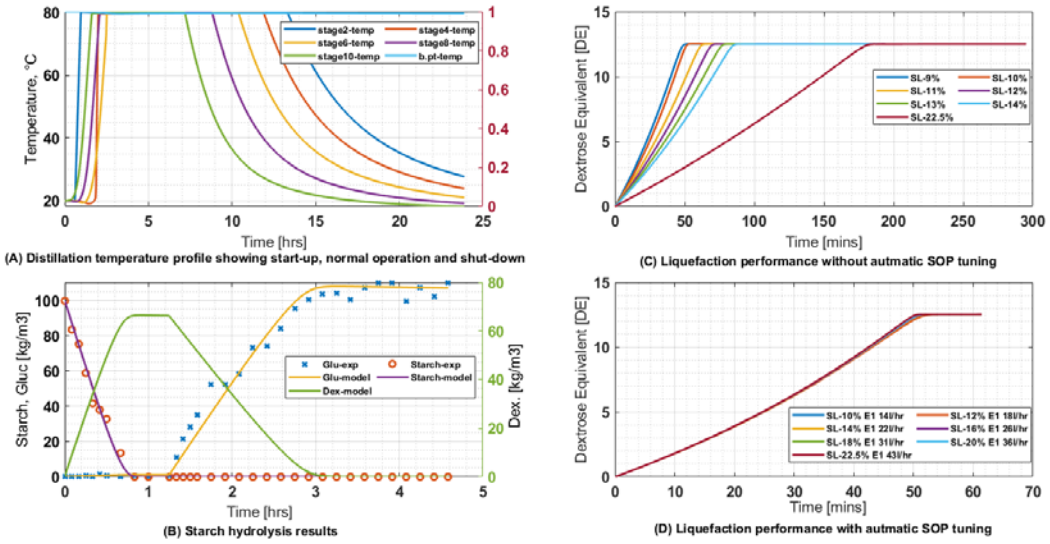

Figure 1. Model results (A & B) and automatic SOP tuning results (C & D)

4. Conclusions

This paper presents the results of the first attempt to incorporate an algorithm for process optimization and automatic tuning of SOPs into an operator training simulator. This extends the usefulness of the traditional OTS beyond operator training to include automatically adjusting production recipe inputs that inform operator corrective action, thereby minimizing material losses and process downtime.

Highlights

- Scale up&down of production of lactic acid bacteria starter cultures for dairy industry
- Model-based process monitoring&control with the pH-value as only input variable
- PAT for determination of population heterogeneity under different pH-gradients
- Growth prediction based on single-cell size distribution measurements

1. Introduction

Oscillatory conditions, which usually appear in large scale bioreactors due to limitations in the power input and extended mixing times, can lead to cell stress and increased occurrence of population heterogeneity. Such heterogeneities are regularly observed in industrial production; however, the underlying mechanisms are seldom perceived or considered in bioprocess development. Since the occurrence of subpopulations may have a significant impact on the productivity of industrial cultures, cellular heterogeneity requires quantification with appropriate monitoring tools [1].

In case of lactic acid bacteria production, pH-gradients are the main concern when facing scale-up, since they lead to growth retardation, a loss of productivity and an altered population heterogeneity.

2. Methods

In order to study the impact of these gradients on the population heterogeneity of *Streptococcus thermophilus* cultures, various scale-down approaches were applied. Firstly, compartmentation of different zones was achieved through two- and three-compartment scale-down reactors (Two-CR and Three-CR, respectively), both consisted of a 10 L nitrogen aerated stirred tank reactor (STR) connected to one or two non-aerated plug flow reactors (PFR), respectively [2]. Base addition was performed from the bottom of one PFR, whilst acid was introduced from the bottom of the second PFR in the Three-CR system. Thus, (i) a zone of high pH-value (i.e. the base addition zone in the industrial reactor, simulated in one PFR), (ii) a compartment with low pH environment (i.e. the zone far away from the base addition, mimicked in the other PFR) and (iii) a homogeneous bulk zone

(simulated in the STR) were achieved in lab scale. Secondly, pulse feeding experiments were performed in a one compartment reactor, so that the whole population was subjected to the same pH shifts.

The physiologic heterogeneity of the population was assessed by means of the morphological heterogeneity in cocci chain length formation under optimal and pH-oscillating environments with *at-line* light microscopy analysis and automated cell image recognition. Furthermore, the consequences for cell growth, substrate conversion and product formation were studied in detail.

3. Results and discussion

The authors observed that the chain length of *S. thermophilus* varies as a response to environmental stress. A narrow distribution of short chain lengths during the exponential phase under optimum conditions was revealed, whilst the cell size distribution was broad and shifted to longer chain lengths under pH-gradients, as induced in scale-down fermentations. It could be shown that the appearance of certain cocci chain lengths is directly correlated to a reduced growth activity. Moreover, the different scale-down approaches were compared to the population heterogeneity detected in the production scale to identify the most suitable design.

By coupling of a mechanistic model [3, 4] to predict macroscopic state variables (such as substrate consumption, biomass growth and by-product formation, among others), a population balance model (PBM) was developed. This needs only the actual pH-value in the bioreactor to predict the cocci chain length distribution *on-line*, which gives information about the current biomass quantity as well as quality in the broth (Figure 1). In this manner, a change in the running process (e.g. increase stirring speed to decrease pH-gradients) is still possible in order to ensure the product characteristics at the harvesting point, with the highest yield.

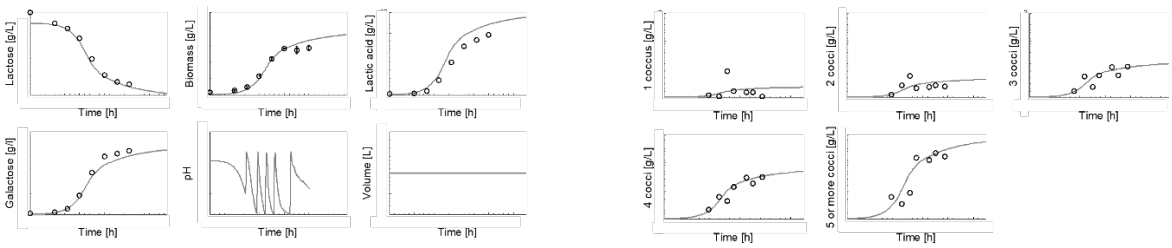

Figure 1. Development of macroscopic variables (left) and of variable chain lengths (right) over fermentation time of a *S. thermophilus* culture under certain pH-gradients. Experimental data (dots) and population balance model (line).

4. Conclusions

The M^3C methodology presented here is able to predict biomass quality (i.e. acidification activity, as a function of the chain length) based solely on the pH-value in the culture broth. Using CFD studies in the industrial scale, pH-gradients and compartmentalization could be easily incorporated into the PBM. This approach, coupled to *in-situ* quantification of the cell size distribution with advanced *on-line* microscopic techniques and image analysis using neural networks (NNs), would enable growth performance prediction in real-time. This would allow for (i) the rapid evaluation of media, (ii) the adjustment of the power input during base addition to keep pH-gradient formation as non-sensitive for process performance, (iii) the determination of a suitable point for harvest under consideration of cell vitality, and (iv) in general the improvement of quality control.

Relational Database for the Description of Fermentation inside a Simulation Software.

Simoneta Caño de las Heras*, Ulrich Krühne, Seyed Soheil Mansouri
Process and Sytems Engineering Center (PROSYS), Department of Chemical and Biochemical Engineering, Technical University of Denmark, Søltofts Plads, Building 229, 2800 Kgs. Lyngby, Denmark
**Corresponding author: simoca@kt.dtu.dk*

Highlights

- Fermentation simulators could be beneficial to asses the feasibility of different kinetic scenarios.
- A database is developed that incorporates information related to kinetic parameters of fermentation models.
- This database is integrated inside a pedagogical software platform, *FermProc*.

1. Introduction

Simulators are well established tools for instructing, design, and development of bioprocesses with the advantages of its portability, safety, user friendliness, and cost-effectiveness [1]. However, commercially simulators commonly work as a black box and consequently, their mathematical models are not displayed and/or being available for its modification. And therefore, it is not possible to recognize the assumptions made [2], [3] complicating the comprehension of the process. Furthermore, simulators are not generally intended to evaluate the feasibility of the simulated scenarios ergo users require a high previous knowledge of the bioprocess. This is highly relevant in case of fermentation processes as their mathematical models have several complexity layers and involve biological, chemical, physical and mechanical components. Moreover, bioprocess simulators commonly suffer from the lack of an organized database for the differentiation and analysis of the model components as well as the aforementioned limitations [4].

In this work, a prototype database that embeds common limits and values of the parameters of bioprocesses, is presented. This database is integrated inside a software platform called *FermProc*[5]. *FermProc* allows the display, reuse and modification of models and it is being developed at the Department of Chemical and Biochemical Engineering of the Technical University of Denmark as a pedagogical software for teaching of bio-manufacturing processes.

2. Architecture of the system

Figure 1 illustrates the functional system architecture. The architecture is designed with modular capabilities and involves the dynamic simulation of the bioprocess with the automatic solution of the model and its display. To do so, a relational database (in SQL) that collects and reuses interrelated rules, usually associated with characteristic values of the bioprocess is developed. This database uses the parameter, constant or variable as the data value. Therefore, a *"parameter set id"* uniquely identifies the record and associates each of them with specific maximum and minimum values. The *"parameter set id"* is connected with the process conditions such as the microorganism, the limiting substrate or bioreactor that may influence the data.

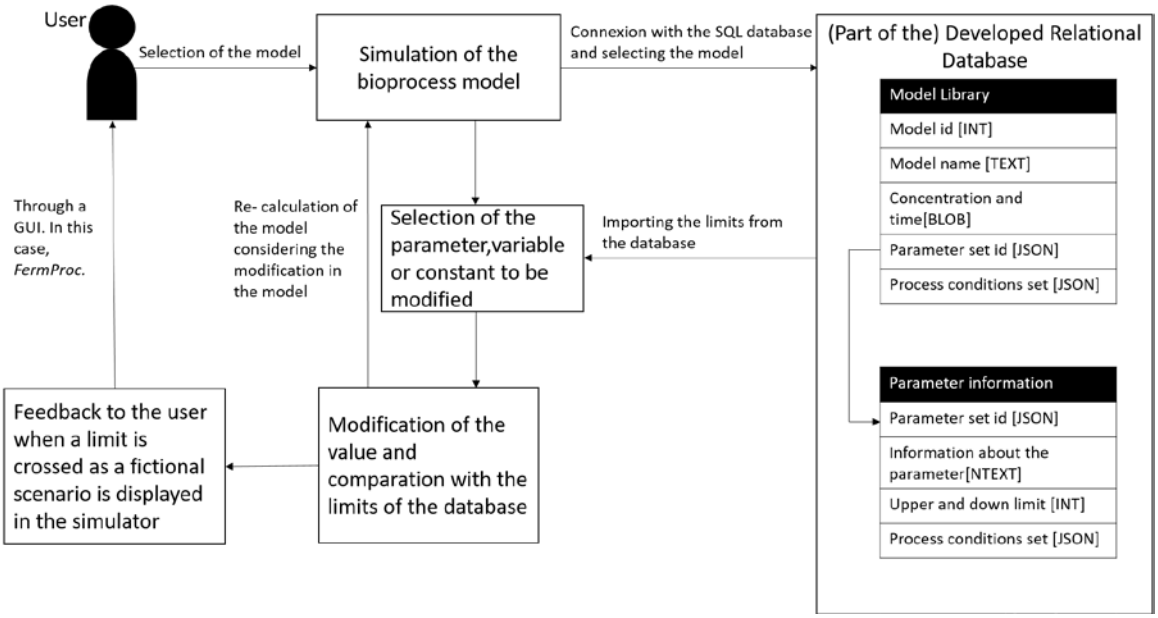

Figure 1. Schematic functional system architecture.

Furthermore, the database includes a theoretical explanation with the source of information so users can trust the database. Finally, an example of the use of the database can be found at https://youtu.be/qhucwjf_i0E. This video shows how a user interacts with a model of the aerobic growth of *Saccharomyces cerevisiae* and how a warming window will pop up when the oxidative yield of the consumption of glucose is modified over the thermodynamic limit [6].

3. Conclusions

Although there are several bioprocess simulators and common values and limits of different parameters involved in fermentation can be found in literature; there is a lack of an integrated system in which this information can be collected and displayed. To fulfill this need, a relational database that stores information about parameters of fermentation processes is developed. Furthermore, the database is implemented in a simulator, called *FermProc,* to facilitate the analysis of fictional scenarios through interactive modifications of the model.

Highlights

- Establishment of a 3-enzyme cascade in a two phase system
- Integrated *in situ* cofactor regeneration and *in situ* product extraction
- Process optimization by enzyme immobilization

1. Introduction

Biotechnical processes are a promising alternative to conventional chemical reactions, if they fulfill certain requirements like less byproduct formation, less intermediate separation, environmentally friendly and sustainable reactions. With different methods to improve the productivity, like efficient cofactor regeneration and simplified downstream processing, these enzymatic reactions are of increasing importance for industry.[1,2] In this study a three enzyme cascade in two phases is evaluated, as shown in figure 1. In the aqueous phase an alcohol dehydrogenase (ADH) is reducing the substrate cinnamal to the corresponding alcohol. Since this enzyme is NADH cofactor dependent an *in situ* regeneration is established by formate dehydrogenate (FDH). The product is extracted *in situ* by an organic solvent to realize the esterification by a lipase to the target product cinnamyl cinnamate.

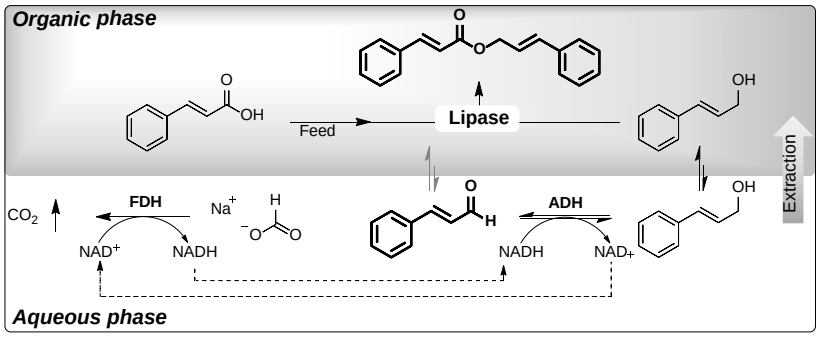

Figure 1. Reaction scheme of the enzyme cascade.

2. Methods

Three different enzymes are investigated, whereby the enzymes used in the aqueous phase are immobilized with different techniques. Characterization of free and immobilized enzymes is performed via activity and kinetic, as well as stability measurements. The whole cascade is carried

out in a reactor concept with an integrated extraction centrifuge and a fixed-bed reactor for the esterification.

3. Results and discussion

A suitable organic solvent has to be identified for the enzymes in the aqueous phase, as well as for the esterification. Buffer saturated with different solvents are screened regarding ADH activity, whereby compounds with high logP values showed the lowest influence on enzyme activity. Xylene is chosen as second phase, due to its high logP value, dissolution of the substrates and good properties regarding process safety. Based on this, the individual enzymes are characterized in xylene saturated buffer and their respective kinetic parameters (Michaelis-Menten) were determined. In addition, the esterification in xylene by an immobilized lipase was carried out and high yields of over 95% for the two reaction steps show the feasibility of this cascade.

To improve the enzyme stability and simplify the downstream processing, immobilization of the biocatalysts in the aqueous phase is investigated in detail, shown in figure 2. Several techniques are screened, whereby cross-linked enzyme crystals (CLEAs) and covalent immobilization on hydrophilic amino-activated supports showed good immobilization yields and the highest residual activities.

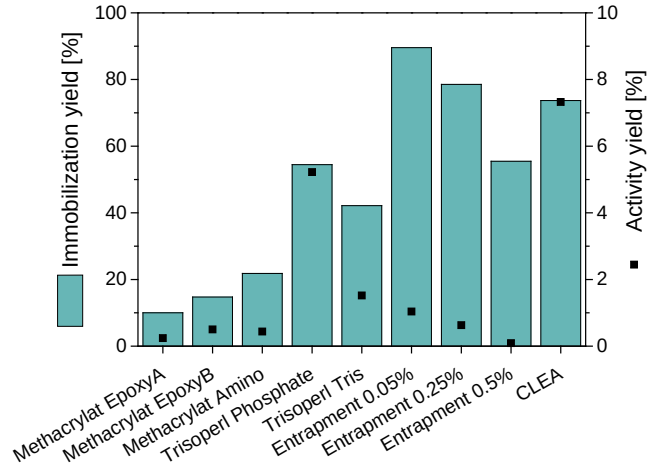

Figure 2. Results of the screened immobilization methods.

4. Conclusions

A multi-enzyme cascade in a two phase system was successfully established and evaluated in detail. Xylene was chosen as suitable organic solvent for the second phase and the enzymes were characterized regarding these reaction conditions. Different immobilization techniques were studied, whereby covalent immobilization on hydrophilic supports showed the most promising results for the ADH. The established system will be further investigated in a larger reactor set-up.

Validation of High Lignin Content Biomass Using Supercritical Water Technology.

Tijana Adamovic[1], Celia Martinez[1], María José Cocero[1]

Highlights

- Selective valorization of high content lignin biomass
- Transformation to lignin-cellulose composites
- Transformation of carbohydrate to sugars with a yield of 88%

1. Introduction

Lignocellulosic biomass is the most abundant and easily grown biomass form. Being composed of three main biopolymers, cellulose, hemicellulose and lignin, it presents a great source of a wide range of chemicals.

SCWH is recognized as a potential hydrolysis technique to decompose lignocellulosic materials due to its properties, low viscosity and high diffusely that facilitate penetration of water into complex biomass matrix, while its low dielectric constant similar to non-polar organic solvents enhances solubility of organic compounds[1]. This technique can be used as a pre-treatment for the selective fractionation of cellulose, hemicellulose and lignin or as a reaction medium to directly hydrolyse the polymers into its constituent[2].

Defatted grape seed is composed of more than 50% of lignin vs 15% of carbohydrates and thus potential feedstock for lignin and aromatic components contained in lignin structure.

2. Methods

Ultra-Fast Supercritical Water Hydrolysis

For biomass fractionation continues pilot plant with a sudden expansion micro reactor was used. The grape seed suspension was pumped up to 26 MPa and instantaneously heated to 385 ^{o}C by mixing it with a SCW stream. The reaction is stopped by depressurizing the product through a high temperature needle valve and therefore instantaneously cooled down. The reaction time was adjusted in the range of 0.16s to 0.65s just by changing the length or the reactor and biomass and water flow.

Analysis

To determine the composition of the raw material and samples Laboratory Analytical Procedure (LAP) from NREL was followed. The analysis used to determine sugar and sugar degradation products is HPLC. The carbon content is determined by Total organic carbon and Elemental Analysis. Gel Permeation Chromatography is used for molecular weight distribution. FTIR and NMR analysis are used to understand the changes in sample structure.

3. Results and discussion

Amount of lignin in solid phase increases with the reaction time (Figure 1.) due to hydrolysis of labile fractions, which is also followed with a decrease of sugars in the solid phase and high yield in the liquid phase (Figure 2.). For reaction time 0.32 s the amount of lignin slightly decreases compared with lower reaction time and this could be the possible time point of lignin hydrolysis. Higher reaction time increase the content of lignin that can be due to lignin repolymerization. This behavior is supported by the sugar yield in the liquid phase. For the reaction time of 0.16 s the yield of sugar in the liquid phase is already high and reach 57%. Further increase in reaction time leads just to a slight increase in sugar yield as the main amount has been already consumed. After 0.32 s the yield of sugar again increases as the new amount of sugars inside the biomass matrix is more available. This is followed by an increase of degradation products during the reaction.

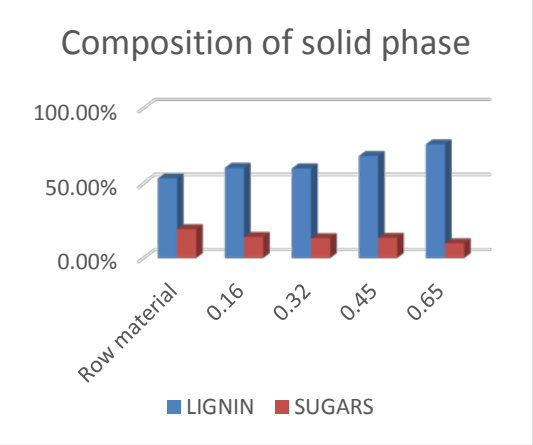

Figure 1. Composition of solid phase

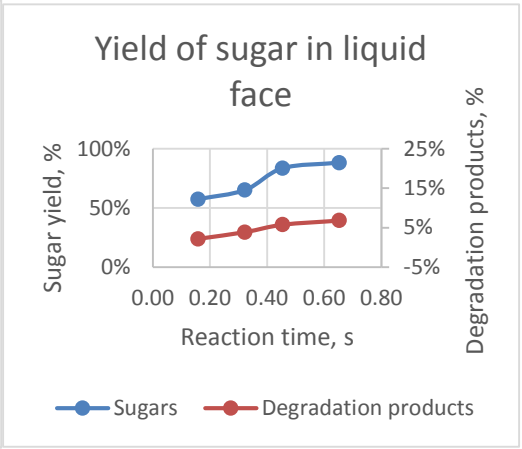

Figure 2. Sugar yield in liquid phase

4. Conclusions

The results of biomass fractionation in SCW show a slight decrease of lignin content in the solid phase at 0.32 s followed with increased sugar yield in the liquid phase that could be due to the lignin hydrolysis and higher availability of sugars at this time. High lignin content in raw material suggests that this biomass could be a great source for aromatic products derived from lignin degradation where more analysis is required in order to determine those products in the liquid phase, while the solid residue could be valorized as lignin-cellulose composites.

Highlights

- Temperature is the most significant factor for light and heavy biocrude yield.
- B/W is not a significant factor for light and heavy biocrude yield.
- Good biocrude and low solids yields were achieved without catalysts or capping agents.

1. Introduction

Residual/dedicated lignocellulosic biomass will be the future main feedstock for sustainable biofuel production, now dominated by lipids, which are criticized, since they rely on food and mainly on imported palm oil. The major effort in the EU focuses on developing new industrial energy chains to produce truly sustainable biofuels/bioenergy from lignocellulosic material. The lignocellulosic ethanol route has achieved full industrial scale worldwide and, consequently, a very wet lignin-rich co-product is made available at the production site in considerable amount and affordable costs [1], whose current use is combustion for heat and power generation. However, being lignin the most abundant renewable source of aromatics in nature, its valorization represents a very attractive opportunity for green chemistry. Several studies addressed the economic valorization of lignin-rich streams (LRS) from lignocellulosic ethanol production, highlighting the importance of co-product valorization to achieve commercial competitiveness [2,3]. Hydrothermal liquefaction (HTL) is a thermochemical process, which can convert biomass into a biocrude by using hot compressed water [4,5]. It is a wet process, which does not require feedstock drying, as it is generally required by other technologies like gasification and pyrolysis. As such, HTL is an attractive approach for the conversion of wet biomass into a liquid intermediate for chemicals and biofuels. HTL generates biocrude as main fraction, along with gaseous products, solids, and an aqueous-phase byproduct. Different behavior in pyrolysis of lignin from different origin was demonstrated in an international round-robin [6] and to date, most of the known HTL studies addressed lignin from pulp and paper or high-purity model compounds [7,8], both of them structurally different from lignocellulosic ethanol LRS, which still needs further investigation. The present work aims at partially filling this gap by preliminary assessing the viability of converting this material.

2. Methods

The LRS was characterized and then processed in a custom-made batch test bench. Two solvent extraction methods were investigated and compared for the extraction of a light and a heavy biocrude fraction. A full factorial design of experiment (5 % significance level) was performed, investigating the influence of process parameters on product yields, biocrude elemental composition, molecular weight and carbon balance. Investigated temperature, time and biomass-to-water mass ratio (B/W) were, respectively, 300, 350 and 370 °C, 5 and 10 min, 10 and 20 % w/w. The biocrudes were analyzed in terms of CHN, ash content, GPC and FT-IR.

3. Results and discussion

The feedstock, as received, contained a high amount of moisture (~70 % w/w on wet basis) and nearly 54 % w/w of lignin on dry basis. The total biocrude yields ranged from 39.8 to 65.7 % w/w. Temperature was the main parameter determining a different distribution between the light and heavy fractions: at 300 °C the higher amount of heavy biocrude was recovered, while at 350 and 370 °C the yield of the light fraction increased, reaching 41.7 % w/w at 370 °C. Instead, B/W ratio did not cause a significant effect on light and heavy biocrude yields. A relatively low amount of solid residue was observed (from 11.4 to 19.5 % w/w), even without catalysts or capping agents. Feedstock carbon content was mainly recovered in the biocrude (up to 77.6 % w/w): the distribution between the light and heavy fractions followed the same trend as the yields. The typical aromatic structure of the LRS was also observed in the biocrudes, indicating that mainly hydrolysis depolymerization occurred. The weight-average molecular weight of the total biocrude was strictly related to process temperature, decreasing from 1146 at 300 °C to 565 g mol^{-1} at 370 °C.

4. Conclusions

LRS was converted without catalysts or capping agents in light and heavy biocrude with a relatively low amount of solid residue. Concerning the biocrudes yields, temperature was the most significant parameter. The elemental analysis suggests that the light biocrude was mainly produced by decarboxylation rather than dehydration, which was more evident for heavy biocrude and solids. The aromatic structure typical of lignin was preserved in the biocrudes, indicating the feedstock was mainly subjected to hydrolysis depolymerization. The decreasing values of the molecular weight with temperature indicated that a consistent fractionation occurred.

Highlights

- Hybrid models have better accuracy in prediction compared to classical PLS models
- Hybrid models have better interpolation and extrapolation capabilities
- Ideal for Experimental Design and process optimization

1. Introduction

Over the last few years, the biopharmaceuticals market has witnessed tremendous growth reaching a value of worth $186,470 million in 2017. Now, the biggest challenge of the industry is to produce high-quality products in a cost–effective manner. To meet the market demands, there is a need for rapid and efficient process development that calls for the use of model-based methods to assist at several stages of process development, monitoring and control. The lack of complete understanding about the metabolic network and reaction pathways observed in the cells, especially mammalian cells hinders the development of First Principle Models (FPMs). Thus, increased efforts have been devoted to the use of statistical models (such as Partial Least Squares – PLS models) using historical, online spectral and sensor data [1]. However, one of the major limitations of statistical models is its invalidity or poor performance outside of the regions not explored in the underlying experiments. As a result, statistical models are not suitable for process design, development and optimization [2]. We propose and quantitatively show the advantages of using Hybrid modeling strategy which explores a synergy between the classical First Principle models and statistical models.

2. Methods

The FPMs provide a mixed system of differential - algebraic equation which often contains specific unknown parameters. The hybrid models establish a synergy by using statistical models to deduce these unknown parameters. Particularly, we pose mass-balance or pseudo mass-balance equations for bioreactor systems and use artificial neural networks to estimate the unknown specific rates. Through different bioprocess case studies, we showcase the added value of hybrid models compared to the state-of-the-art PLS models, in terms of: Predictive accuracy, interpolation and extrapolation capabilities and application in design of experiments for optimization of titer (concentration of monoclonal antibody produced).

3. Results and discussion

Hybrid models have the lowest errors in prediction for the key state variables (Figure 1, Left). Lower prediction errors ensure reliable models that can be used as soft sensors to replace expensive analytics. Secondly, given a fed – batch system with glucose feed from day 3, hybrid models correctly predict a daily continuous decrease in glucose concentration whereas the PLS models are not capable of incorporating the feeding strategies in a physically representative manner. Additionally, Hybrid models is seen to predict process variables accurately outside of the trained or observed operating conditions highlighting its potential application in *in-silico* design of experiments and process optimization (results not shown here).

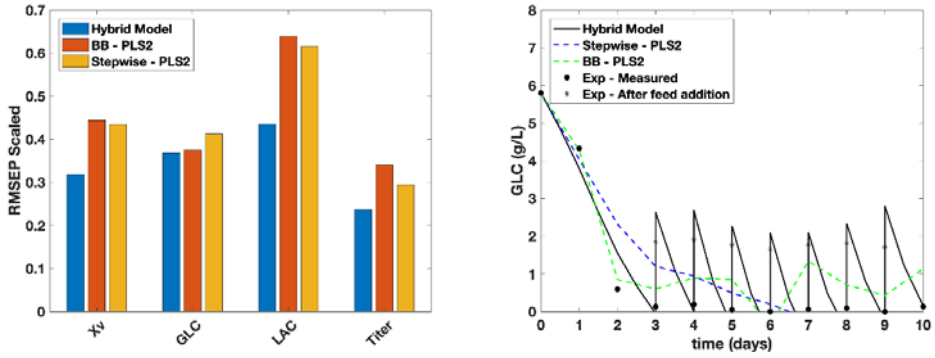

Figure 1. (Left) Comparison of the accuracy of the hybrid model against two statistical models (both based on PLS) in terms of standardized errors in prediction for viable cell density (Xv), Glucose (GLC), Lactate (LAC) and titer. (Right) The concentration of glucose predicted by the three models as a function of time along with the experimental observation.

4. Conclusions

A success in efficient data management and analytics is expected to have a tremendous effect on improving process development strategies and reducing manufacturing costs, thus making these therapies more available to society. We show that a modest modeling effort is sufficient to generate a hybrid model capable of predicting the complete evolution of the process variables and titer solely based on the initial conditions and the process operating conditions. Hybrid modeling also shows good interpolation and extrapolation capabilities in comparison to statistical models, which face intrinsic limitations to predict outside their training process condition space. This extrapolation capability is not only central for model–based process optimization but also for process scale–up, technology transfer and decision-making in process development. Thus, we strongly believe in investing efforts in the direction of hybrid modeling for process optimization and further extend its application to process monitoring and control.

Production of lactic acid from the organic fraction of municipal solid wastes using *B. coagulans*.

J. Pablo López-Gómez*, Roland Schneider, Peter Unger, Joachim Venus.

Leibniz Institute for Agricultural Engineering and Bioeconomy

**plopezgomez@atb-potsdam.de*

Highlights

- OFMSW hydrolysate contains more than 50 g/L of fermentable sugars.
- *B. coagulans* was able to grow without the addition of any extra nutrients
- Glucose is completely consumed and LA final concentration reached 60 g/L.
- The conversion yield for the process was 0.79 g_{LA}/g_{sugars}

1. Introduction

Investigations into new substrates for the production of chemicals and energy have become more demanding in recent years; not only looking for renewable sources but also for those that are cheap residues. This study focuses on the valorization of the organic fraction of municipal solid waste (OFMSW) also known as biowaste. On average, 40% of this abundant residue, with an estimated yearly production of 88 million tonnes, is landfilled in the EU. Besides posing an environmental risk, landfilling also disregards the potential of the material for being utilized as the substrate in other processes. The OFMSW, is rich in both carbon and nitrogen sources, which makes it an interesting material for the production of value added chemicals through fermentation. This study evaluates a hydrolysate produced from the OFMSW for the production of l-lactic acid. Besides the numerous applications of this versatile platform chemical, its utilization for polylactic acid (a biodegradable plastic) synthesis has recently raised interest on its production. *B. coagulans* are homofermentative l-lactic acid producers, with low nutritional requirements and the ability of growing at 52°C (reducing risks of contamination) which make them of interest for the valorization of waste streams. A *B. coagulans* isolate was used for the fermentations.

2. Methods

The substrate for the fermentation was a hydrolysate of the OFMSW. It was obtained from IMECAL SA (Valencia, Spain). Chemical compositional analysis of the substrate was performed for the determination of sugars, organic acids, minerals and nitrogen content. *Bacillus coagulans* A160 (Leibniz Institute for Agricultural Engineering and Bioeconomy, Germany) was employed for the fermentation of the OFMSW hydrolysate. The inoculum for the 1 L scale bioreactor was prepared in MRS broth (Merck, Germany) with dolomite EVERZIT Dol 0.5-2.5 mm (Evers, Germany) as buffer, at an orbital shaker set at 100 rpm, 42 °C for 13 h. Following preliminary lab scale fermentations a technical scale fermentation was carried out in a 72 L BIOSTAT UD bioreactor (B-Braun Biotech, Germany) containing 30 L of OFMSW hydrolysate. Fermentation was carried out at 52 °C and pH 6. Stirring occurred at 300 rpm using a double Rushton turbine. Regulation of pH was carried out by adding 20% (w/w) NaOH. The inoculum, 5% (v/v), was

prepared in a 2 L fermentation vessel containing 1 L of OFMSW hydrolysate. Samples were taken regularly for the quantification of sugars and lactic acid.

3. Results and discussion

Results for the compositional analysis of the OFMSW hydrolysate show that, in most cases, the hydrolysate has a concentration of glucose higher than 50 g/L. Results for the variation in concentrations of sugars and lactic acid throughout the fermentation are shown in Figure 1.

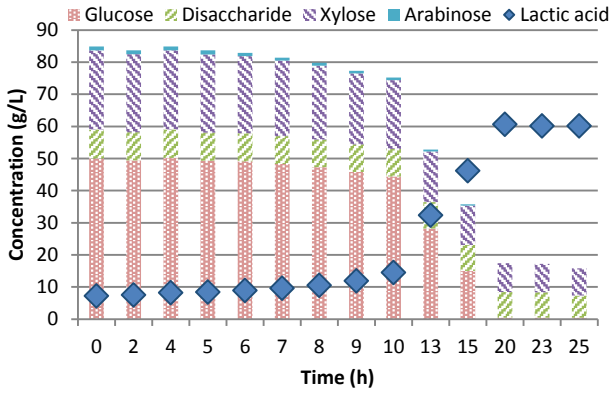

Figure 1. Variation in the concentrations of sugars and lactic acid during a fermentation of OMSW hydrolysate in a technical scale bioreactor (30 L working volumen). The strain used was B coagulans A166 and the fermentation was performed at 52°C and pH was controlled at 6.

LA had a concentration of 7.25 g/L at the start of the fermentation reaching a maximum value of 60.71 g/L by the end of the fermentation. Analysis of enantiomeric purity gave a result of 93.85% for L-LA. As shown in the figure above, the initial concentration of total sugars was around 83 g/L. From that, 50 g/L was glucose, 24.5 g/L xylose, 9 g/L disaccharides and 1.25 g/L arabinose. The fermentation was stopped when the production of LA ceased, by that point the remaining concentration of total sugars was 15.80 g/L. That represents a consumption of approximately 81 % of the initial amount of sugars. The conversion yield for the process was 0.79 g_{LA}/g_{sugars} (79 % conversion).

4. Conclusions

The hydrolysate from OFMSW is a good substrate for the production of lactic acid with a total sugars concentration in the hydrolysate exceeding 70 g/L (50g/L for glucose). Furthermore, the hydrolysate is able to support the growth of the bacteria without the addition of any other nutrients and without any apparent inhibitory effects. After fermentation using *B. coagulans* conversion yield for the process was 0.79 g_{LA}/g_{sugars} and a LA final concentration of 60.71 g/L were achieved.

Startup of a tubular Microbial Electrolysis Cell for biogas upgrading

Lorenzo Cristiani*, Marco Zeppilli, Mauro Majone

Department of Chemistry Sapienza University of Rome, Piazzale Aldo Moro 5 00185 Rome, Italy

**Corresponding author: Lorenzo.cristiani@uniroma1.it*

Highlights

- Biogas Upgrading through bioelectromethanogenesis
- Fluidynamic and polarization curve characterization
- Conversion of electrical current into methane

1. Introduction

Biogas, the main product of the anaerobic digestion (AD) process, is a gas mixture mainly composed by carbon dioxide and methane. To obtain biomethane, with a high percentage of methane (>95%), is necessary a purification to remove the impurities such as NH_3, H_2S, and an upgrade step to remove the CO_2. These last steps are economically expensive and usually the biogas is utilized for the cogeneration of electricity and heat, however, an innovative strategy for biogas upgrading consist in the utilization of a microbial electrolysis cell (MEC) in which the reduction of carbon dioxide to methane is performed by a biocathode. The bioelectromethanogenesis reaction is made by electroactive microorganisms who convert CO_2 into CH_4 (Villano et al., 2010). Here, a fully biological tubular Microbial Electrolysis Cell (MEC) has been developed for the upgrading of biogas produced by a pilot scale two stage AD reactor operated with real agricultural waste from a cattle farm, mainly composed by manure and straw and crops residues. Inside the MEC, the bioreduction reaction occurred in a cathodic chamber converting the CO_2 into CH_4 while the oxidation of the organic matter by an anodic biofilm partially sustained the energy demand of the process. Before the inoculation of the tubular MEC, the fluidynamic of the anodic chamber has been characterized by a tracer test while a polarization curve permitted the description of the potential distribution in the reactor. After the inoculation of the anodic and cathodic chamber the batch startup phase has been conducted by controlling the anodic potential at 0.2V vs. SHE.

2. Methods

The empty volume of the MEC was 12 L; The anodic and cathodic chambers were filled with graphite granules with a concentric configuration, the chambers were separated by a tubular anion exchange membrane (AEM). The synthetic biogas (70-30 % v/v N_2-CO_2) has been fed from the bottom of the biocathode, the graphite granules bed allowed the growing electroactive biofilm on the surface area, available for the mass transfer from gaseous to liquid phase and vice versa. The bioanode was fed with a synthetic mix of organic substrates (glucose, peptone, yeast extract and acetic acid). The MEC polarization was controlled by a three-electrode configuration, in which the anode chamber resulted the working electrode. NH_4^+ was used as tracer for the tracer test analyzed with the Nessler method.

3. Results and discussion

The tracer test permitted to calculate the hydraulic residence time (58 minutes) and the porosity of the graphite granules (0.57), moreover the test showed the complete hydraulic separation of the two chambers. In figure 1 shows the concentration of NH_4^+ during the tracer test.

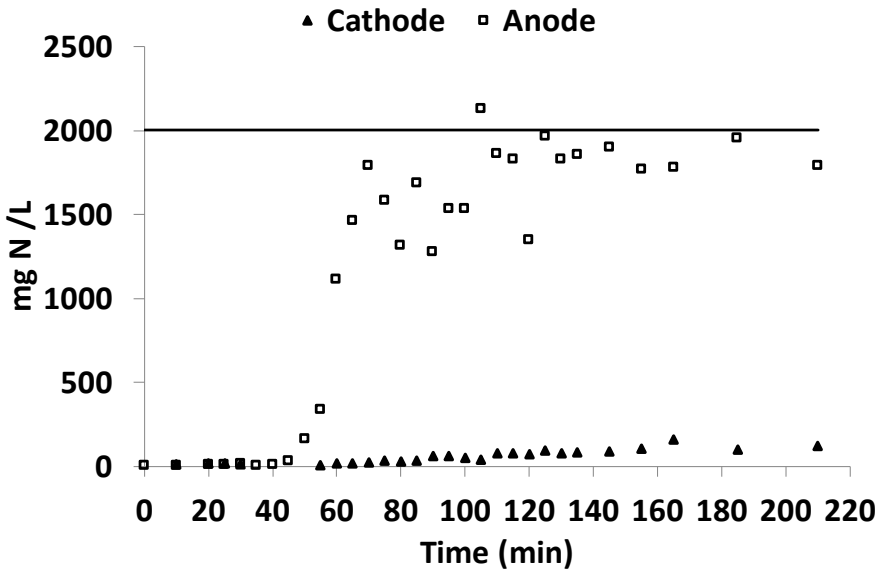

Figure 1. Nitrogen concentration during the tracer test.

The polarization curve of the tubular MEC showed the dependence of the anodic and cathodic electrodic potentials as well as the current flowing in the circuit as a function of the applied potential difference. After the preliminary characterization of the fluidynamic and of the electrodic potentials, the anodic and cathodic chamber have been inoculated with an activated sludge and an anaerobic sludge, respectively. The anodic potential was set at +0.2 V vs SHE and it was fed with the synthetic mix solution with a batch configuration. After nine days from the inoculation of the MEC, the electric current profile showed the production of a current around 100 mA, indicating the capability of the anodic biofilm to consume the organic matter by suing the anode as electron acceptor. The startup process went on for 35 days reaching a maximum of 120 mA, while in the cathodic chamber, the methanogenic biofilm produced 45 mmol/d of methane with an average cathode capture efficiency (i.e. the conversion of the current into methane) around 100 %.

4. Conclusions

The new tubular configuration MEC startup was successfully performed by using synthetic mixture of organic substrates, that permitted the development of electroactive biofilms in the anodic and cathodic chambers to perform the bioelectromethanogenesis reaction, sustained by the COD anaerobic oxidation

Valorization of distillers dried grains with solubles for the production of enzymes

Jasper Driessen, Solange I. Mussatto

Biomass Conversion and Bioprocess Technology Group,
Novo Nordisk Foundation Center for Biosustainability, Technical University of Denmark
**Corresponding author: jasdri@biosustain.dtu.dk*

Highlights

- Optimization of lignocellulosic biomass pretreatment
- Adaptive laboratory evolution for increased robustness to hydrolysate-associated inhibitors
- Optimization in small-scale fermenters to study scale-up and scale-down effects for increased industrial applicability

1. Introduction

The total production volume of bioethanol reached 96 billion liters in 2015 and economic projections estimating a steady increase until 2020 [1] [2]. A vital part (20%) of the total plant revenue is generated by selling of distillers dried grains with solubles (DDGS) as animal feed. However, since DDGS can only account for 30% of the wildstock feed (dry basis) due to palpability and excessive protein issues, a saturated animal feed market is expected lower DDGS market prices [2]. Bearing these developments in mind, the need of an innovative method to generate value to DDGS grows.

The global industrial enzymes market should reach $7.0 billion by 2023 from $5.5 billion in 2018 at a compound annual growth rate (CAGR) of 4.9% for the period 2018-2023 [3]. Although the industrial production of enzymes is well established, the growing market, high production costs and high level of competition in a changing market have pressed industry to seek new sustainable alternatives for their processes [4] [5]. Next to capital investment (50%), the highest cost factor of industrial enzyme production is associated to raw materials (33%) [6]. Last decades, researchers started to look into using agro-industrial lignocellulosic waste streams as raw material for enzyme production [6].

2. Methods

In this project, we propose an innovative bioprocess for the valorization of DDGS by using it as raw material for enzyme production (Fig.1). First, characterization of feedstock and optimization of biomass pretreatment are required to produce a suitable hydrolysate-based medium. Combining molecular biology tools for strain development and bioreactor design principles for optimized fermentation conditions will ensure that all aspects of enzyme production are covered. In the last phase, the optimized production strain is optimized for different process parameters in small-scale bioreactors. Final experiments in large-scale fermenters are used to validate strain productivity.

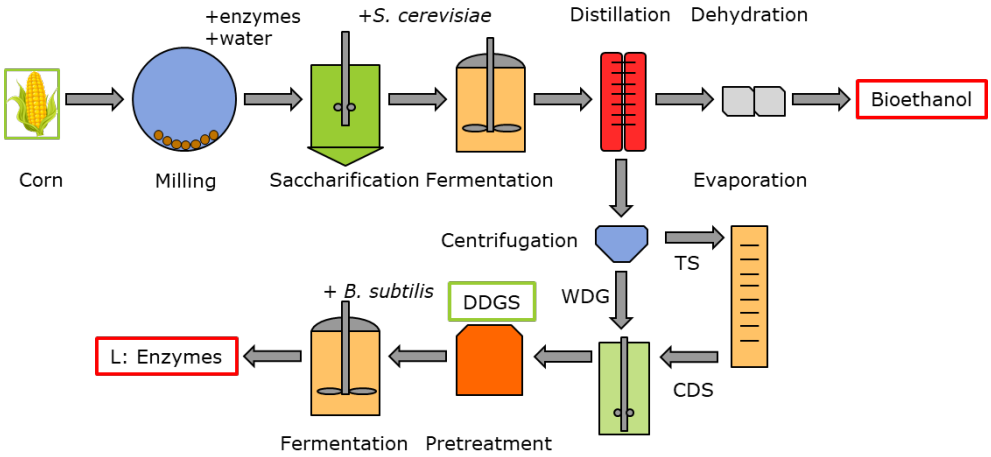

Fig. 1 Valorization of DDGS by enzyme production

3. Results and discussion

DDGS is a highly available material (32.3 kg DDGS /100 kg grains in a dry milling process), rich in nutrients and carbon sources (crude protein 24.9%, cellulose 16%, starch 5.2%, xylan and arabinan 13.5% w/w) [2] [8]. The high amount of sugars released after biomass conversion as well as the crude proteins serve as source of energy, carbon and nitrogen to sustain microbial growth during fermentation. Considering the price and composition of DDGS, valorization via biomass conversion for enzyme production seems to be a promising strategy.

4. Conclusions

The integration of DDGS to a multi-stream process could lead to the generation of different value added products, increasing economic viability and reducing DDGS market saturation associated to the growing bioethanol industry. Insights gained in this project should result in clear and applicable recommendations for the industry.

Development of a high pressure bioreactor system for the production of biomethane from CO2 using an axenic methanogenic culture as biocatalyst

Sébastien Bernacchi[1,*], Arne H. Seifert[1]

Krajete GmbH, Josef Perger-Straße 2, 3031 Pressbaum, Austria

Highlights

- Gas to gas (GtoG) converting bioprocess
- CO_2-BMP, an axenic unsterile methanogenic archaea-based process using a fully defined mineral medium for growth
- Gas limitation and liquid limitation in gas converting bioprocesses
- Continuous and intermittent bioprocessing of industrially sampled H_2/CO_2 gas mixtures

1. Introduction

Over recent years the interest in new biofuel generations, based on converting gaseous substrate(s) such as carbon dioxide (CO_2), carbon monoxide (CO) or hydrogen (H_2) to gaseous product(s), arose. An example for such a gas converting bioprocess is the biological methane production process using CO_2 as sole carbon source (CO_2-BMP) [1]. Axenic cultures of *Methanothermobacter marburgensis* grown in a defined mineral medium already proved that high conversion rates of CO_2 and H_2 to methane (CH_4) can be reached [2]. However, this bioprocess was often described in literature as a gas transfer limited bioprocess [3]. Therefore, the kinetic limitation towards an increased methane productivity cannot be overcome solely by the growth of more biomass during continuous operation. More important is the development of a suitable bioreactor system that allows reaching a high mass transfer of the limiting gaseous substrate (H_2) in the liquid phase once an appropriate feeding strategy is applied to maintain sufficient biocatalyst in suspension for converting all the dissolved reactive gases. This work will present development steps [4], [5], methods [6], [7] as well as the applied bioprocess control approach [8] that enabled to construct and operate a custom designed and manufactured high pressure 20 L bioreactor system to overcome the so far existing performance limitations. In this setup, a methane evolution rate (MER) higher than 1.4 $mol_{CH4}\ L_{broth}^{-1}\ h^{-1}$ was reached using an axenic chemostat culture of *Methanothermobacter marburgensis* grown on a defined mineral medium at pressures up to 16 bar while using solely CO_2 as carbon source. The application of this feed forward control strategy enabled to predict and control biomass growth during operation which in return allowed to convert more than 99% of the applied 2.9 vvm [$NL_{gas}\ L_{broth}^{-1}\ min^{-1}$] of H_2-CO_2 into a high purity bio-CH_4 (>95 Vol.% CH_4 in the raw wet gas).

2. Methods

The integrated modular development workflow that will be presented consists of studying the biomethanation process from different angles and using different "levels" of pressurized H_2 and CO_2 gas mixtures to unscramble both, the potential physiologic limitation that could arise on one

side, and the benefits of high pressure on the reaction kinetic on the other side. The following aspects have been investigated: pressure tolerance, media demands, feed strategy development for fermentation and validation runs in continuous culture to reach performances above 20 kg_{CH4} m^{-3} h^{-1} (MER > 1250 $mmol_{CH4}$ L_{broth}^{-1} h^{-1}) in steady state production in order to support process simulation and tecno-economic assessment.

3. Results and discussion

A reference culture of *Methanothermobacter marburgensis* was used to validate the application of the feed forward strategy concept and demonstrate the possibility to control gas transfer limited bioprocesses. This allowed reaching the desired stability for operations as well as predicting media demand when elaborating specific feed strategies for the different operational profiles. An example of a dynamic intermittent operation is shown in **Figure 1**.

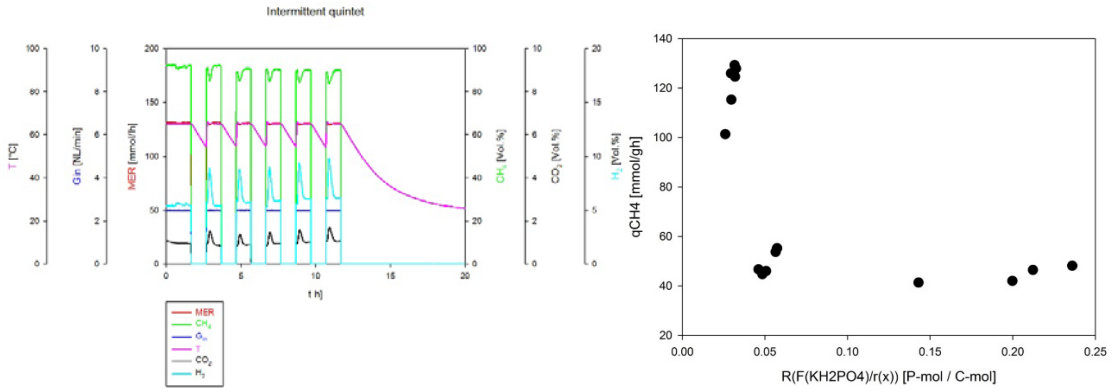

Figure 1. Feed forward strategy application to a CO2-BMP intermittent operation allowed uncoupling biomass growth control from methane production by varying the biocatalyst performances.

The feed strategy used to predict and control operations has been validated in pressure less conditions and further used for designing the cultivation medium for high pressure experiments where pseudo-steady state conditions had to be applied. After that, the know-how on the bioprocess was used for engineering, designing and building a custom-made pressure resistant CSTR that allowed to transfer axenic cultures to an elevated pressure environment (up to 16 barg). The latter allowed reaching unprecedent productivities using solely CO_2 as carbon source.

4. Conclusions

The application of an interdisciplinary modular development approach [9] to the CO2-BMP process allowed on one side assisting the prediction works for tecno-economic analysis [10] and process scale up while on the other hand elaborating a control strategy for the bioprocess suited for a vast range of operational regimes. This resulted in reaching high performances (methane evolution rate (MER) higher than 1.4 mol_{CH4} L_{broth}^{-1} h^{-1}) with sufficient methane (CH_4 > 95 Vol.% for the raw wet gas) that allow to reach most of EU countries gas grid specifications after a final purification step. Greatly acknowledge is the funding from the European Union's Horizon 2020 research and innovation program under grant agreement number 679050 (project: CELBICON).

Highlights

- Use of carbonic anhydrase (CA) to enhance CO_2 solubilization.
- Different concentrations of CA tested.
- Use of a fixed bed trickle down system to enhance CO_2 solubilization.
- Comparing the two different strategies and their combination.

1. Introduction

In recent times, CO2 has started to be used as a building block to produce a wide range of chemicals and products *via* biological processes. This has drastically changed the point of view, from seeing it just as a pollutant, to consider it as an economic substrate. This idea totally fits in the idea of circular economy, reducing greenhouse gases (GHG) emissions and converting CO2 into a high value product.

However, one of the major bottlenecks in the conversion of CO_2 into desired molecules *via* industrial biotechnology is the low yield of the target compounds. Among the different factors responsible for this low productivity, issues regarding gas availability should be addressed, like gas-liquid mass transfer and CO_2 solubility.

This study assesses two different strategies and their combination, a fixed bed trickle down system (TBR) [1] and a robust enzyme carbonic anhydrases (CA) [2], [3]. The improvement of gas-liquid mass transfer and CO_2 solubility enhance further 3-hydroxypropionic acid (3-HP) production using the *Cupravidus necator*.

2. Methods

Temperature and pH are two physical conditions that must be defined to promote the solubility of CO_2 and enhance the performance of the selected microorganism or enzyme. In this case, the experiments are performed at 30ºC (optimal temperature for *Cupravidus necator*) and at pH 8 (being the bicarbonate the main chemical species at liquid phase). The solution has a buffer of K^+-PO_4^{3-} and each experiment takes place in 3 hours.

Figure 1 shows the two main strategies for CO_2 solubilisation. On one hand, CO_2 is introduced in a 1 L stirred vessel filled with the buffer solution with and without CA. On the other hand, a TBR filled with Raschig rings (6x6mm) is first optimized in terms of liquid flow and gas flow ratio (in countercurrent) and then the optimized concentration of CA is introduced in the system.

Samples are withdrawn regularly during each experiment to study the kinetics of CO_2 absorption.

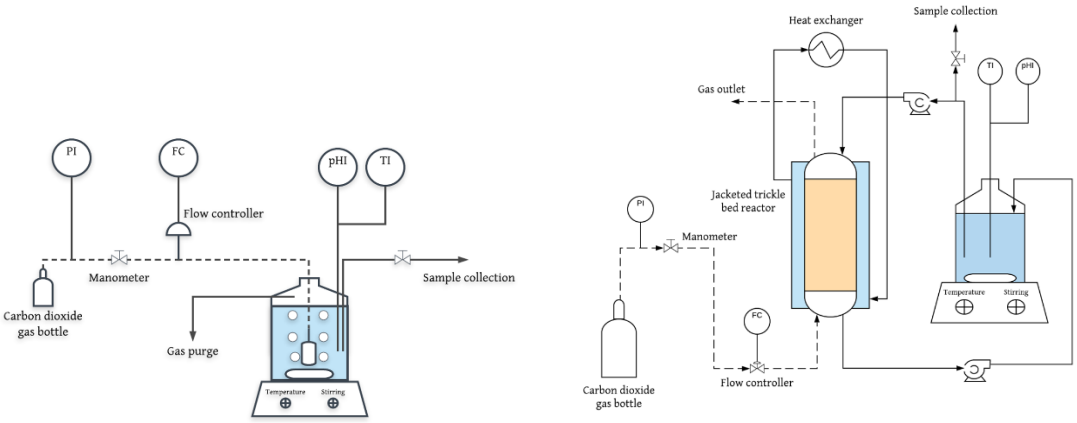

Figure 1. Experimental set-up for solubilization in vessel (left) and in TBR (right).

3. Results and discussion

Table 1 shows the preliminary results of CO_2 absorption in different conditions.

Table 1. Preliminary results on CO_2 absorption.

	Water	Buffer	Buffer + CA	TBR
CO_2 absorbed (%)	6,49	16,34	17,91	39,67

As it can be seen, the use of the buffer increases significantly the amount of CO_2 absorbed as the pH is maintained at 8. The use of CA has a slightly positive effect, but further experiments using higher concentration of CA are needed. Furthermore, the TBR presents the better result in terms of CO_2 adsorption and the use of CA in this system is expected to increase this value even more.

4. Conclusions

The use of CA and TBR has proven to be effective strategies to enhance CO_2 solubility. This will allow the conversion of CO_2 into desired molecules *via* industrial biotechnology to have a higher yield of the target compounds such as 3-HP (as is the case of the project in which this study is framed) and other chemicals and products *via* biological processes.

Highlights

- Continuous conversion of organic acids to solvents
- Minimized loss of glucose in effluent
- Optimized bioprocess for maximum specific uptake rates of organic acids

1. Introduction

Emerging technologies are sought to utilize a multi-feedstock biorefinery process to efficiently convert industrially based lignocellulosic waste streams, such as black liquors or hydrolysates, into high value-added chemicals such as butanol. However, the use of those feedstocks is due to their volatile composition and quality quite challenging.

2. Goal

As initial conversion step of those feedstocks we use the 'carboxylate platform' to produce organic acids which are then supplied to a bioreactor for the production of solvents with solventogenic clostridia. Thereby the ratio and total concentration of those acids as well as the pH are known to significantly affect their uptake rate and thus subsequently the production of solvents [1, 2]. For the prolonged and efficient conversion of waste streams to butanol it is crucial to optimize the bioprocess for high specific uptake rates of organic acids.

3. Methods

The organism *C. saccharoperbutylacetonicum* was grown on a modified Clostridial Growth Medium (CGM). Fermentations are carried out on a parallel bioreactor system (Eppendorf DASGIP) controlled at 30 °C, stirred at 100 rpm and constantly purged with 5 L h^{-1} of sterile N_2 to maintain anaerobic conditions as well as to monitor the production of CO_2 and H_2 with a Micro GC Gas Analyzer (Inficon). Samples are frequently collected from the reactor for HPLC analysis (Shimadzu), determination of the cell dry weight (CDW) and measurement of the optical density (OD).

4. Results and discussion

Previously, we demonstrated the successful uptake of supplied butyric and acetic acid and their conversion to solvents in batch and fed-batch fermentations. We also could confirm that glucose has to be present in the medium for this conversion to function, as it serves both as source of ATP

and electrons for the conversion of butyric acid to butanol as well as carbon source for biomass growth [3]. In this work, we aim to operate a continuous fermentation. As we only want to use glucose, which is necessary for the conversion of acids, the concentration of glucose in the reactor will be kept in a limiting state by applying a pH controlled feeding strategy. With this system, we additionally also minimize the loss of unmetabolized glucose via the effluent stream. Finally, this will ensure an efficient consumption of substrate while maintaining a high uptake rate of fed organic acids for the continuous conversion to solvents.

5. Conclusions

We aim to demonstrate the continuous uptake of butyric and acetic acid and their conversion to solvents. The gained knowledge from this work is a first and important step towards establishing long term stable conversion of volatile lignocellulosic waste streams to butanol for next generation biorefineries.

Valorisation of municipal solid waste for succinic acid production via continuous fermentation and value added products through biorefinery

Eleni Stylianou, Dimitrios Ladakis, Chrysanthi Pateraki*, Apostolos Koutinas

1 Agricultural University of Athens, Iera Odos 75, 11855, Athens, Greece;

**Corresponding author: paterakichr@aua.gr*

Highlights

- Organic fraction of municipal solid waste (OFMSW)
- Biorefinery development
- Continuous fermentation
- Technoeconomic evaluation

1. Introduction

Nowadays renewable resources can be used as a potential feedstock for the production of biobased and value-added products. Municipal solid waste (MSW) generation is continuously increasing worldwide. The organic fraction of municipal solid waste (OFMSW) contains high amounts of lipids, protein, pectins and complex polysaccharides. Valorisation of OFMSW though a biorefinery approach could lead to the production of value-added products. Hydrolysis of OFMSW results in the production of a carbon and nutrient rich fermentation supplement. Succinic acid is one of the most important platform chemicals in the bio-economy era. Succinic acid production via continuous fermentation can lead to increased productivities, resulting in an economic feasible process. In this study OFMSW was hydrolysed with commercial enzymes and value-added products (lipids, proteins, pectins) have been subsequently extracted through biorefinery development. OFMSW hydrolysate has been used as the sole fermentation feedstock for the production of succinic acid by *A. succinogenes* via fed-batch and continuous fermentations. Furthermore, technoeconomic evaluation for succinic acid production has been carried out.

2. Methods

The organic fraction of municipal solid waste (OFMSW) was treated with commercial hydrolytic enzymes. Furthermore, through biorefinery development lipids were recovered with hexane and proteins were separated using ultrafiltration with 3 kDa membrane cut-offs. The remaining fraction was treated with acidified water at high temperatures and pectins were recovered with ethanol precipitation. OFMSW hydrolysate was used for continuous fermentations with *Actinobacillus succinogenes* 130Z in a 2L bench top bioreactor. Different dilution rates were evaluated in continuous cultures. The temperature was 37 ◦C, agitation was 100 rpm and continuous sparging of CO_2 at 1 vvm flow rate were contestant throughout the fermentation. C6 and C5 sugars and organic acids were analysed by high-pressure liquid chromatography (HPLC) with refractive index (RI) detector (Shimadzu) and an HPX-87H (7.8 x 300 mm) column (Aminex). The temperature of the

column was 65 °C and the mobile phase was a 10 mM H_2SO_4 aqueous solution with 0.6 mL/min flow rate. A techno-economic analysis of continuous fermentations was developed in order to investigate the commercial viability of biotechnological succinic acid production. The process design of the mass and energy balances was developed in Unisim software.

3. Results and discussion

OFMSW hydrolysate sugar concertation was around 90 g/L. The major carbon source fraction was glucose (84.5 %) followed by xylose (8.4 %), while glycerol, sucrose, galactose, arabinose, mannose and fructose were less than 2.5 %. Free amino nitrogen and inorganic phosphorus concentration was 203.6 mg/L and 100.6 mg/L, respectively. Lipids, proteins and pectins were recovered from the MSW hydrolysate at 90%, 50% and 40% yields, respectively. OFMSW hydrolysate was utilized for succinic acid production in fed-batch and continuous mode. Fed-batch fermentation in OFNSW hydrolysate resulted in more than 35 g/L of succinic acid. Continuous fermentation was carried out at different dilution rates and productivity achieved was higher than 1.5 g/L/h using OFMSW hydrolysate. Technoeconomic evaluation resulted in a minimum celling price of succinic acid below 2.5 $/kg.

4. Conclusions

OFMSW is an ideal raw material for the production of biobased products. Furthermore, various value-added products could be extracted from OFMSW. Succinic acid production was carried out in fed-batch and continuous cultures using OFMSW hydrolysate as the sole carbon source.

Highlights

- Addition of HCOOH allows achievements of higher biocrude yields at higher biomass loadings.
- Addition of HCOOH increases the H/C molar ratio of biocrude.
- Detected production of light hydrocarbons from hydrothermal co-liquefaction of sewage sludge and formic acid.

1. Introduction

The biocrude produced by non-catalytic hydrothermal liquefaction (HTL) has a too high heteroatom content to be used directly as a fuel [1-3]. Several studies found that different H_2 initial pressures during HTL experiments were ineffective in improving the biocrude yield [4-6], nevertheless it was observed that higher initial pressures of H_2 brought an improvement of the concentration of light compounds in the biocrude, decreasing the average molecular weight of biocrude oil. To date H_2 is mainly generated from fossil sources and realization of a possible hydrogen economy from alternative sources presents many challenges. The use of a liquid hydrogen storage media could represent for the HTL process an alternative solution to avoid the mass transport resistance associated to gaseous H_2, furthermore Biller and Ross [7] observed that the addition of selected organic acids had similar effects than the addition of molecular H_2. According to these premises, we studied the influence of formic acid as hydrogen donor on the yield and quality of the biocrude produced by HTL of sewage sludge (SS). Formic acid was selected because it can decompose to hydrogen and carbon dioxide under mild conditions [8] and it can be produced by electrochemical reduction of carbon dioxide, an appealing process to capture atmospheric carbon dioxide under the form of a useful chemical [9].

2. Methods

SS provided by WWTP of Palermo, Italy (A.M.A.P. spa) and formic acid (Alpha Aesar 97 vol%) were used in HTL experiments. $CoMo/Al_2O_3$ (Albemarle, KF1022 cylindrical units) was used as catalyst. Acetone and cyclohexane (Sigma Aldrich, analytical grade) were used to recover the biocrude. A stirred stainless steel reactor with a volume of 30 mL was filled with 10 g of slurry changing the SS loading from 10 to 20 and 30 % w/w, formic acid loading was fixed at 1.8 % w/w. When used catalyst was added with a concentration of 10 %w/w with respect to SS. Set point temperature was reached by a software controlled ceramic heater with a typical heating rate of 13 °C/min and the reaction

time was considered to start when the set-point temperature was reached. The procedures adopted for products separation after HTL tests are the result of the optimization of the methods reported in our previous work [10]. The yields of the products were expressed in dry ash free (daf) form (i.e. referred to the organic content of the feedstock) as reported in the literature [10,11]. All experiments were repeated twice and mean values are reported. Elemental analyses of the biocrudes was performed in a Perkin Elmer 2400 series II elemental analyzer. Biocrude yield was determined after stripping of recovery solvents (daf %vw/w). Light hydrocarbons evaporated during stripping were condensed in a cold trap. Their relative amounts were estimated in term of fractional chromatographic areas (A%) after gas–chromatography analyses of the liquid (GC AutosystemXL Perkin Elmer equipped with a column Zebron ZB-FFAP).

3. Results and discussion

At a SS loading of 30% w/w, the biocrude yield increased from 39±2% w/w to 55±2% w/w when formic acid was added. Furthermore an increase of H/C molar ratio (from 1.54 to 1.96) was observed in the biocrudes produced in the presence of formic acid. The work herein, starting from the observed results found in literature, tried to evaluate the effect of formic acid on the performances of the hydrothermal co-liquefaction process characterizing also the produced light compounds. A technique to recover and to to trap solvent vapours during the stripping process of the biocrude phase was optimized and light hydrocarbons (C10-C18) were effectively detected by gas-chromatography analyses of the trapped phases. By means of this technique cumulative chromatographic area associated to light hydrocarbons increased from 7 to 32% when HCOOH was added at 10% w/w loading of SS.

4. Conclusions

Formic acid, obtainable from electrochemical reduction of carbon dioxide, showed promising result in improving the yield and the quality of biocrude generated from HTL of SS. Furthermore in the presence of formic acid, an increase of produced light hydrocarbons compounds was observed, and a better closure of the mass balance was obtained.

Process development for the bioproduction of L-malic acid with *Aspergillus oryzae* DSM1863

Vanessa Schmitt[1], Katrin Ochsenreither[1]

1 Karlsruhe Institute of Technology (KIT), Institute of Process Engineering in Life Sciences, Section II: Technical Biology, 76131 Karlsruhe, Germany

**Corresponding author: Vanessa.schmitt@kit.edu*

Highlights

- Repeated-Batch cultivations increase the maximal productivity compared to fed-/batch cultivations.
- The highest product titers can be achieved with calcium carbonate as neutralization agent.

1. Introduction

L-Malic acid is a C4-dicarboxylic acid and a potential key building block for a bio based economy. Currently, malic acid is synthesized petrochemically. It is mainly used in the food and beverages industry, in metal cleaning and pharmaceuticals. Due to its bifunctionality, malic acid can also serve as polymerization starter unit and cross linker. A sustainable alternative to petroleum based synthesis is the microbial production of L-malic acid from renewable resources [1]. As CO_2 fixation is involved in biosynthesis, high yields are possible and at the same time greenhouse gases can be reduced. The mould *Aspergillus oryzae* is known for its high production capacity for L-malic acid and has received GRAS status, making it a promising candidate for industrial scale fermentations [2]. The microbial L-malic acid production with *A. oryzae* DSM1863 was evaluated in laboratory scale experiments to gain a better process understanding and to identify obstacles for the transformation into the industrial scale. Different aspects including pH regulation and cultivation strategy were investigated.

2. Methods

Batch, fed-batch and repeated-batch cultivations were performed in in 500 mL shake flasks with baffles and a working volume of 100 mL. A defined medium with glucose as substrate was used. Calcium carbonate was added in advance of the fermentation and as required during the fermentation for pH-regulation. Furthermore, different neutralization agents, including carbonates and hydroxides of calcium, magnesium and sodium, were tested in 2 L bench top fermenters with a working volume of 1.4 L. All fermentations were performed for at least one week and samples were taken daily. Substrate, product and by-product concentrations were measured via HPLC to determine the process characteristics (titre, yield and productivity). Additionally, pictures of the fungi were taken to document macroscopic changes of the morphology.

3. Results and discussion

In repeated-batch cultivations, the productivity was higher and the productive phase was prolonged compared to batch cultivations, in which the L-malic acid concentration reached its maximum after about one week. On the other hand, the productivities in the fed-batch cultivations were lower as in repeated batch cultivations.

The addition of calcium carbonate was proven to be crucial for the L-malic acid production. In reactor experiments with alternative neutralizing agents product titers were significantly lower. Hence, the positive effect of calcium carbonate cannot only be explained by the positive effect of pH-regulation. In addition, the precipitation of L-malic acid as calcium malate plays an important role in the L-malic acid production, as it lowers the acid concentration within the media, thereby preventing product inhibition.

4. Conclusions

In summary, the results obtained from shake flask cultivations proved the suitability of repeated-batch fermentations for the L-malic acid production with *A. oryzae*. The high productivities in repeated-batch fermentations compared to lower productivities in batch and fed-batch cultivations suggest that product inhibition limits the L-malic acid production, while substrate inhibition is of minor importance. The next step would be the upscaling of the repeated-batch fermentation to reactor scale. Furthermore, continuous fermentations with in situ product recovery seem to be an interesting research topic.

Calcium carbonate proved to be the best neutralizing agent for the L-malic acid production with *A. oryzae* DSM1863 in terms of product concentrations by preventing product inhibition. However, by resolving the calcium malate with sulfuric acid in downstream processing, huge amounts of gypsum are produced, generating extra costs for waste disposal. Therefore, liquid neutralizing agents like sodium carbonate or hydroxide should be considered as an alternative, despite the lower product titers observed. Additionally, the issue of product inhibition should be tackled by strain development and/or by applying in situ product removal.

Highlights

- Orange peel
- Bacterial cellulose
- Biorefinery development

1. Introduction

Citrus residues represent an interesting renewable feedstock because of its wide availability and propensity to yield chemicals and materials. The worldwide citrus production in 2016/17 was 63.3 million tonnes with oranges dominating market share at 80 %. 1 Citrus peel represent the 50% of the total fruit mass and considered as low-value by-product stream from the corresponding processing industries. Orange peels contains bio-active compounds such as D-limonene and pectin as well as important amounts of carbohydrates (potentially more than 80 % of peel weight) 2 that can be used as feedstock for the production of fermentative products such as bacterial cellulose.
Bacterial cellulose (BC), is a highly functional biopolymer that can be find applications in numerous sectors including pharmaceutical, broadcasting, food industry, paper manufacture and mining. Bacterial cellulose (BC) produced mainly via fermentative procedures of Acetobacter species utilizing numerous carbon sources. This study evaluates the potential development of a biorefinery concept focusing on the utilization of orange peels for the production of BC and various value-added co-products.

2. Methods

The valorization of orange peels starts with the recovery of soluble sugars followed by the extraction of bioactive compounds (D-limonene and pectin) while the remaining solid fraction (mainly cellulose) was treated with commercial hydrolytic enzymes. Soluble sugars were removed with water at 60 oC, D-limonene extraction was carried out using the hydro-distillation method and the pectin using acidified water at pH 1.5 with 0.5 M HCl. The remaining solid residue was treated with commercial enzymes for the production of a sugar rich hydrolysate. The hydrolysate mixed with the fraction of the soluble sugars and used as a substrate for bacterial cellulose production via fermentation using the bacterial strain of *Komagataeibacter sucrofermentans* DSM 15973.

3. Results and discussion

The hydrolysate of the orange peel in combination with soluble sugar consist an eventual feedstock for the cultivation of K. sucrofermentans leading to a bacterial cellulose concentration of 6.4 g/L, a yield equal to 0.34 g/L and a productivity of 0.61 g/L/d. D-limonene and pectin extraction reach the values of 3.2 g and 12 g per 100 g of dry orange peel respectively.

4. Conclusions

Orange peel is an attractive raw material for the production of bio-based products. The bacterial strain of Komagataeibacter sucrofermentans DSM 15973 efficient cultivated in low cost feedstock derived from orange peel treatment with adequate production of bacterial cellulose in high yield and productivity values.

Highlights

- *Yarrowia lipolytica* was engineered to efficiently convert xylose into lipids
- Isomerase-base pathway enabled *Y. lipolytica* high-yield lipid production from xylose
- Isomerase-based pathway supported simultaneous co-fermentation of glucose and xylose

1. Introduction

Lignocellulosic biomass is one of the most attractive renewable resources for fuels and chemicals production. *Yarrowia lipolytica*, non-conventional oleaginous yeast, is a promising host for biodiesel and oleochemical production from lignocellulosic biomass. With advances in metabolic engineering, *Y. lipolytica* efficiently converts glucose into lipids up to 90% of its cell mass [1]. Yet, *Y. lipolytica* hardly utilize xylose, the second most sugar component of lignocellulosic biomass, limiting high-yield lipid production from lignocellulosic biomass.

2. Methods

To efficiently produce lipids from lignocellulosic biomass, we developed an efficient xylose utilizing *Y. lipolytica* harboring isomerase-based pathway. To do so, we first introduced xylose isomerase pathway, and then evolved the rationally engineered strain to better support xylose metabolism. The xylose utilizing performance of the engineered strain was evaluated during xylose fermentation as a sole carbon source, and during the fermentation of lignocellulosic hydrolysates.

3. Results and discussion

The newly developed xylose utilizing *Y. lipolytica* (YSXAK) showed high-yield lipid production from xylose as a sole carbon source. The lipid yield of isomerase-based xylose utilizing strain of YSXAK was five times higher than that of an oxidoreductase-based strain with cofactor imbalance issue [2]. Moreover, YSXAK simultaneously utilized both glucose and xylose to produce lipids suggesting efficient co-fermentation of lignocellulosic biomass. To understand the different genetic background contributed to efficient xylose utilization, comparative whole-genome sequence analysis was conducted identifying beneficial mutations occurred during evolutionary engineering.

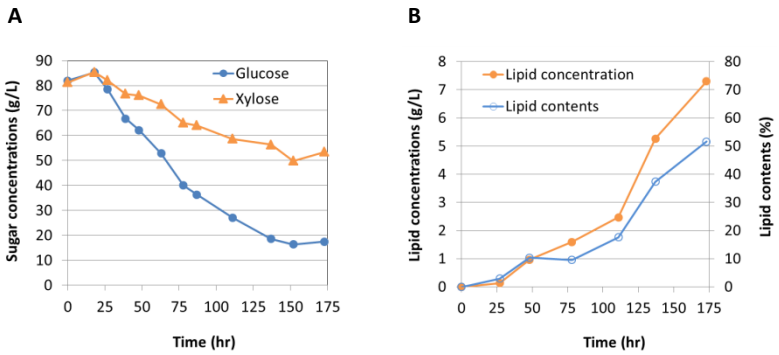

Figure 1. Sugar consumption and lipid production of xylose utilizing *Y. lipolytica* during glucose/xylose co-fermentation

4. Conclusions

Through combinatorial engineering, we developed an efficient isomerase-based xylose utilizing strain of *Y. lipolytica*, and demonstrated high-yield lipid production from xylose and simultaneous co-fermentation of glucose and xylose. This study shows the potential of xylose utilizing *Y. lipolytica* harboring an isomerase pathway for more economical and sustainable biodiesel and oleochemical production from lignocellulosic biomass.

Highlights

- Single cell measurement for intracellular concentration and co-culture monitoring
- *In situ* microscopy identifies budding and non-budding yeast for viability analysis
- Chain length distribution of lactic acid bacteria is related to metabolic activity
- Focus beam backreflection measurement for *on-line* optimization of feedstock pretreatment

1. Introduction

Monitoring tools for the liquid phase of bioprocesses are often restricted to a very few parameters. This might be insufficient if data from the single-cell level is required. While several *off line* tools have been commercialized, not many were adjusted and applied *in line* in bioprocess development and control.

This presentation aims to show the importance of single-cell based measurements and population heterogeneity for scale up and scale down of bioprocesses; recent advances achieved [1]; the potential of such methods to recognize and quantify the impact of unfavorable cultivation conditions in several microbial bioprocesses; and finally several examples of successful application for process optimization, including feedstock pre-treatment and determination of intracellular components on the single-cell level. Examples of long chain fatty acid accumulation in heterotrophic algae, budding in yeast, chain length determination in lactic acid bacteria, optimization of feedstock pretreatment for anaerobic digestion and the application in co-cultures are presented.

2. Methods

Among the techniques that are able to capture the morphological characteristics of cells in real time, automated imaging technologies are promising, because they provide additional information about cellular structures, shape and cell aggregation beyond size. Photo-optical *in situ* microscopy (ISM) and 3-dimensional holographic microscopy (DHM) were used in this study to measure the morphological dynamics in eukaryotic cultures on a single-cell basis, with heterotrophic algae and yeast as examples [2,3]. ISM was used further to monitor the chain length distribution of lactic acid bacteria (LAB). Both, yeast and LAB, were monitored under homogeneous and heterogeneous conditions in a scale down multi-compartment approach. The relation of morphological changes and metabolic activity and growth vitality in relation to scale up effects is assessed for both cases.

A second technique (focus beam backreflection) describes the monitoring of the particle size distribution in culture broth of anaerobic digestion. This method was successfully used to evaluate the efficiency of pre-treatment methods for hydrolysis based on the particle size, while distinguishing between non-living feedstock particles and active cells.

3. Results and discussion

Based on the morphological and optical cell features, the intracellular accumulation of the polyunsaturated fatty acid docosahexaenoic acid (DHA) was monitored in real-time on a single cell level in cultivations of the heterotrophic algae *C. cohnii* [2]. This methods allows to quantify the product yield of a process instead of time consuming *off line* gas chromatography analyses. It further allows to optimize process conditions under consideration of population heterogeneity, as productive cells can be distinguished from weak cells fractions.

Multi-compartment scale-down reactors were used to investigate the influence of gradients, as they occur in large scale, on the morphological heterogeneity in *Saccharomyces cerevisiae* cultures and relate this to process performance [3]. Budding of yeast was monitored *in line* in batch cultivations with ISM [4]. The ratio of budding and total cells was successfully applied to differentiate between the different cultivation stages and to predict growth. Vitality and viability of such cultures can be measured with ISM.

In large-scale lactic acid bacteria production, the main concern is the uneven distribution of the pH value, mainly due to the external addition of base to compensate the acid produced by cells. In order to study the impact of these gradients on the population heterogeneity in various scales, different scale-down approaches were applied, especially multi-compartment systems and pulse-based parallel experiments. A relation was found between gradient formation in large scale cultivations and the development of the chain length formation of *Streptococcus thermophilus*, which allows for an *on line* estimation of the viability. A growth rate prediction based on the cell size distribution was feasible.

The last example shows how feedstock pre-treatment, in particular with ultrasound, can be optimized by particle size measurement with laserlight focus beam back reflection. The same technology allows to distinguish between circular and spiral-shaped organisms, which seems to be a promising feature for the investigation and finally control of co-cultures up to the large scale.

4. Conclusions

The information, which is gained by ISM and laserlight focus beam back reflection can be coupled with population balance models, which enable a model-based prediction of growth and production performance. Coupled with automated image analysis, real-time monitoring and the concept of “population control” [1] becomes possible for a wide range of bioprocesses.

Highlights

- *Klebsiella oxytoca* KMS006 produced 2,3-BD from cassava starch with impressive yields.
- 1% (v/v) α-amylase was only used for releasing reducing sugars from cassava starch.
- Cassava starch is a promising feedstock for the economical production of 2,3-BD.
- The fermentation of 2,3-BD was performed in low salt medium to lower production cost.

1. Introduction

2,3-Butanediol (2,3-BD) is one of the building block chemicals which can be used in a variety of industrial applications [1]. Currently, the feasibility of 2,3-BD fermentation on a large scale depends on the use of cheaper renewable resource. The utilization of an inexpensive carbon source such as cassava starch has attracted attentions for the biotechnological production of 2,3-BD from an economic point of view. A metabolically engineered *K. oxytoca* KMS006 was engineered to enhance 2,3-BD production yield by gene deletion and metabolic evolution [2]. However, this strain does not efficiently ferment cassava starch due to low expression of *malS* encoding for *α*-amylase [3]. Thus, an external *α*-amylase enzyme was utilized to release fermentable sugars from cassava starch. The aim of this study was to investigate the optimal condition for enzymatic hydrolysis of cassava starch with α-amylase to obtain fermentable sugars for the production of 2,3-BD by *K. oxytoca* KMS006 in a simple batch fermentation.

2. Methods

Cassava starch (140 g/L or 130 g/L) was gelatinized in 2.5 L bioreactor with 1 L AM1 buffer (pH 6.0) (4) by autoclave at 121 °C for 20 min. A commercial α-amylase was added at concentration of 1% (v/v) into the bioreactor in order to covert cassava starch into sugars with two different conditions: before or after autoclaving. In this last case, the enzymatic hydrolysis step was carried out at 400 rpm during 3h. In both cases, the fermentation was then initiated by inoculation with *K. oxytoca* KMS006 at an initial OD_{550} of 0.1 and carried out at 37 °C, 400 rpm and 0.8 vvm [5,6]. The pH of fermentation broth was maintained at 6.0 by automatic addition of 3 M KOH.

3. Results and discussion

To achieve a high 2,3-BD concentration from cassava starch, α-amylase was utilized to convert cassava starch to fermentable sugars. When the enzyme was added before autoclaving (Fig. 1A), the hydrolysis was not completed, probably due to the inactivation of α-amylase at high temperature. When α-amylase was added after autoclaving, the hydrolysis reaction was carried out for 3 h during temperature dropped from 85 to 45 °C. In this case, a maximum efficiency of starch hydrolysis was obtained as cassava starch concentration (130 g/L) was completely converted to reducing sugar (Fig. 1B). It resulted after fermentation of a final 2,3-BD concentration of 64.8 g/L with a yield of 0.46 g/g and productivity of 1.25 g/L/h at 52 h 8 with few by-product formed (about 3.8 g/L of succinate and acetate).

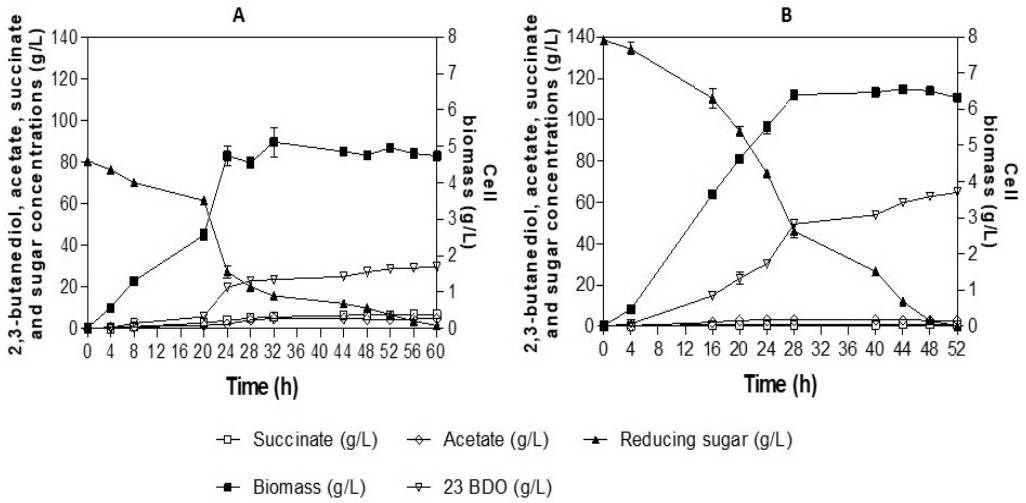

Figure 1. 2,3-BD fermentation from cassava starch using *K. oxytoca* KMS006. **A)** ±-amylase was added into bioreactor before autoclave **B)** ±-amylase was added into bioreactor after autoclave at H85 °C and hydrolysis for 3 h.

4. Conclusions

These results indicated that the fermentable sugars from cassava starch can be obtained by combined heat treatment with autoclave and solely α-amylase. In addition, cassava starch can be considered to be one of the most promising feedstock for cost-effective 2,3-BD production by *K. oxytoca* KMS006.

In situ on site applicable aptasensor using sandwich-type binding pair of Aptamers

Man Bock Gu*
Department of Biotechnology, Korea University, Seoul, Rep. of Korea
*e-mail: mbgu@korea.ac.kr

Aptamers are single-stranded nucleic acids having molecular recognition properties similar to antibodies, and isolated by *in vitro* selection and amplification process, SELEX. This nucleic acid aptamer is well-known with its stable feature, quick and easy developement, cost-effective production *in vitro*, and so on. To find a most effective atpamer screening method has always been a goal, especially for obtaining a pair of aptamers binding at different sites of a single target. This talk will start with how a pair of aptamers are innovatively screened consecutively, by using a new nano-material, graphene, without the immobilization of targets. A few of successful examples using immobilization-free screening of the pair of aptamers will be presented, which are inevitable for being applied in a stripe-type platform, which could be a reliable platform for commercialization eventually. Finally, a couple of examples for protein biomarkers and pandemic viruses will be presented about how the pair of aptamers were successfully implemented on both lateral flow assay biosensing platform and in situ on site applicable aptasensors by using a mini-potentiostat.

Highlights

- The reaction network including main and by-products was experimentally determined.
- A kinetic model was developed for the second-step of the ethanol to butadiene process.
- The experimental observations were explained through the model parameters.

1. Introduction

1,3-Butadiene is a valuable conjugated diene which is industrially produced as a co-product of naphtha steam cracking. It is used primarily as a chemical intermediate and as a monomer in the manufacture of synthetic rubbers, most of which are destined to the automobile industry. The onset of the US shale gas has impacted the 1,3-butadiene market as the change in feedstock for steam cracking to ethene have resulted in a lower 1,3-butadiene production. Therefore, while the 1,3-butadiene market shrank, the global 1,3-butadiene demand continued to grow. In that context, the conversion of bioethanol to 1,3-butadiene arises as an interesting and environmentally friendly alternative in a highly competitive and unstable marketplace.

In the literature we can find very few kinetic studies of the ethanol to 1,3-butadiene conversion, and none of these studies includes the effect of co-feeding water among with the feedstock. That way, we aim to develop a formal kinetic model describing the main reactions pathway that can predict the catalyst performance in a range of operating conditions close to the optimum.

2. Methods

The catalyst was prepared following the methodology reported in the work of Chae et al. [1]. Catalytic tests were carried out in a continuous flow fixed-bed reactor at 300-350 ºC, 0.22-1.63h^{-1}, 0-7.5% w/w water in the feedstock, ethanol/acetaldehyde mole rate between 1.7 and 2.7, ethanol partial pressure of 0.13 bar and atmospheric pressure. The bed was divided into three sections. The top section was a SiC bed, the middle one comprised a bed of catalyst (0.3-0.5 mm) diluted in the necessary amount of SiC to obtain a bed length of 13 cm, and the bottom section was also a SiC bed. All sections were separated by a glass wool plug. The ethanol was fed with an HPLC-pump

and N_2 was used as carrier gas. The reactor output line was electrically traced and insulated to avoid product condensations before analysis by an Agilent 7890A on-line gas chromatograph (GC) equipped with two flame ionization detectors (FID) and a thermal conductivity detector (TCD).

3. Results and discussion

Making use of the tests carried out in the laboratory-scale reactor, a kinetic model was developed. The reaction scheme considered for the calculation of the balance is a simplification of the most accepted reaction pathway nowadays, lumping some products like olefins and the major lump "others" that includes a huge amount of compounds with little contribution such as acetone, propanal, butanal, methanol, and so on. The differential mole balance equations were solved obtaining an initial guess of the kinetic parameters assuming constant molar flow along the reactor and solving the algebraic system. These rough parameters were used as initial guess values for solving the differential mole balance equations along the reactor.

- Main reaction: $C_2H_5OH + C_2H_4O \rightarrow C_4H_6 + 2H_2O$
- Ethanol dehydration: $2\ C_2H_5OH \rightarrow (C_2H_5)_2O + H_2O$
  $C_2H_5OH \rightarrow C_2H_4 + H_2O$
- Butenes formation: $2\ C_2H_5OH \rightarrow C_4H_8 + 2H_2O$
- Tishenko reaction: $2C_2H_4O \rightarrow CH_3COOC_2H_5$
- Etilacetate to "other compounds" lump (Butanal): $2\ CH_3COOC_2H_5 + C_4H_8O_2 \rightarrow 2C_4H_8O + 2H_2O$
- "Other compounds" lump formation: $C_2H_5OH + C_2H_4O \rightarrow C_4H_8O + H_2O$
- Heavy compounds formation (Diethoxyethane): $3\ C_2H_5OH + 1.5C_2H_4O \rightarrow 1.5C_6H_{14}O_2 + 1.5H_2O$

4. Conclusions

The main products observed while co-feeding ethanol and acetaldehyde over a TA_2O_5/SBA15 catalyst were 1,3-butadiene, ethene, diethyl ether, ethyl-acetate, butenes and heavy compounds. The developed kinetic model may be used to design and optimize an industrial facility. The proposed model fitting concurs with the experimental results.

Biorefinery development using spent coffee grounds for the products of bacterial cellulose and value-added products

Sofia Maina, Erminta Tsouko, Apostolis Koutinas*

Department of Food Science and Human Nutrition, Agricultural University of Athens, Iera Odos 75, 11855 Athens, Greece

Highlights

- Phenolic-rich extracts, oil and protein can be extracted from spent coffee grounds
- Hemicellulose hydrolysate has been used for bacterial cellulose production
- Spent coffee grounds is a promising resource for biorefinery development

1. Introduction

The development and implementation of biorefineries dealing with renewable resources strongly depends on the heterogeneity and availability of the feedstock in combination with the profitability of the whole process. Spent coffee grounds (SCGs) are generated as waste streams through the production of instant coffee and coffee brewing and they amount to approximately 6 million t annually [1]. SCGs are rich in polysaccharides and protein [2]. The high carbohydrate content renders SCGs a promising substrate for bioprocesses including carotenoids, poly-(hydroxyalkanoates), enzymes and bioethanol [3]. The recovery of natural antioxidants (mainly caffeine), proteins and lipids contained in SCGs, could enhance the viability and sustainability of a biorefinery development. Under this concept, the main objectives of this study were the fractionation of SCGs for the recovery of value-added products and the production of bacterial cellulose from hemicellulosic hydrolysates derived after diluted acid or enzymatic hydrolysis of hemicellulose.

2. Methods

The fractionation of SCGs included the extraction of phenolic compounds, oil, protein and carbohydrates. Initially, phenolic compounds were extracted and evaluated in terms of total phenolic content (TPC) (via Folin-Ciocalteu method) and antioxidant activity index (AAI) (via 2,2-diphenyl-1-picrylhydrazyl-free radical scavenging method) using ethanol as solvent under different solid to liquid ratios and extraction time. The main phenolic compounds of the extract were identified and quantified employing HPLC-DAD. The phenolic-free solids were subsequently used for oil extraction. The SCGs to solvent ratio and the extraction time were evaluated. The remaining

SCG solids were used for protein recovery. The extraction process included alkaline treatment followed by acidic precipitation at the isoelectric point of the corresponding proteins. At a final step, the remaining lignocellulosic-rich solids were pretreated by mild chemical and enzymatic processes to the respective monomeric sugars. The galactose and mannose rich hydrolysate obtained was utilized for bacterial cellulose production by *Komagataeibacter sucrofermentans* DSM 15973 under batch mode. The physiochemical properties of the produced bacterial cellulose were determined and evaluated.

3. Results and discussion

Phenolic compounds from SCGs were extracted applying an environmental friendly and cost-effective process using aqueous ethanol under mild temperature conditions. SCGs exhibited the highest TPC (15 mg gallic acid equivalents-GAE/ g dry sample) with a liquid-to-solid ratio of 10:1 after 20 minutes of extraction. According to the obtained AAI, extracts were classified as strong antioxidants. Extraction of oil with hexane and n-propanol resulted in high oil recovery (higher than 95%). Protein extraction reached a recovery yield of 92% with high purity.

The hemicellulosic hydrolysate rich in mannose and galactose was utilized as the sole carbon source for bacterial cellulose production with the bacterial strain *K. sucrofermentans*. Bacterial cellulose concentration of 2.4 g/L was achieved after 6 days of fermentation. Properties determination of the produced bacterial cellulose showed enhanced water holding capacity and degree of polymerization. The IR spectrum of bacterial cellulose indicated that the bacterial strain *K. sucrofermentans* synthesizes both Iα and Iβ cellulose types, with Iα cellulose being the dominant type.

4. Conclusions

SCGs were effectively utilized as renewable resource for the development of an integrated bio-refinery leading to extraction and production of high added value products. This approach enables the exploitation of SCGs adding value to this abundant and low-cost feedstock. Further study should focus on practical and novel concepts for potential applications of the obtained products in the food and oleochemical industry.

Highlights

- High resolution inline microscopy
- Monitoring fatty acid production by microalgae
- Correlation of Budding Index with growth dynamics in yeast fermentations
- Multidimensional and real-time image analysis

1. Introduction

The present work describes the development and methodology to apply a microscopy probe for the measurement of the sizes, shapes, colors and concentrations of particles in biological processes. To date, the direct measurement of these parameters inside the process is a challenge, since the monitoring instrumentation has to be applicable under various process conditions and in different process phases. High particle concentrations, different particles in multiphase systems or changing particle features and velocities are challenging for an inline measurement method. For microscopy in particular, overlapping signals and background can disturb object identification. Nevertheless, recent advances in photo-optics and image processing allow to generate images with a high level of details even under demanding process conditions. This makes it easier to extract individual features from the images. Coupled with image analysis, it allows precise and automated real-time measurements of particle size, shape and concentration.

In this study, an inline microscopy probe was particularly developed for the application in microbial bioprocesses, in which the microbe changes its morphology during the process phases. In a first study, morphological changes in fed-batch cultivations of the heterotrophic algae *Crypthecodinium cohnii* were monitored. It is shown that both size and shape changes relate to the intracellular accumulation of the polyunsaturated fatty acid docosahexaenoic acid (DHA).

In a second study the morphological heterogeneity in yeast fermentations of *Saccharomyces cerevisiae* is investigated by inline microscopy. By means of automatic image analysis, various budding states of the yeasts can be investigated. It is possible to classify budding yeasts with a daughter cell and non-budding yeasts into two different classes. The relation of the two different size and shape distributions resulting from the two classes can be correlated with the growth activity at any point during the process, and thus conclusions on the growth dynamics can be derived.

2. Methods

The general working principle of inline microscopy is bringing the focal plane of the microscopic objective into the sample, which is usually the flow regime inside a process. Therefore, inline microscopes need to be more compact and robust to be integrated into a process. The acquired images are analyzed with an artificial neural network. The employed U-Net is a deep convolutional network for a more advanced segmentation of images. The network learns to segment images in an end to end setting.

3. Results and discussion

In this study, changes in the cell size distribution of the heterotrophic microalgae *C. cohnii* were tracked with an offline holographic microscopy and an inline photo-optical microscopy probe (Figure 1 – a). The accumulation DHA, which is a product of major interest as a dietary supplement for fish production leads to a larger cell diameter (Hillig et al., 2014). On the basis of the cell size and broadness of the size distribution, the applied inline photo-optical measurements enabled to distinguish between cells in the growth phase with little or no intracellular lipid droplet accumulation and production phase with lipid droplet accumulation (Figure 1 – b).

Under conditions of low growth and high fatty acid accumulation, the cell sizes and its distributions were changing accordingly. The correlation between the predicted inline measurements based on the Sauter mean diameter and the measured intracellular DHA content with GC-FID was confirmed and showed a maximum coefficient of determination (R) of 0.983 by regression analysis (Figure 1 – c).

The results obtained by digital holographic and the side scatter values from flow cytometry, which was performed as golden standard method for single cell measurement, were in good agreement with the inline microscopy, which enables this method to photo-optically measure DHA content in real-time (Marbà-Ardébol et al., 2017).

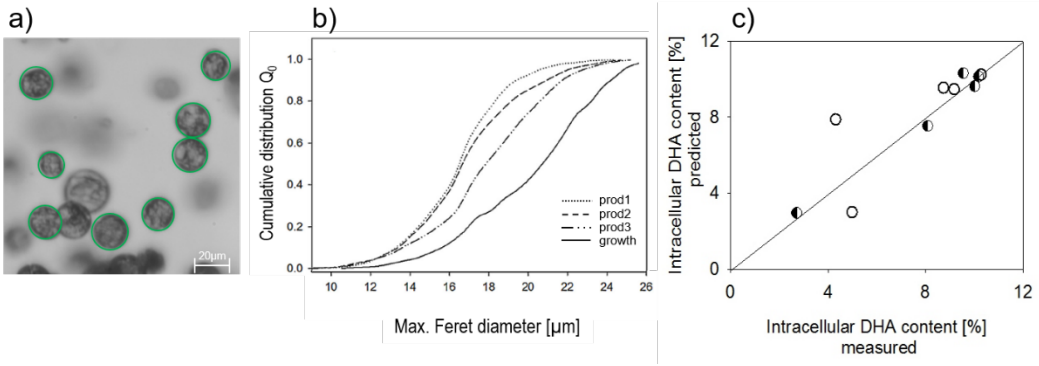

Figure 1: a) Segmented cells, b) Cumulative size distributions in different growth states, c) Second order correlation between DHA content measured offline (GC-FID) and predicted DHA content based on the measured Sauter mean diameter with inline microscopy. Values used for calibration (◐) and for prediction (○).

Yeast is one of the most important species in biotechnology. In this study Baker's yeast *S. cerevisiae* and its morphological changes during fermentation is monitored inline. The morphology of yeast cells is altering during maturation, depending on the growth rate and cultivation conditions. Inline microscopy was used to monitor such morphological changes of individual cells directly in the cell suspension. With automated image analysis it was possible to analyze budding and non-budding cells in parallel based on a trained artificial neural network. Deviations between automated and manual counting were considerably low (Figure 2 – a and b).

The homogeneity among the population during the growth phase increased and at growth retardation, the portion of smaller cells increased due to a reduced bud formation. The maturation state of the yeast cells was determined by the budding index, which Is defined as the ratio between the number of budding cells and the total number of cells. Inline monitoring showed a linear correlation between the budding index (BI) and the growth rate during the batch cultivation (Figure 2 – c and d). An real-time differentiation of growth activity across all process stages of several batch cultivations in complex media became feasible (Marbà-Ardébol et al., 2018b).

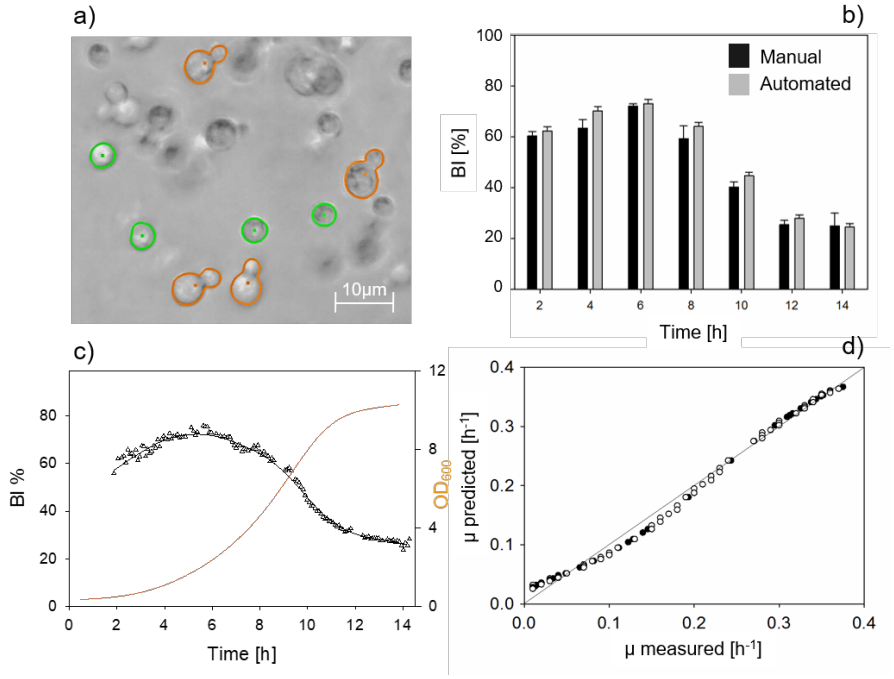

Figure 2: a) segmented and classified cells into budding and non-budding cells, b) Comparison between the budding indices obtained automatically (black bars) and with manual counting (gray bars) resulting in a confidence interval R^2=0,99, c) monitored BI as determined with inline microscopy and OD_{600} of cultures, d) the correlation of predicted and measured growth rates.

4. Conclusions

The presented inline microscope provides accurate automatic particle recognition in highly concentrated disperse systems and provides statistically robust parameters within short calculation times (<5min). The consideration of population heterogeneity based on morphologic features becomes feasible. The method allows both, a deeper understanding of functional relationships in bioprocesses as well as process control - by faster response on process changes.

Highlights

- Online-monitoring of capture step of human fibroblast growth factor (FGF) 2
- Multi-analytical approach (Fluorescence, ATR/FTIR, UV, refractive index, …)
- Various statistical learning methods (PLS, Lasso, structured additive regression)
- Prediction errors of approx. 0.5 mg/ml (protein quantity), 200 ppm (host cell protein) and 300 ppm (dsDNA)

1. Introduction

Downstream processing (DSP) describes the purification of biopharmaceuticals with a chromatographic step being the main part. Conventional online sensors such as UV/Vis, pH or conductivity probes are currently used for monitoring this process. Unfortunately, key process parameters such as the concentration of various impurities (e.g. host cell protein HCP or double-stranded DNA, dsDNA) are thereby not accessible requiring time-, labor- and cost-intensive offline measurements of the fractionated eluate [1].

2. Methods

A conventional chromatographic workstation (Äkta Pure 25, GE Healthcare, Sweden) equipped with a multi-wavelength UV/Vis detector (the wavelengths 214, 260 and 280 nm are monitored), a conductivity and a pH probe, was enhanced with a mid-IR spectrometer (MATRIX-FM, Bruker, USA), a fluorescence detector (AvaSpec-ULS-TEC, Avantes, Netherlands), a multi-angle light scattering (MALS) spectrometer (miniDAWN TREOS, Wyatt, USA) as well as with a differential refractive index (RI) detector (Optilab T-rEX, Wyatt, USA). The chromatographic capture step of human fibroblast growth factor 2 (FGF-2) expressed in *E. coli* was monitored. On- and corresponding offline data for protein concentration and purity (HCP and dsDNA) were measured for 16 runs resulting in an extensive data set. Traditional chemometric methods such as partial-least squares (PLS) or principal component regression (PCR) were compared with penalized techniques (ridge and Lasso regression) and structured additive regression (STAR) [2,3]. All computations were performed in the R statistical computing environment [4].

3. Results and discussion

Figure 1 depicts the performance of a quantity model on an independent test run showing good agreement between model predictions and measured values determined for the 15 fractions. On average (over 6 test runs) an accuracy of 0.51 mg/ml (root-mean-squared error) is observed and can be expected for future applications of the model. A reduction of more than 30% in prediction error can be achieved compared by using spectroscopic data compared to models based on UV, conductivity and pH as predictors. Similarly, for HCP and dsDNA errors of approximately 200 and 300 ppm, respectively, are obtained.

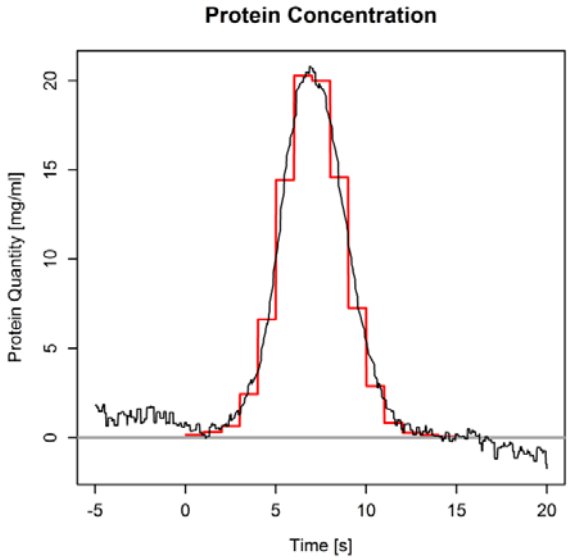

Figure 1. Performance of a structured additive regression (STAR) model for the protein concentration on a new test run – online prediction on a time grid of 1 second (black) and concentration values determined by offline measurements for 15 fractions of 1 ml each (red). Five minutes before and after the elution peak (15 min) are shown.

4. Conclusions

Particularly non-linear STAR models in combination with boosting as a variable selection method allow for a reliable prediction of critical process quantities such as the protein concentration, host cell protein and dsDNA content. While traditional sensors (UV/Vis, pH and conductivity) might be sufficient for the protein concentration, spectroscopic sensor systems are essential for modeling the impurities.

Valorization of effluents from wood processing industry by removal of bioactive polyphenols and subsequent fermentation

Martin Lindemann[1*], Bernhard Widhalm[1], Cornelia Rieder-Gradinger, Thomas Kuncinger[2], Ewald Srebotnik[3]

1 Competence Centre of Wood Composites and Wood Chemistry, Linz, Austria; 2 Fritz Egger GmbH & Co. OG, Tiroler Straße 16, Unterradlberg, Austria; 3 Institute of Chemical, Environmental and Bioscience Engineering, Technische Universität Wien, Vienna, Austria

**Corresponding author: m.lindemann@wood-kplus.at*

Highlights

- Novel use of effluents from wood processing industry / Circular Economy approach
- Isolation of bioactive polyphenols
- Effluents as cultivation medium for *Pseudomonas sp.*
- VOC reduction by microbial degradation of aldehydes and terpenes

1. Introduction

Large quantities of effluent arise from MDF (Medium Density Fiberboard) production by squeezing out water from steam-pretreated softwood chips, resulting in a high load of TOC (total organic carbon). This process water stream is rich in wood extractives and is mainly composed of various carbohydrates, polyphenols, and organic acids, particularly fatty and resin acids. Process water treatment is laborious and costly, requiring sedimentation, flocculation, biological treatment as well as membrane filtrations and reverse osmosis. In this project, we therefore focus on the utilization of this currently unused process stream by recovering valuable bioactive compounds such as resin acids, lignans, and stilbenes as well as using the remaining carbohydrate rich stream as a carbon source for cultivation of VOC- (volatile organic compound) degrading microorganisms [1]. Since aldehydes and terpenes are among the main sources of VOC in the wood processing industry, these microorganisms may be applied onto woody raw materials as a possible approach to lower VOC emissions of wood products such as fiberboards.

2. Methods

A scalable fixed bed adsorption system for the removal and selective recovery of polyphenols (lignans and stilbenes) from MDF process waters was developed. Before adsorption, fibers and non-colloidal substances were removed from process water by centrifugation, while colloidal fatty and resin acids were removed by filtration through a 30 kDa cut-off membrane. Polyphenols where then isothermally adsorbed on a medium pressure liquid chromatography column packed with a regenerable macroporous, cross-linked pyrrolidone-based (PVPP) resin. Gradient elution of the adsorbed polyphenols from MDF process waters was optimized using a Ø 25 mm adsorber column (5.8 g resin, 15 ml min^{-1}). The carbohydrate rich stream resulting from polyphenol removal was used as a pre-cultivation medium for *Pseudomonas sp.* with terpenes as additional carbon source. The microbial biomass was then applied onto pine wood strands. VOC emissions from

manufactured boards were collected on Tenax TA, desorbed in a thermal desorber and analyzed by means of GC-MS.

3. Results and discussion

Lignans and stilbenes were adsorbed onto PVPP, while highly polar substances such as sugars and sugar alcohols, however, were not retained and remained in the flow-through. Adsorbed lignans were then eluted in successive fractions containing the individual lignans in different proportions, followed by pinosylvin in a separate fraction. (**Figure 1**). The capacity of the PVPP for 7-hydroxymatairesinol (HMR) as a model lignan was determined to be 37.4 mg g^{-1} at 1% breakthrough (data not shown).

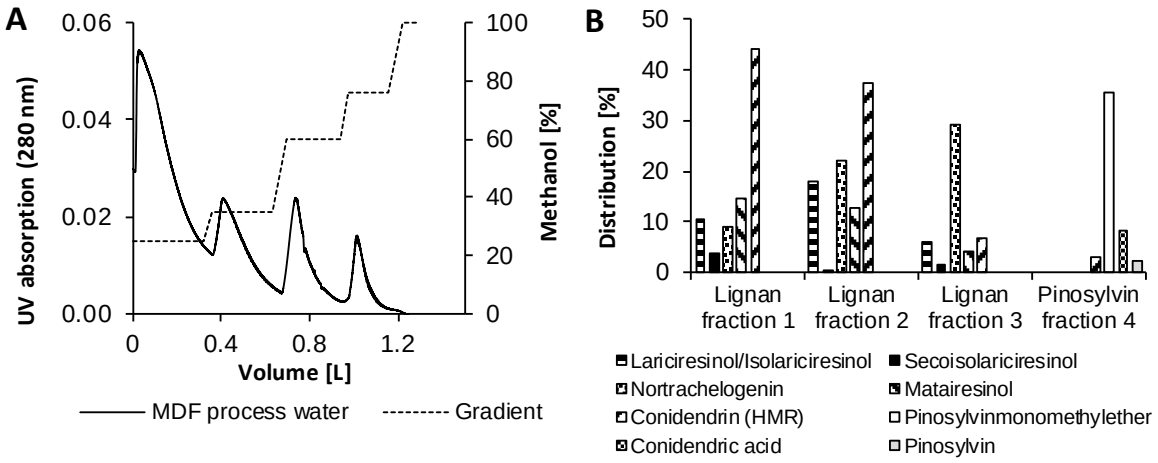

Figure 1 (A) Gradient elution (10 mM H_3PO_4, Methanol) of polyphenols after adsorption monitored at UV 280 nm. (B) Distribution of polyphenols in the collected fractions from gradient elution shown in (a).

Cultivation of *Pseudomonas sp.* in process effluents, after removing polyphenols by adsorption onto PVPP, did prove successful. Microbial pre-treatment of the pinewood strands resulted in a 20% reduction of the TVOC (Total VOC) value within only 6h, increasing to 55% reduction after 48h.

4. Conclusions

PVPP was shown to be particularly suitable for the selective adsorption and subsequent recovery of lignans and stilbenes from complex process effluents. The resulting carbohydrate rich stream after adsorption was successfully used as a cultivation medium for *Pseudomonas sp.* without further adjustments. These results provide a solid basis for technical implementation and, furthermore, the profitable utilization of otherwise valueless industrial process effluents.

Enzymatic hydrolysis of Olive Solid Waste for extraction of polyphenols and reducing sugars using different cellulase enzymes

Carlos Zambra[1*], Susana Nieto[2], Pedro Lozano[2], Julio Romero[3]

1 Departamento de Ingeniería Mecánica, Universidad de Talca, Curicó-Chile; 2 Departamento de Química, Universidad de Murcia, Murcia-España; Departamento de Ingeniería Química, Universidad de Santiago, Santiago-Chile

**Corresponding author: czambra@utalca.cl*

Highlights

- Olive Solid Waste have high concentration of valuable compound.
- Enzymatic hydrolysis would allow increases the polyphenols concentration and reducing sugar.
- The enzymes can be recovered by means filtration.

1. Introduction

The intake of natural antioxidants and waste valorisation are issues of great importance for improving human health and achieve a modern and efficient industry. Powerful natural antioxidants can be found in high concentrations in waste from the olive oil industry [1]. The high concentration of fiber in the Olive Solid Waste (OSW) suggest that enzymatic hydrolysis with cellulase enzymes would allow to obtain an increase of the polyphenols concentration and reducing sugar. In this work the enzymatic hydrolysis of OSW is studied. One of the main drawbacks associated with the use of enzymes are, in many cases, their high production costs. It is for this reason that the recovery of the enzyme from the mixture obtained from the enzymatic hydrolysis is studied.

2. Methods

OSW samples were obtained directly from an olive oil factory located in the Maule Region, Chile. Three types of cellulase enzymes, Celluclast®, Viscozyme L® and Carezyme®, were used in the enzymatic hydrolysis tests. Before being used the enzymes were filtered in a cartridge vivaflow 50 (Sartorious) of 30,000 MWCO (molecular weight cut off). Once filtered, they were refrigerated at 5 ° C until they were used. Samples of 20 grams of OSW and distillate water were mixed with enzymes in volumes of 2.5 ml and 4 ml to obtain a final volume of 182.5 ml in an Erlenmeyer flask. The enzymatic hydrolysis was conducted at 50°C, pH 4.8 and 170 rpm in an incubator and orbital stirring YIHDER (LM-450D). The duration of enzymatic hydrolysis was 120 min. The total polyphenol content and the presence of reducing sugars were determined by colorimetric methods with the Folin-Ciocalteu and the 3,5-dinitrosalicylic acid (DNS) reagent, respectively. A method to recovery the enzyme was tested. The final mixture of the enzymatic hydrolysis was placed in filters Vivaspin Turbo 15 (30,000 MWCO) Sartorious® and these in turn in a Gemmy centrifuge (PLC-0.5) at 2000 rpm for 30 min. The retained liquid is used to carry out a new enzymatic hydrolysis. The cycle is

repeated five times. The recovery of the enzyme is quantified according to the yield in the increase of total polyphenols obtained in each cycle.

3. Results and discussion

Figure 1(a) shows the final concentrations of total polyphenols obtained after 120 minutes of enzymatic hydrolysis with two different volumes of enzyme added (2.5 ml and 4 ml). The total polyphenol content did not exceed 0.01 (g GAE/100 g DM) when hydrolysis was performed without adding enzyme. This value is practically the same to the measured initially (not showed in Fig. 1). All the enzymes tested increase the concentration of total polyphenols. The enzyme Celluclast® achieved the best performance with respect to the increase in total polyphenols (1.01 g GAE/100 g DM for 4ml of added enzyme) while the one with the worst performance was Carezyme® (0.2 g GAE/100 g DM). In figure 1(b) it is observed that the content of reducing sugars has no variation when hydrolysis is performed without adding enzyme (0.45 g glucose / 100 g DM). The enzyme Viscozyme L® showed the best performance to increase the concentration of reducing sugars (19.8 g glucose / 100 g DM for 4 ml of added enzyme). Figure 1 (c) shows the results of total polyphenols after six cycles of enzymatic hydrolysis. The enzyme used in this case was Viscozyme L. Figure 1 (c) shows the results of total polyphenols after six cycles of enzymatic hydrolysis operation. In this study, the increase in the concentration of polyphenols by enzymatic hydrolysis using the liquid retained in the filter, was associated with the quantity of enzyme recovered. Between each one of the cycles of operation the procedure of recovery of the enzyme described in the previous section was carried out. The enzyme used in this case was Viscozyme L. The relative percentage difference of the concentration of total polyphenols reached by the enzymatic hydrolysis decreases up to 68 percent after six cycle of operation

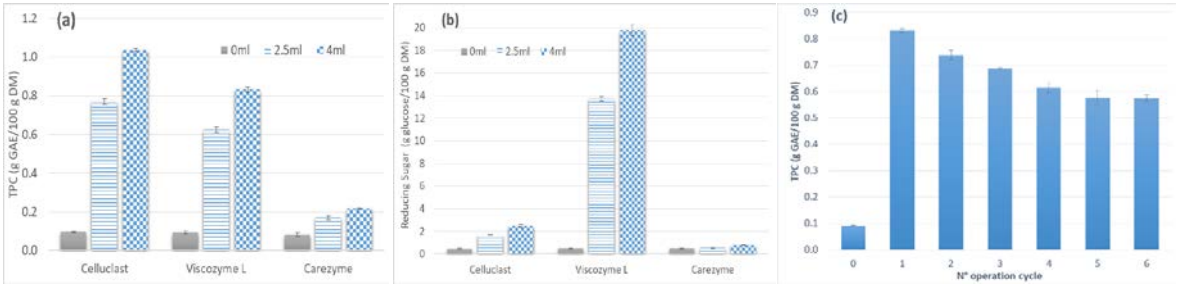

Figure 1. Concentration of total polyphenols (a) and reducing sugars (b) from OSW with three different enzymes and total polyphenols concentration obtained in each operation cycle after the recovery by filtration.

4. Conclusions

In this work was studied the increase in the concentration of total polyphenols content (TPC)) and the reducing sugar (RS) in the OSW using three types of cellulase enzyme. The Celluclast® and Vizcozyme L® shown the best yield for total polyphenol content and reducing sugar increases, respectively.

The physical method studied to recuperate the enzyme shown that its activity to augment the total polyphenols content decrease up to a 68 percent after six operation cycles.

Highlights

- Spent sulphite liquor was used as feedstock for microbial oil production
- Microbial oil derived esters were produced via enzymatic synthesis
- Phospholipids caused inhibition on the transesterification process

1. Introduction

Waste valorization through microbial and enzymatic bioprocesses contributes to the growth of bioeconomy and the elimination of the severe environmental impact caused by the petrochemical industry. Spent sulphite liquor (SSL) is the concentrated liquid stream generated by the pulp and paper industry. Valorisation of SSL through fermentation is challenging due to the high content of inhibitory compounds, such as lignosulphonates (LS), phenolics and organic acids. However, the presence of C5 and C6 sugars create an important feedstock for fermentation processes.

Oleaginous fungi of the phylum *Zygomycota* and yeasts (e.g. *Lipomyces starkeyi*) have been reported to effectively produce lipids, when cultivated on lignocellulosic-derived hydrolysates. *Zygomycetes* can produce γ-linolenic acid (GLA) [1]. Microbial oils rich in GLA can be used in the food industry, nutraceuticals and cosmetics [2]. They have also been used for the production of biodiesel and oleochemicals, such as biolubricants and wax esters [3].

The objective of this study was the valorisation of SSL as fermentation feedstock for microbial oil production using oleaginous yeast and fungal strains aiming to the improving fermentation efficiency through the evaluation of different fermentation conditions (carbon to nitrogen ratio and LS concentration) in batch and fed-batch fermentations. In the case of fungal fermentations, the optimum conditions were identified for the production of GLA-rich microbial oil. GLA-rich lipids from *C. echinulata* were subsequently used as feedstock for the production of bio-based esters via enzymatic synthesis in a solvent-free system. The reaction conditions evaluated were temperature, substrate molar ratio and biocatalyst quantity. Under the optimized conditions, the impact of individual lipid classes to esters yield was assessed.

2. Methods

The yeast *L. starkeyi* DSM 70296 and 2 fungal strains *C. echinulata* ATHUM 4411 and *Mortierella isabellina* ATHUM 2935 were utilized for the production of microbial lipids. Initially, the effect of carbon to nitrogen ratio (calculated and expressed as carbon to free amino nitrogen ratio - C/FAN ratio) was evaluated for all microbial strains using nanofiltrated SSL (30 g/L total sugars and 5 g/L of LS) in shake flask fermentations. The best C/FAN ratio for each microorganism was applied and

the effect of various LS concentrations on lipid production was evaluated using sugar-simulated SSL. Sugar-simulated SSL was prepared using commercial sugars (xylose, glucose, galactose, mannose and arabinose) at the same proportion as in diluted nanofiltrated SSL. Subsequently, *L. starkeyi* and *C. echinulata* were selected for further evaluation in fed-batch fermentations using a bench-top bioreactor. Nanofiltrated SSL was used as fermentation medium. In the case of *L. starkeyi*, experiments were conducted at various C/FAN ratios.

Microbial oil and fractionated lipid classes, including neutral lipids (NL), glycolipids plus sphingolipids (GL+SL) and phospholipids (PL), were used with isopropanol and 2-ethylhexyl alcohol for the enzymatic production of fatty acid esters in a solvent free system catalyzed by Novozyme 435. Transesterifications with microbial oil were studied at various temperatures, substrate molar ratios and enzyme quantity. Transesterifications using NLs were carried out at various molar ratios. The effect of glycolipids plus sphingolipids (GL+SL) and phospholipids (PL) fractions on conversion yield of isopropyl esters was evaluated in mixtures with NL.

3. Results and discussion

In fed-batch fermentation, *L. starkeyi* showed the highest lipid production (40.9 g/L) at a C/FAN ratio of 173. In shake flask fermentations of *M. isabellina*, TDW and microbial oil content were highly inhibited when 10 g/L and 50 g/L of LS were applied. In the case of *C. echinulata*, lipid and GLA contents were positively affected with increasing C/FAN ratios leading to the highest values of 60% and 18.8%, respectively. Removal of phenolic compounds (61%) was also observed by the fungal strain. Fed-batch cultures of *C. echinulata* in bioreactor resulted in total dry weight of 12.2 g/L with a lipid content of 56% in media containing 5 g/L LS. Fed-batch fermentations demonstrated that GLA formation was strongly affected probably due to the applied aeration and agitation.

Transesterification reactions were initially optimised and subsequently transesterifications were conducted using NL, GL+SL and PL. The presence of GL+SL and PL fractions negatively affected enzymatic ester synthesis. Transesterification of the NL fraction with isopropanol and 2-ethylhexanol led to the highest conversion yield of 80.2% and 73.8%, respectively.

4. Conclusions

The present study showed that *L. starkeyi* and *C. echinulata* could tolerate high LS concentrations. Fed-batch bioreactor cultures of *L. starkeyi* under the optimum C/FAN ratio, resulted in high cell density (81.1 g/L) and high lipid content (50%). *C. echinulata* was able to produce PUFAs-rich microbial oil (60%) with simultaneous phenolics removal in batch fermentation.

The efficient enzymatic conversion of GLA-rich microbial oil into esters using Novozyme 435 was demonstrated. Enzymatic synthesis was mainly affected by temperature and substrate molar ratio. Results showed that the different lipid fractions have a key role in enzymatic activity and conversion yield. Specifically, conversion yield was higher when microbial oil was free of PL and GL+SL fractions.

Highlights

- Efficient downstream processing of complex biological streams
- Hybrid process by integration of EBA and SMB technologies
- Development of novel equipment for implementation of an EBA-SMB process
- Experimental results prove that the innovation resulted in enhance techno-economic efficiency

1. Introduction

Product stream from a fermentation step is water-based (> 80 wt %) and contains dissolved and suspended impurities. As the choice of technologies define the downstream process efficiency and resulting costs, it is critical to apply innovative and efficient unit operations to achieve people, planet and profit demands [1]. One or more unit operations are employed in each block of downstream processing. An approach to enhance efficiency of such a process is by integrating one or more operating principles into a single unit [2]. The current article emphasizes the integration of expanded-bed adsorption(EBA) and simulated moving-bed (SMB) technologies [3] for selective product capture from unclarified fermentation broth.

2. Methods

An EBA-SMB system with 8 columns, 5 inlets and 5 outlets per column was designed with a bed level detecting mechanism. The recipe consisted of defined zones including adsorption, adsorption wash, elution, elution wash, regeneration and regeneration wash that each EBA column went through during the SMB operation. After validating the system, experiments were performed to purify gamma-amino butyric acid (GABA) from unclarified fermentation broth containing up to 100g GABA/l and 16 g *Escherichia coli* biomass /l. The process conditions studied include,

i. Change in amount of feed fed/ml settled bed resin volume (SBV) to determine the maximum resin binding capacity that can be achieved
ii. NaOH concentration in elution buffer to shows its impact on elution recovery and product titer
iii. Number of columns in series in feed and elution zones for improved separation efficiency and recovery
iv. Entrainment rejection (ER) to prevent yield losses
v. Fractionation of product rich elution stream

3. Results and discussion

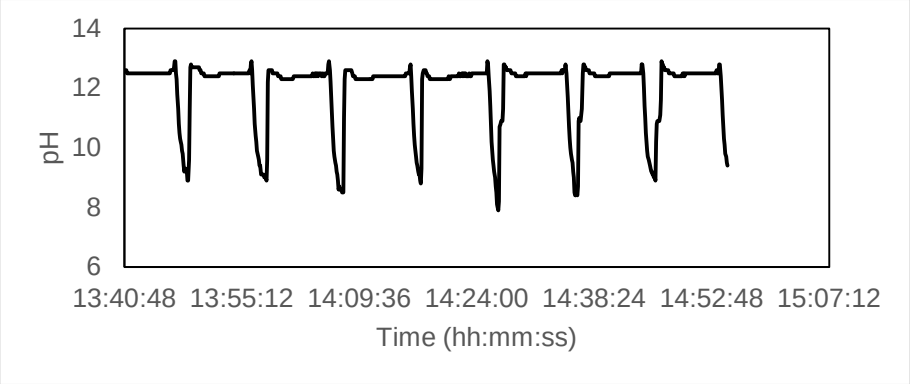

Figure 1. Outlet pH profile while different columns move through the product collection position after 2 cycles

It was observed that decreasing the amount of feed/column and increasing the number of columns in feed zone from 1 to 2 and entrainment rejection had a positive impact. By this approach GABA bound in feed zone increased from about 50 % (EXP001, 002, 003) to about 74 % (EXP004). However, the decrease in BV of feed/column resulted in 39 % reduction of binding capacity. Further, it was identified that due to the 8-column configuration and other critical zones including adsorption wash and elution, the number of columns available for feed zone was limited to 2. Therefore, to achieve further increase in yield and higher binding capacities, it is required to configure more than 2 columns in feed zone. The experiments performed to study the impact of buffer strength proved that by increasing NaOH content from 5 to 8 wt% in elution buffer, GABA recovery increased from about 55 % (EXP001) to about 84 % (EXP003). This, along with fractionation resulted in increase of product titer from 33 g/L to 47 g/L. Further, from the impurity analysis, it was also determined that the one step EBA-SMB purification of unclarified fermentation broth resulted in a product stream containing about 40 g/l GABA with purity >92 % and >98 % removal of biomass.

4. Conclusions

The experimental results proved that the EBA-SMB technology processed complex biological feed streams in one-step by integrating both biomass separation and selective product capture. The desired product purity was achieved. EBA-SMB design was validated by processing feed stream for several SMB cycles. No leakages and pressure buildups were noted. The integration and control strategy not only enabled stable operation, but also provided flexibility for process optimization. Thereby indicating improved techno-economic feasibility for industrial scale implementation. Further, parameters like the number of columns in a zone, feed loaded/SBV and elution buffer strength were identified to be critical to achieve optimal process performance.

Bio Recovery of Platinum and Palladium From Spent Automotive Catalysts Using the Cyanogenic Bacterium *Chromobacterium Violaceum*.

Salman Karim, Yen-Peng Ting*

Department of Chemical and Biomolecular Engineering, National University of Singapore, Singapore 117585;

**Corresponding author: chetyp@nus.edu.sg*

Highlights

- Development of two-step bioleaching process for Pt and Pd recovery from SAC.
- Pretreatment of catalysts significantly removed the non-target metals.
- Subsequent bioleaching with *C. violaceum* showed recovery of Pt (52%) and Pd (59%).

1. Introduction

Spent automotive catalysts (SAC) are rich in platinum group metals (PGMs: platinum, palladium, and rhodium) [1]. The recovery and recycling of PGMs from SAC is important due to the need for resource conservation and environmental protection [1-3]. Hydrometallurgical and pyrometallurgical processes which are conventionally used for metal recovery are unfortunately highly pollutive. In recent years, there has been increasing interest in the use of bio-hydrometallurgical processes for metal recovery since this approach constitutes a green process [4]. Studies have reported that mesophilic bacteria such as *Chromobacterium violaceum* produce cyanide as a secondary metabolite which may be used in metal extraction due to its ability to form water soluble complexes with many metals. One such study on the recovery of gold from electronic waste by *C violaceum* reported a 23% gold recovery from pretreated electronic waste [5]. In the present study, an environmentally-friendly, sustainable, and an effective process for platinum (Pt) and palladium (Pd) recovery from spent auto catalysts was developed. As a preliminary step, SAC was first pretreated to remove interfering metals at the early stage due to its negative effect on the bio metallurgical processing. Bioleaching was subsequently conducted with *C. violaceum* for enhanced Pt and Pd recovery.

2. Methods

Ultrasonic-assisted nitric acid (US-HNO_3) pretreatment was performed in order to remove interfering (non-target metals Cu, Zn, Fe, and Ti) which otherwise compete with PGMs for the formation of metal-cyanide complexes. Central composite design was used to optimize the factors (US duration, US power, US frequency, HNO_3 conc., and temperature) in the pretreatment process. Using a *C. violaceum*, platinum and palladium were subsequently recovered from the pre-treated SAC in a two-step bioleaching process (where the SAC was added to the bacterial culture after the maximum cyanide concentration has been attained). Various factors affecting the biorecovery (pH, glycine conc., pulp density, additional oxidant H_2O_2, and temperature) were also examined using

central composite design. Multivariate optimization i.e. response surface methodology (RSM) was used to develop the models for optimization of the SAC pretreatment and bioleaching studies.

3. Results and discussion

The interactive effects of various factors were studied in an empirical response surface methodology (RSM) model for process optimization. For SAC pre-treatment study, results showed significant removal of Cu (75%) and Zn (84%) under optimal conditions (US duration 60-90 min, US power 90-108W, US frequency 37kHZ, HNO_3 conc. 7-9M, and temperature 70°C). Subsequent bioleaching of the pre-treated SAC using *C. violaceum* resulted in a recovery of platinum (52%) and palladium (59%) from pre-treated SAC under optimal conditions (pH 9.5, pulp density 0.5 %w/v, glycine conc. 8-10 g/L, H_2O_2 conc., 0.08 %v/v, and temperature 30 °C) over five days [Figure 1].

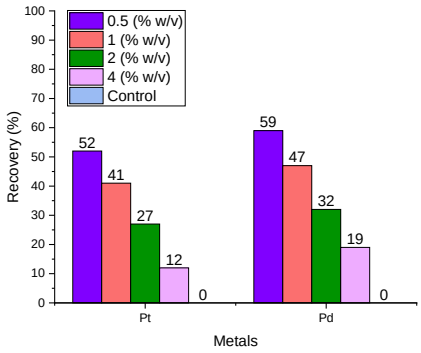

Figure 1. Pt and Pd recovery in two-step bioleaching by *C. violaceum* from SAC (pretreated SAC samples, pH 9.5, glycine conc. 8g/L, H_2O_2 conc., 0.08 %v/v, and temperature 30 °C) at various pulp densities.

4. Conclusions

Overall, this study demonstrates (i) the effect of ultrasonic assisted pretreatment for maximal removal of interfering base metals from SAC and (ii) the potential of cyanogenic bacteria for the recovery of Pt and Pd from SAC under two-step bioleaching process.

Highlights

- Systematic biodegradation kinetics of lupanine enantiomers in *P. putida* LPK411.
- A different metabolic pathway for each enantiomer exists.
- Systematic transcriptional kinetics of gene expressing lupanine hydroxylase.
- Systematic transcriptional kinetics of global genes in lupanine biodegradation.

1. Introduction

Lupanine constitutes the main quinolizidine alkaloid contained in *Lupinus albus* seeds. Owing to the useful functionalities of its asymmetric structure, this toxic compound has attracted considerable attention in biotechnological industries and may serve as a starting material for semi-synthesis of a range of novel high added-value compounds [1]. *L. albus* snack manufacturing generates excess of wastewater containing lupanine, while the most common process for lupanine elimination requires exhaustive boiling and leaching of seeds in water [2]. Biodegradation is a promising, greener alternative for detoxification of the wastewater generated. Thus, the objective of this study was to decipher the metabolism of lupanine biodegradation in *Pseudomonas putida* LPK411.

2. Methods

Microbial cultures: Lupanine enantiomers' biodegradation was investigated during fermentation of *P. putida* LPK411 using initial D-(+)-lupanine and L-(-)-lupanine concentration of 0.75 g L^{-1} respectively. The cultures were maintained at 31 ^{o}C, pH 7 and 100 rpm.
Analytical techniques: Culture samples were withdrawn at regular intervals and biomass concentration was determined by absorbance at 600 nm on a UV/VIS spectrophotometer. Lupanine concentration was measured using GC analysis [3].
Molecular biology techniques: Total RNA isolation, cDNA synthesis and Quantitative Real-Time Polymerase Chain Reaction (Q-RT-PCR) was conducted as previously described [4].

3. Results and discussion

Lupanine in nature exists in a racemic mixture of two enantiomers (D-(+)-lupanine and L-(-)-lupanine) [5]. Biodegradation kinetics of D-(+)-lupanine and L-(-)-lupanine was investigated during fermentation of *P. putida* LPK411. Two batch experiments were performed. The results

demonstrated that *P. putida* LPK411 can degrade D-(+)-lupanine, while L-(-)-lupanine concentration was only slightly reduced (Fig. 1). The latter indicates a different metabolic pathway for each enantiomer [6]. Moreover, LPK411 fermentations fed with racemic lupanine clarified that the strain is capable of achieving more than 95% enantiomeric excess of L-(-)-lupanine enabling the fermentative production of enantiopure L-(-)-lupanine, which avoids the application of other costly and laborious chemical methods.

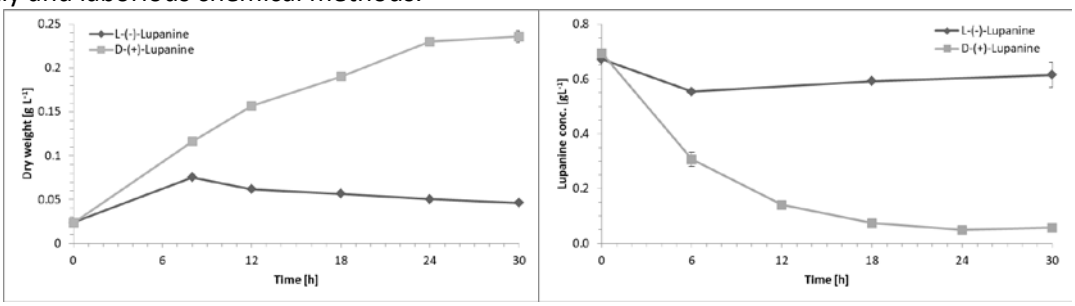

Figure 1. Lupanine enantiomers biodegradation by *P. putida* LPK411. (A) Microbial growth (expressed as dry cell weight), (B) concentration of D-(+)-lupanine and L-(-)-lupanine during fermentation.

Thus far, only a few studies have focused on metabolic mechanisms of quinolizidine alkaloids, such as lupanine. Lupanine hydroxylase catalyses the first reaction of lupanine biodegradation in *P. putida*. The specific enzyme is active only upon D-(+)-lupanine [6] biodegradation. Moreover, we have reported that *P. putida* LPK411 produces three main metabolic products during lupanine fermentation [7]. In this study, we systematically and consistently monitor the transcriptional kinetics of the gene expressing lupanine hydroxylase as well as global genes which may play a critical role during lupanine biodegradation in *P. putida*. We base our hypotheses on the lupanine derivatives' structures previously observed as well as on the selective catabolism of each enantiomer, which could potentially activate carbon catabolite repression (CCR) mechanisms.

4. Conclusions

Deciphering the lupanine biodegradation pathway by a *Pseudomonas* species provides fundamental knowledge of the metabolism during quinolizidine alkaloids biodegradation, which is expected to enhance bioprocess development for the production of high-added value compounds from lupanine wastewater.

Laccase-catalyzed degradation of micropollutants – Relation between the degradations of bisphenol A and diclofenac when in a mixture

Rosalie Pype[1], Frédéric Debaste[1]

1 Department of Transfers, Interfaces and Processes, Université libre de Bruxelles, Av. F.D. Roosevelt 50, ULB CP165/67, 1050 Brussels, Belgium

**Corresponding author: rosapype@ulb.ac.be*

Highlights

- Bisphenol A radicals enable the degradation of Diclofenac in mixes.
- A kinetic relation can be established between the degradations of BPA and DCF.
- That relation is independent of the initial concentrations and enzymatic activity.

1. Introduction

A micropollutant is a substance that has a negative impact on the organisms of the environment even at very low concentrations (ng/L to µg/L). An important source of micropollutants in surface waters is the release of wastewater treatment plants (WWTPs) effluents [1]. Enzymatic treatments have been studied as a mean to remove micropollutants. One of the most studied enzymes is laccase, an oxidase that oxidizes its substrate to form a reactive radical with the concomitant reduction of molecular oxygen to water. The formed radicals can then undergo non-enzymatic reactions [2]. Several papers highlighted that interactions took place between the compounds when several micropollutants were present in a mix [3,4]. In this study, the mechanisms underlying micropollutants removal were investigated in single-compound reactions and binary mixes, as well as the impacts of the interactions on the degradations kinetics including a relation between the degradations of the two compounds.

2. Methods

Laccase-catalyzed degradations of bisphenol A (BPA) and diclofenac (DCF) were performed at 20°C in phosphate buffer (pH7). The solution Novozym 51003, a commercial laccase preparation from Novozymes, was used as the enzyme source. The laccase activity was determined has described in [5]. The reactions were performed using BPA and DCF in single-compound medium (5 mg/L and 10 mg/L) and mixes (5 mg/L each, 5 mg/L BPA with 10 mg/L DCF and 10 mg/L BPA with 5 mg/L DCF) with either 3000 U/L or 1500 U/L of laccases. Samples were withdrawn at 0h00, 0h30, 1h00, 2h00, 3h00, 4h00, 5h00 and 6h00 of reaction. They were immediately mixed with 30 µL of sodium azide 1M to stop the enzymatic reaction and centrifuged before being analyzed through HPLC-UV. All experiments were performed in triplicate.

Chemical equations and reaction rates were used as a basis to determine the kinetic relation between the degradations of BPA and DCF.

3. Results and discussion

In single-compound reaction, the degradation of BPA at a given time was higher for a higher enzymatic activity (3000 U/L) and for a higher initial concentration (10 mg/L). The augmentation of the degradation when a higher enzymatic activity is used is expected as the laccase catalyze the reaction. The increase of the degradation when a higher concentration of BPA is used can be explained by the reaction of the radicals formed through the laccase-catalyzed oxidation of BPA with BPA molecules.

When in single-compound reaction, DCF was not degraded by laccase. That can be linked to the fact that the laccase contained in Novozym 51003 is a laccase with low redox-potential from *Myceliophthera thermophila*. So, as DCF is more recalcitrant than BPA, its degradation can be impossible for that laccase in the considered conditions.

However, DCF was degraded up to 47% after 6h in presence of BPA. That can be explained by the radicals formed through the laccase-catalyzed oxidation of BPA reacting with DCF. The degradation of DCF (X_{DCF}) was found to be directly linked to the degradation of BPA (X_{BPA}) no matter what the reaction conditions were (see Figure 1). By building a kinetic model, the relation between these two degradations was evaluated by $X_{DCF} = 1 - (1 - X_{BPA})^k$ where k is a constant.

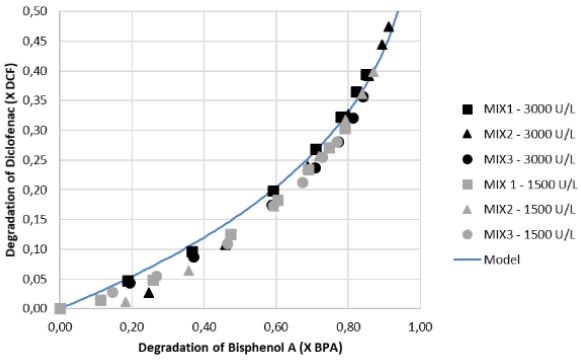

Figure 1. Degradation of DCF in function of the degradation of BPA obtained at the same reaction time. MIX1 = 5 mg/L BPA + 5 mg/L DCF, MIX2 = 10 mg/L BPA + 5 mg/L DCF, MIX3 = 5 mg/L BPA + 10 mg/L DCF. All reactions were performed at pH 7 and 20°C in triplicate (mean values of triplicates plotted). Model is the modelled relation between X_{DCF} and X_{BPA} where the constant k is 0.25.

4. Conclusions

The radicals formed through laccase-catalyzed degradation of BPA can react with other compounds present in the medium. Radicals participate to the degradation of BPA in single-compound medium and enable the degradation of DCF in mixes. A kinetic relation can be established between the degradations of BPA and DCF independently of the initial concentrations and enzymatic activity in the range of the tested conditions.

Highlights

- Membrane aerate biofilm reactor (MABR) is a promising, ecological and economic new technology for biological wastewater treatment.
- The potential role of microfungi in biological wastewater treatment has not received the attention merited, despite their metabolic ability to degrade many organic environmental pollutants.
- Hollow fiber as Accurel PP S6/02 are good for supplying air to fungal biofilm.

1. Introduction

A innovating wastewater treatment is the Membrane Biofilm Reactor (MBfR) based on the transfer of a gas through a membrane to a biofilm. The outer surface of biofilm is in contact with a liquid phase containing the substrates to be metabolized [1].

In a common wastewater treatment using MBfR the biofilm is formed by activated sludge organisms, but in this work it was studied the possibility to develop a biofilm using different fungal strains. [2]

The use of fungi to remove pollutant from environment components is called mycoremediation and is a new eco-friendly technology. Fungi can survive and grow at high concentration of many pollutants and some strains are used in wastewater treatment [3].

In this work a laboratory-scale reactor study was carried out by using commercial hydrophobic hollow fiber membranes, in polypropylene. The aim of work is to verify the capability of different fungi to grow and degrade synthetic or real wastewaters using air through a membrane.

2. Methods

Two common fungal strains usually used for mycoremediation were selected for the biofilm formation on the membrane surface: *Trichoderma harzianum* Rifai group and *Penicillium expansum* Link. The membrane bioreactors were realized starting from commercial fibers Accurel PP S6/2 (3M, Germany).

A small batch MABR consisted of 3 L glass flasks containing a model wastewater and hollow fiber membranes (about 20 cm^2 of the membrane surface area) immersed in the liquid phase and connected to an air feeding line at atmospheric pressure.

Another MABR was built using a hollow fiber membrane module of about 600 cm^2, where the feed was recirculated from a wastewater tank (Fig.1).

Various experiments aimed at evaluating the oxygen transfer rate were carried out at different air and liquid velocities. The biofilm growth was monitored and various operating parameters, as well as temperature, air velocity, and oxygen consumption and demand were studied using model and real wastewaters.

3. Results and discussion

In batch conditions the *Penicillium expansum* showed a better ability than *Trichoderma harzianum* to form a biofilm on the hollow fiber outer surface. In recirculation mode, the oxygen transfer performance of the membrane without biofilm was better by increasing the air and liquid velocity. Adhesion and growth of different fungal strain were tested using the same hollow hydrophobic fibers. The MABR performance where oxygen was supplied directly to the biofilm through the membrane was compared with the one of a suspended aerated biomass reactor based on a conventional sparger.

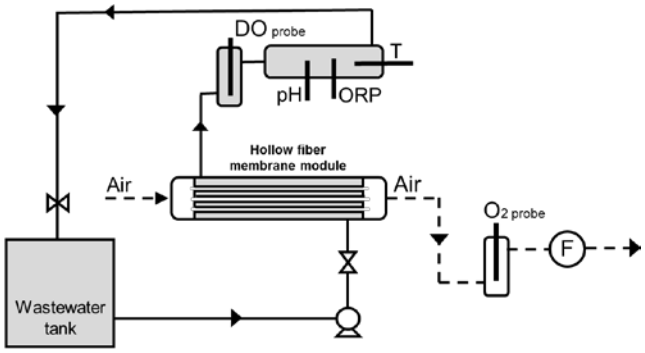

Figure 1. Membrane Areated Biofilm Reactor Plant scheme used for oxygen transfer and fungal growth experiment.

4. Conclusions

Some fungal strains are able to form a stable biofilm on the membranes Accurel PP S6/02. A preliminary screening revealed which strains are able to metabolize simple and more complex organic pollutants. Supplying oxygen directly thought the hollow fiber is an efficient approach to improve the kinetics of the pollutant degradation process. The fungi that have been tested show a different adherence on Accurel PP S6/02 and different capability to degrade the substrate, but it is still research is needed to explore new type of fungi and the substrates tested.

Highlights

- The potential of tertiary MBBRs was investigated in terms of MPs removal.
- MPs biodegradation by the biofilm was higher than by the suspended biomass.
- The profile of the microbial abundance reveals acclimation of the biofilm biomass.

1. Introduction

Nowadays, the scientific community is faced with the newly-born challenge of micropollutants (MPs) in aquatic resources. Since effluents of wastewater treatment plants have been globally recognized as the main source of these compounds in the aquatic environment, additional steps during wastewater treatment are one of the best options to reduce the release of these compounds into surface waters. To date, identification of technically and economically feasible advanced wastewater treatment options for elimination of MPs from secondary-treated effluent like adsorption processes, advanced oxidation processes and membrane filtrations is gaining importance. Regardless of these options that are recognized costly and laborious, there has been lower attention to innovative and cost-effective moving bed biofilm reactors (MBBRs) so far. High sludge retention time (SRT) obtaining in low hydraulic retention time (HRT) has given a dazzling attitude to MBBR reactors for high-efficient removal of carbon, nutrients and recently MPs. In the present work, we provide further insights into the key parameters involved in the removal of four MPs from secondary-treated municipal wastewater using a pilot-scale MBBR reactor. The biodegradation mechanisms were pointed out as the main removal pathways and the structural behavior of the microbial abundance was followed over the time.

2. Methods

Four identical lab-scale glass MBBR reactors, each with an effective volume of 3.1 L, were operated in a parallel mode under the ambient temperature, fed by a synthetic effluent after seeding with activated sludge. While two of them were used as references, the both others were fed with the MPs (17ß-Estradiol, Diclofenac, Naproxen, et 4n-Nonylphenol). Biofilm development on the surface of Z-MBBR carriers was monitored by microscopic observation (Epifluorescence and SEM).

Samples for MPs measurements were shipped to an indipendant laboratory named La Drome, located in France – to be analyzed under the license of COFRAC by LC-MS-MS measurements). Meanwhile, the biomass profile were characterized by means of DNA extraction and qPCR analysis through the large groups of the microbial [1].

3. Results and discussion

After stepwise establishment of a mature biofilm, abiotic and biotic removals of MPs were studied. Since no MPs reduction was observed by the both photodegradation and volatilization, abiotic removal of MPs was ascribed to the sorption onto the biomass. Target MPs i.e. Naproxen, Diclofenac, 17ß-Estradiol and 4n-Nonylphenol, arranged in the ascending order of hydrophobicity, abiotically declined up to 2.8%, 4%, 9.5% and 15%, respectively. MPs absorption onto the suspended biomass was found around two times more than the biofilm. When comparing abiotic and biotic aspects, we found that biotic removal outperformed its counterpart for all compounds as Diclofenac, Naproxen, 17ß-Estradiol and 4n-Nonylphenol were biodegraded by 72.8, 80.6, 84.7 and 84.4%, respectively. The effect of the changes in organic loading rates (OLRs) was investigated on the pseudo-first order degradation constants (kbiol), revealing the dominant biodegradation mechanism of co-metabolism for the removal of Diclofenac, Naproxen, and 4n-Nonylphenol., while 17ß-Estradiol obeyed the biodegradation mechanism of competitive inhibition. As summarized in figure 1, biotic removals of all MPs were quantified higher in the biofilm compared to the suspended biomass. [1]

The specific monitoring of the microbial community (figure 2) by molecular biology tools allowed us to understand the key role of some microorganisms in the degradation of targeted MPs, to identify those suitable and potentially involved in this degradation. A major presence of *Actinobacteria* was pointed out.

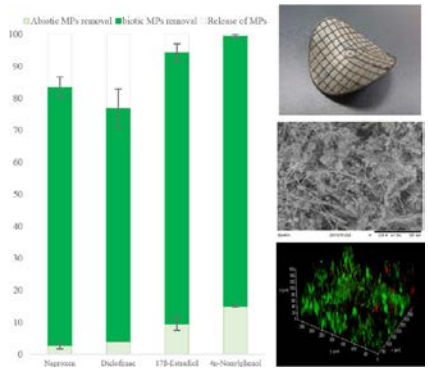

Figure 1. Contribution of micropollutants removal mechanisms

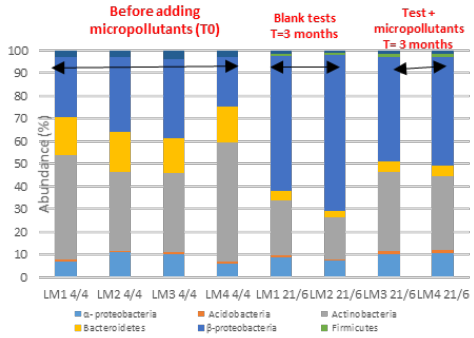

Figure 2 Microbial abundance in the mixed liquor – large groups (same type of data available for biofilm)

4. Conclusions

To draw a conclusion, a quite high removal of recalcitrant MPs is achievable in tertiary MBBRs, thanks to a biomass acclimation with microbial community selection, making them a promising technology that supports both pathways of co-metabolism and competitive inhibition.

Highlights

- Removal of pesticides from aqueous solutions.
- Supported ionic liquids (SILPs) for solid-phase extraction (SPE).

1. Introduction

Due to the continuous growth of population and related anthropogenic activities, many toxic compounds are released and are reaching the environment [1]. A common type of these pollutants, are pesticides, which include herbicides, fungicides and insecticides. Pesticides comprise a wide group of chemical compounds, ranging from organo-phosphates, carbamates, to pyrethroids [2]. They are widely used to prevent crops destruction and to increase the agriculture productivity, leading to their accumulation in the food chain and to the contamination of air, water and soil [2]. According to the EU Directive on water quality [3], the maximum allowed concentration for pesticides in water is 0.1 µg/L for individual compounds and 0.5 µg/L for total pesticides. In general, pesticides tend to be environmentally persistent, thereby increasing the probability of exposure by non-target organisms [4]. Thus, a particular area of interest is on effective alternatives for environmental treatment of wastewater and groundwater supplies [1]. In recent years, a variety of methods including biodegradation, photodegradation, chemical precipitation, hydrolysis, oxidative degradation, ion exchange, flocculation, neutralization, membrane separation, ultrafiltration, and adsorption strategies have been applied for the treatment of pesticides from wastewaters [5].

Recently, supported ionic liquids (SILPs) have been described as an alternative adsorbent material for solid-phase extraction [6]. Ionic liquids (ILs) are organic salts, which by definition present a melting point below 100°C. Among other interesting features, one of their most relevant characteristics is their tunability. ILs can be designed to present a set of particular characteristics by changing the cation/anion chemical structure – a property that is transferred to SILPs. Based on these advantages, herein we propose the development of a more efficient and economical alternative technique for the removal of pesticides from water using SILPs.

Several supported ionic liquids (SILPs) silica-based materials were synthesized and characterized. Kinetic and equilibrium experimental data were obtained, and models were fitted for imidacloprid, a systemic neural toxic insecticide [4], used here as a model pesticide.

2. Methods

The synthesis of SILPs was previously described [7]. Briefly, commercial silica gel was used as the starting material for SILPs synthesis. In the first step, activated silica particles react with 3-

chloropropyl-methoxysilane, in order to obtain chloropropyl silica (SilprCl). Then, SilprCl material reacts with 1-methylimidazole or other reagents as the source of the cation (see Figure 1). Several techniques were used to characterize these materials. The adsorption kinetics and isotherms of each prepared SILP for imidacloprid were determined at 25°C.

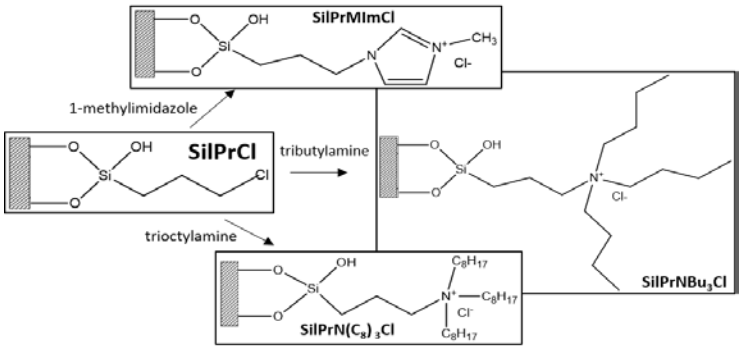

Figure 1. Schematic representation of the prepared SILPs and reagents used as source of the cation.

3. Results and discussion

Adsorption experiments were carried out, including studies of the adsorption kinetics and adsorption isotherms for the prepared materials for imidacloprid. It was found that when using the $SilPrNBu_3Cl$ material the adsorption of imidacloprid is fast (less than 10 min in equilibrium), reaching values of the equilibrium concentration of adsorbate in the solid phase (q_e) of 0.027 $mmol.g^{-1}$.

4. Conclusions

The prepared SILPs show promising results for the removal of imidacloprid from aqueous solutions with high adsorption efficiencies. The best identified SILPs are being tested for the removal of other pesticides from aqueous media, as well as the materials reuse.

Highlights

- Alternative biotech-process to provide a high-purity 2-PE.
- Possibility and benefits of *CAJB* use as microbial cultivation broth.
- Synergistic effect between sugar concentration and L-Phe/precursor.

1. Introduction

2-Phenylethanol (2-PE) is an aromatic compound with rose-like odours used as a food, cosmetics and perfumery additive. Currently, this aroma is produced from natural rose extracts and chemical synthesis in high-cost processes. Due to this problem, the biotechnological pathway has been described in current literature as a promising alternative process to provide a high-purity 2-PE in an environmentally friendly process (**Etschmann** *et al.* 2002). Significant reports have described the use of *Kluyveromyces marxianus* as the best 2-PE producers. In fact, some yeast strains produce 2-PE by the Ehrlich pathway (**Fabre** *et al.* 1997; **Wittmann** *et al.*, 2002; **Schrader** *et al.* 2004). In this context, a biotech-system has been investigated for the 2-PE production by *K. marxianus* using cashew apple (*Anacardium occidentale L., CAJB*) as a nutritional substrate for microbial cultivation. *CAJB* is a native fruit from Tropical America discarded as an agricultural by-product. Considering the rich composition, CAJB can be used as a low-cost carbon source and other media components, that greatly influence the 2-PE productivity. This study not only explored the possibility and benefits of *CAJB* use, but also describes the role of L-phenylalanine (L-Phe) as a metabolic-key in bioreactions-chain which leads to 2-PE synthesis.

2. Methods

Microorganism: *Kluyveromyces marxianus* ATCC 36907 was used for 2-PE production. **Cultivation Broth**: CAJB (133.4 ± 2.4 g/L total sugar) was used as microbial cultivation broth. Additional L-Phe concentrations (1.0; 3.0; 4.0 and 10.0 g/L) were used in CAJB. All the assays were conducted using a Tec-Bio bioreactor (performed at 35°C, 250 rpm, 2 L/min air, using 750 mL/75 mL of inoculum). **Analytical Methods**: Cell concentration was measured by gravimetric method and 600nm optical density using a spectrophotometer. Sugar concentration measurement were performed using HPLC/RID and Aminex® column (150 mm x 7.8 mm) at 65°C. 1 mmol/L H_2SO_4 was used as eluent at a 0.4 mL/min flow rate. 2-PE concentration was also determined by HPLC/UV (at

254 nm) using Nova-Pak® C18 (5μ, 4.6mm x 150mm) at 35 °C and. Acetonitrile/water (40:60 v/v) was used as eluent at 0.8 mL/min flow rate.

3. Results and discussion

2-PE is synthesized *via* L-Phe transamination to phenylpyruvate, which is decarboxylated to phenylacetaldehyde and finally reduced to 2-PE. This classical Ehrlich pathway (EP) description suggests the important role of L-Phe and thus, it can be predicted that the synthesis of 2-PE is highly influenced by L-Phe in media composition. In fact, the results for cell (X) growth and product (P) accumulation with different concentrations of L-Phe (illustrated by Table 1) confirmed this hypothesis when we evaluated 1.0-3.0 g/L L-Phe, although the similar results for the concentrations of 3.0; 4.0 and 10.0 g/L showed no significant differences in the metabolite production.

Table 1- Description of yield (Y), kinetic (μ) and volumetric productivity (Q_X and Q_P) parameters obtained for *K. marxianus* ATCC 36907 cultivation using CAJB.

Parameter	L-Phe Concentration (g/L)			
	1.0 (g/L)	3.0 (g/L)	4.0 (g/L)	10.0 (g/L)
$Y_{X/S}$ (g/g)	0.115	0.128	0.133	0.135
$Y_{P/S}$ (g/g)	0.004	0.006	0.006	0.006
$Y_{P/X}$ (g/g)	0.035	0.051	0.046	0.049
Q_P (g/L.h)	0.007	0.011	0.011	0.011
Q_x (g/L.h)	0.205	0.244	0.245	0.254
$\mu_{Xmáx}$ (1/h)	0.511	0.342	0.863	0,600

This observation might also reflect the effects of the CAJB complex composition, interfering in the 2-PE bioconversion. Parallel experiments using synthetic broth (10 g/L glucose and 3 g/L L-Phe) pointed 0,028 g/L.h for Q_P. Thus, we can suppose the important metabolic role of L-Phe in 2-PE synthesis when we use nutritionally-poor broths. When we use CAJB the synergistic effect between sugar concentration and L-Phe is more evident. The accelerated cell growth (μ) indicates intensive C-N-energy deviation to the biomass synthesis and limiting EP. EP is still limited by 2-PE inhibition. 2-PE at even low-concentrations could start biological *sensing* mechanisms, limiting EP and 2-PE productivity even when we use appropriate broths or L-Phe high-concentrations.

4. Conclusions

These results suggest that CAJB is an appropriate, unconventional medium for bioproduction of 2-PE by *K. marxianus* ATCC 36907. Also, these results pointed out the synergistic effect between sugar/L-Phe concentration and 2-PE inhibition as an important mechanism for the process optimization.

Biocompatible electroextraction of proteins from microalgae: protein characterization by mass spectrometry

Vincent BLANCKAERT, Hélène GATEAU, Justine MARCHAND, Benoît SCHOEFS*

Metabolism, Bioengineering of Molecules from Microalgae and Application , Mer Molécules Santé, IUML – FR 3473 CNRS, Le Mans University, Le Mans, France

Corresponding author: benoit.schoefs@univ-lemans.fr

Highlights

- Water-soluble proteins can be electroextracted from green algae
- The electroextraction is biocompatible
- 50% of the proteins originate from the chloroplast

1. Introduction

The increase of human populations and the expansion of cities contribute to an accelerated depletion of agricultural lands and natural resources. To overcome these difficulties, alternative sources of molecules are searched. Among these, microalgae are promising because they produce various molecules with pharmaceutical, nutritional and cosmetic properties (Mimouni et al., 2012). Biotechnological extraction process of these molecules starts with growing biomass, then harvesting microalgae and processing according to a definite downstream program. Vinayak et al. (2015) pointed out disadvantages of these downstream processes i.e. unselective extraction of intracellular compounds, requiring additional purification step(s), waste generation but also energy and time consumption. The need to increase the durability of biotechnological processes requires the development of new extraction methods such as electroextraction. Here, the identification of biocompatibly electroextracted proteins from the green alga *Haematococcus pluvialis* is reported.

2. Methods

Haematococcus pluvialis was grown mixotrophically. Proteins were electroextracted using pulse electric fields (PEF) of 0.5 or 1 kV cm^{-1}. After concentration and filtration, proteins were solubilized and separated by 1DE and 2DE. The resulting material was analysed by mass spectrometry: NanoLC/ESI LTQ-Orbitrap Velos ETD and MS/MS. The raw data were obtained after searching with Mascot Daemon search engine. *Chlamydomonas* was used for comparison because *H. pluvialis* belongs to the same order and it is a model organism (Marchand et al. 2018). Peptides and proteins were confirmed by generating a random peptide Bank "decoy", where the threshold of false positives has been set at 1% for peptides and proteins.

3. Results and discussion

The protein MW ranged from 12.4 to 164.9 kDa confirming that the proteins electroextracted are in a system without proteases. Proteins were identified by microsequencing after 1DE using nanoLC/ESI LTQ-Orbitrap Velos ETD and MS/MS. At maximum 36 proteins could be identified (1

kV cm^{-1}) among which 16 proteins were also electroextracted at 0.5 1 kV cm^{-1}. The localization of the identified proteins indicates that they originate from different cell compartments (Table 1). The comparison of the proteins patterns obtained with PEF of 0.5 kV cm^{-1} (Fig 1A) and 1 kV cm^{-1} (Fig 1B) when analysed by 2DE revealed that 8 spots were present only with PEF at 1 kV cm^{-1}.

Table 1. Identity of the 5 top scoring electroextracted

Uniprot/Protein	MW (kDa)	Peptide matches 0.5/1 kV cm^{-1}	Role and location
Ribulose bisphosphate carboxylase large chain	52.6	0/23	Carboxylation Oxidative fragmentation of the pentose Location: chloroplast
14-3-3 protein	29.3	0/20	Chaperonne Location: subcellular
14-3-3-like protein related	29.5	0/18	Chaperonne Location: subcellular
Tubulin beta chain	49.6	0/17	Constituent of microtubules Location: cytoplasmic
ATP synthase subunit beta	43.8	0/15	ATP synthesis coupled proton transport Location: chloroplast

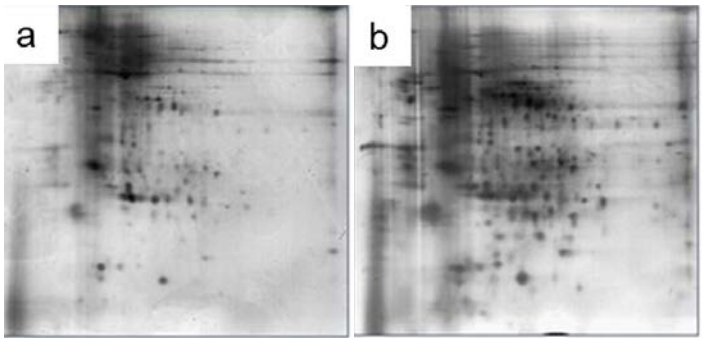

Figure 1. 2-DE of protein electroextracted from *Haematococcus pluvialis* PEF at (a) 0.5 kV cm^{-1} or (b) 1 kV cm^{-1}.

4. Conclusions

PEF of 1 kV cm^{-1} were more efficient in protein electroextraction than 0.5 kV cm^{-1} from the green alga *H pluvialis*. This work confirms the possibility of using PEF technology in blue biotechnology and opens new avenues for the development of biocompatible extraction possibilities.

Microbial cathodes formed from salt marsh sediment may boost the development of microbial fuel cells

Mickaël Rimboud, Alain Bergel, Marie-Line Délia*

Laboratoire de Génie Chimique, Université de Toulouse, CNRS, INP, UPS, Toulouse, France

**Corresponding author: marieline.delia@ensiacet.fr*

Highlights

- Halotolerant O_2-reducing biocathodes were designed using salt marsh sediments
- Maximal current density reached 2.9 A m^{-2} under air saturation at 0.22 V/SCE
- An unusual Gammaproteobacteria was among the dominant bacteria of the biocathodes
- In MFCs the biocathodes led to the highest power density obtained using biotic cathodes

1. Introduction

Microbial fuel cells (MFCs) associate a bioanode, where the catalyst is a microbial biofilm, with a biotic or abiotic cathode. As MFCs consume organic matter as the fuel at the anode, they can produce electrical current by simultaneously abating the organic matter contained in an effluent. MFCs may consequently be promising systems for effluent treatment [1]. Unfortunately, the ionic conductivity of common effluents is far too low to hope an electrochemical process fairly performs. MFC development must therefore be considered in the context of highly saline and hypersaline effluents [2].

Salt marsh sediments have previously demonstrated to be efficient inocula for the design of halotolerant bioanodes working under polarization at +0.1 V/SCE, and saline conditions up to 60 $g.L^{-1}$ NaCl [3,4]. Nevertheless, no efficient cathode exists yet for ensuring O_2 reduction at the neutral pH values, which are required by the bioanodes. No metallic catalyst is known to be efficient for O_2 reduction around neutral pH.

Here, a solution to this issue is proposed by designing O_2-reducing biocathodes from salt marsh sediments. The biocathodes were firstly designed and characterized independently, in electroanalytical conditions. Then, coupled with a bioanode, they led to the highest power density produced so far in highly saline media, using microbial catalysts on both electrodes.

2. Methods

All O_2-reducing biocathodes were designed under polarization at +0.1 V/SCE (chronoamperometry) on graphite felt electrodes. Their electrochemical behaviour was characterized by mean of chronoamperometry and cyclic voltammetry (1 mV s^{-1}). The current produced during operation of MFCs was recorded flowing through a 1200 Ohm resistance. Polarization curves were recorded every 72 hours. Biofilms on electrodes were imaged using epifluorescence microscopy. After extraction, bacterial DNA was sent for 16S-pyrosequencing to RT-Lab Genomics, Lubbock, Texas.

3. Results and discussion

The 8 biocathodes displayed similar electrochemical behaviour. O_2 reduction current started after 3 days of polarization and maximal current density reached 2.0 A m^{-2}, with peaks up 2.9 A m^{-2} during voltammetry recording (1 $mV.s^{-1}$). Current density fluctuated during the 30 days of polarization but was never lower than 0.4 A m^{-2}. Voltammetric recordings evidenced oxygen reduction starting around +0.4 V/SCE. These values are of the same order than the best recorded in the literature for O_2-reducing biocathodes in usual media [5,6].

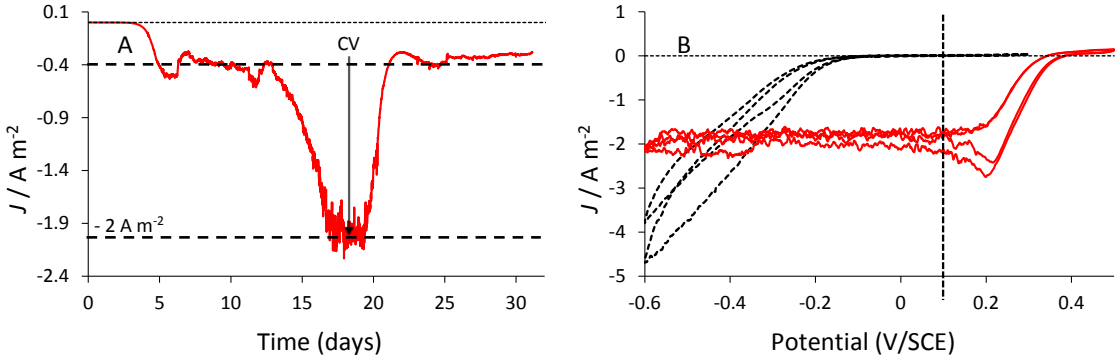

Figure 1. Representative current production recorded with a O_2-reducing biocathode. A: polarization at +0.1 V/SCE; B: Cyclic voltammetry recorded on day 17.5.

Biofilm imaging showed fair colonisation of the felt electrodes. Population analyses of the 8 biocathodes revealed similar microbial populations; their profile were significantly different from previous anodes, notably lacking Deltaproteobacteria. Orders counting potentially autotrophic genera (Rhizobiales and Rhodobacterales) were highly represented, together with an unusual Gammaproteobacteria, phylogenetically closed to *Thioalobacter thiocyanaticus,* a known chemoautotrophic strain. They may play a key role in inorganic carbon fixation and so the sustenance of the whole biofilm [7].

The biocathodes coupled to bioanodes prepared as previously described led to microbial fuel cells that operated for more than 13 days and produced up to 272 mW m^{-2}.

4. Conclusions

The efficient halotolerant O_2-reducing biocathodes designed here, in a reproducible way, should be a key element boosting the actual development of MFCs for the treatment of highly saline and hypersaline effluents.

Integrated Separation in a Complex 2-Phase Multienzymatic Cascade Reaction System

Jens Johannsen[1*], Claudia Engelmann[2], Andreas Liese[2], Georg Fieg[1], Paul Bubenheim[2], Thomas Waluga[1]

1 Institute of Process and Plant Engineering, Hamburg University of Technology
2 Institute of Technical Biocatalysis, Hamburg University of Technology

**Corresponding author: jens.johannsen@tuhh.de*

Highlights

- A complex 2-phase multienzymatic cascade reaction system is introduced.
- A pilot plant is successfully set up for a continuous process.
- Extractive centrifugation for *in-situ* intermediate recovery is implemented.
- Influence of the extraction temperature on the total production efficiency is evaluated.

1. Introduction

In the field of white biotechnology the sustainable production of flavors and fragrances is increasingly gaining attention [1]. Enzymatic reactions allow for high selectivity and purities under mild reaction conditions, less by-products, and therefore enabling an overall sustainable production process [2]. In this contribution, a novel *in-vitro* multienzymatic cascade reaction system for the continuous and sustainable production of cinnamyl cinnamate from cinnamyl aldehyde in a 2-phase system is introduced. Two co-factor coupled dehydrogenases are used in a water-based buffer system, thus ensuring co-factor regeneration within the reaction pathway. An extractive centrifugation allows for a reaction integrated intermediate separation with an organic phase, consequently enhancing the productivities of the dehydrogenases. In the organic phase, a lipase is used to catalyze an esterification reaction of the intermediates resulting in cinnamyl cinnamate formation. During extractive centrifugation the organic phase is saturated with water, thereby decreasing the lipase activity in the last reaction step. In this contribution, the pilot plant set up, as well as experimental results are presented. Reaction kinetic data of all enzymes were determined. A computer model for the simulation of the cascade reaction is introduced. Experiments in pilot scale were performed, and process parameters were analyzed. Possible solutions to counter the challenge of product saturation in the organic phase are presented and evaluated.

2. Methods

The kinetic data of the two-substrate red-ox reactions catalyzed by the dehydrogenases was determined in the buffer system saturated with the organic solvent. Using ACM© from AspenTech a mathematical model was implemented. Experiments of the co-factor coupled red-ox reactions were performed to validate the model.

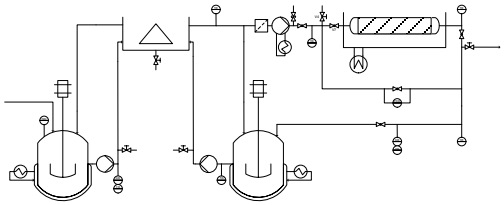

Figure 1. Pilot scale reactor set up with integrated downstream processing.

Experiments of the lipase catalyzed esterification reaction of cinnamyl alcohol and cinnamyl acid to cinnamyl cinnamate were performed in a pilot scale reactor (Figure 1) at the temperature optimum of the lipase (60 °C) to evaluate possible solutions to increase lipase activity. Firstly, the temperature during integrated extraction was varied. Secondly, an integrated adsorption unit operation to dry the organic phase was analyzed.

3. Results and discussion

For the dehydrogenases the maximum activities are 11.3 U/mg and 0.1 U/mg respectively, however, the solubilities of the substrates limit these activities during operation. Exemplary for the results of the pilot scale experiments, Figure 2 shows the lipase activity for extraction temperatures of 15 °C, 30 °C and 60 °C. In all cases, the esterification reaction itself was carried out at a temperature of 60 °C. It can be shown that a temperature decrease of 75 % in the extraction step leads to an activity increase of over 300 %. The activity increase can be explained by analysing the water saturation concentration of the organic phase exiting the centrifuge (Figure 3). A temperature decrease of 75 % during extraction results in a 75 % lower water saturation concentration, thereby decreasing the side product concentration prior to the esterification reaction. These results show that further drying of the organic phase is desirable. Hereby, promising results were achieved using an additional integrated adsorption step.

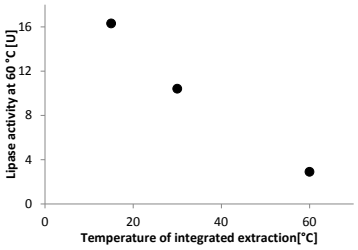

Figure 2. Lipase activity for different extraction temperatures.

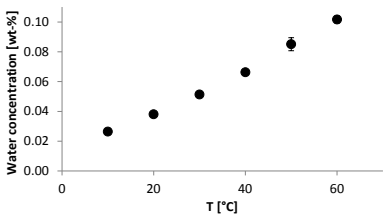

Figure 3. Temperature dependent water solubility in the organic phase.

4. Conclusions

A novel 2-phase multienzymatic cascade reaction system for a continuous and sustainable production of cinnamyl cinnamate is introduced. The kinetic data of the dehydrogenases was determined. A mathematical model was implemented. Additionally, a pilot scale reactor set up for a continuous production of cinnamyl cinnamate is presented. Exemplary for the analyzed process parameters in pilot scale operation the influence of the extraction temperature on the lipase activity was evaluated. Lipase activity was increased by over 300 % by decreasing the extraction temperature from 60 °C to 15 °C. These results can now be compared to an adsorption step prior to the lipase reaction. They are also helpful for a further development of the mathematical model.

Highlights

- *Yarrowia lipolytica* W29 was able to grow on hydrocarbons (hexadecane and hexadecene).
- *Candida tropicalis* demonstrated an extraordinary ability to grow on phenolic compounds.
- Lipase and microbial lipids were produced from hydrocarbons and olive mill wastewater.

1. Introduction

Large amounts of pollutant compounds are present in industrial effluents and, often, they are not totally degraded by physical and/or chemical methods before the discharge into the environment. Hydrocarbons and phenolic compounds are two examples of pollutants present in agro-industrial effluents, respectively in petroleum refinery effluents and olive mill wastewater (OMW). Biodegradation strategies involving microorganisms to simultaneously degrade these wastes and obtain high added-value products become an interesting approach, since the abundance of these compounds ensures the economic viability of bioprocesses while prevents major environmental problems. This work address the study of the ability of yeast species to grow on hydrocarbons and phenolic compounds as sole carbon and energy source. Moreover, the production of valuable compounds from these wastes was also assessed.

2. Methods

96-well microplate experiments were used to evaluate the ability of: (a) 6 yeast species (*Candida tropicalis* ATCC 250, *Candida utilis* CBS 621, *Candida cylindracea* CBS 7869, *Yarrowia lipolytica* CBS 2075, *Yarrowia lipolytica* W29 and *Pichia pastoris* CBS 2612) to grow on 1 $g \cdot L^{-1}$ hydrocarbons (hexadecane) and 1 $g \cdot L^{-1}$ phenolic compounds (catechol, tyrosol and phenol) as sole carbon source; (b) *Yarrowia lipolytica* W29 to grow on different concentrations of hexadecane or hexadecene (1 $g \cdot L^{-1}$ - 10 $g \cdot L^{-1}$); and (c) *Candida tropicalis* to grow on different diluted OMW-based media (5 % - 50 %). Batch experiments in 250-mL Erlenmeyer flasks were carried out to confirm the ability of: (a) *Y. lipolytica* W29 to grow on hexadecane (10 $g \cdot L^{-1}$), hexadecene (7.5 $g \cdot L^{-1}$) and a mixture of both hydrocarbons (5 $g \cdot L^{-1}$ of each hydrocarbon); and (b) *C. tropicalis* to grow on undiluted OMW. The effect of oxygen mass transfer was studied in 500-mL Erlenmeyer flasks, by raising the volume of flask headspace, for both yeast strains. Biomass concentration, lipase activity, microbial lipids content and long chain fatty acids were quantified as described by Lopes et al. [1]. Reducing sugars and total phenols were measured as described by Gonçalves et al. [2].

3. Results and discussion

The first screening carried out in 96-well microplates demonstrated: (a) the extraordinary capacity of *C. tropicalis* to grow in all phenolic compounds tested; and (b) the ability of *Y. lipolytica* W29 to grow on hexadecane. A considerable *Y. lipolytica* W29 growth was obtained in media with 10 $g \cdot L^{-1}$ of hexadecane or hexadecene comparatively to the control (without carbon source). It was also observed that *C. tropicalis* was able to grow on diluted OMW up to 50 % (v/v) medium. In fact, in this condition, a 3-fold improvement on cellular growth was obtained compared to the control (without carbon source). In Erlenmeyer flasks experiments, it was confirmed that *Y. lipolytica* W29 was able to grow on hydrocarbons-based media and using a mixture of hexadecane and hexadecene as carbon source led to an enhancement of final biomass concentration. In these substrates, the yeast had the capability to produce valuable compounds, namely lipase and microbial lipids. The increase of oxygen mass transfer, by raising the volume of Erlenmeyer headspace, had a clearly positive effect on cellular growth, intracellular lipids accumulation and lipase production, especially with hexadecane as carbon source (Table 1).

Table 1. Values of maximum biomass (Xmax), microbial lipids content, microbial lipids concentration and maximum lipase activity obtained from hydrocarbons by *Y. lipolytica* W29 batch cultures in flask experiments.

Flask	Hydrocarbon	Xmax ($g \cdot L^{-1}$)	Microbial lipids (%, w/w)	Lipids concentration ($g \cdot L^{-1}$)	Lipase ($U \cdot L^{-1}$)
250 mL	Hexadecane	3.5 ± 0.02	8.7 ± 0.7	0.3 ± 0.03	1260 ± 125
	Hexadecene	3.0 ± 0.01	9.9 ± 1.4	0.3 ± 0.04	610 ± 112
	Mixture	5.1 ± 0.04	8.5 ± 0.8	0.4 ± 0.003	567 ± 134
500 mL	Hexadecane	4.7 ± 0.03	15.1 ± 0.1	0.7 ± 0.001	2730 ± 304
	Mixture	7.3 ± 0.05	6.6 ± 0.1	0.5 ± 0.01	868 ± 270

Candida tropicalis was able to grow in undiluted OMW and consume almost all of phenolic compounds in Erlenmeyer flask experiments. A considerable amount of microbial lipids was also produced. The increase of oxygen mass transfer led to an improvement on cellular growth and reducing sugars consumption. However, total phenols consumption and intracellular lipids accumulation were not significantly affected by the raise of Erlenmeyer headspace (Table 2).

Table 2. Values of maximum biomass (Xmax), reducing sugars consumption, total phenols consumption, microbial lipids content and microbial lipids concentration obtained from OMW by *C. tropicalis* batch cultures in flask experiments.

Flask	Xmax ($g \cdot L^{-1}$)	Reducing sugars consumption (%)	Total phenols consumption (%)	Microbial lipids (%, w/w)	Lipids concentration ($g \cdot L^{-1}$)
250 mL	16.3 ± 0.03	38.2 ± 1.1	84.2 ± 0.9	18.3 ± 1.5	3.0 ± 0.8
500 mL	32.0 ± 0.4	55.7 ± 1.3	85.2 ± 0.6	19.8 ± 1.9	6.3 ± 0.8

4. Conclusions

This work demonstrated the potential of: (a) *Y. lipolytica* W29 to degrade hydrocarbons-contaminated effluents; and (b) *C. tropicalis* to degrade phenolic-rich effluents. Both yeast strains were able to produce valuable compounds, lipase and microbial lipids, from these pollutants. Microbial lipids, due to its composition (rich in oleic and linoleic acids) can be used to obtain biodiesel, a renewable fuel.

Organophosphate pesticide degradation in a continuous biocatalytic membrane reactor

R. Mazzei, G. Vitola, T. Poerio, L. Giorno

Institute on Membrane Technology, National Research Council, ITM-CNR, via P. Bucci, 17/C, I-87030 Rende (Cosenza), Italy

**Corresponding author: r.mazzei@itm.cnr.it*

Highlights

- Continuous biocatalytic membrane reactor development (BMR) to hydrolyse organophosphates
- Significant improvement of immobilized phosphotriesterase stability respect to the free enzyme
- High organophosphate degradation (90%) by the BMR
- Long term stability of the BMR (1 year)

1. Introduction

Organophosphates (OPs) are highly toxic compounds used as pesticides and nerve agents. The devastating effects, reported in different studies, on the environment and human health indicate a serious scenario for both instantaneous and long terms effects. Bio-based strategies for OPs degradation seem the most promising solutions, particularly when extremophiles enzymes are used. These systems permit OPs degradation with high efficiency and specificity under mild conditions. However, as frequently observed, enzymes can easily lose activity in batch systems, so that a strategy to improve biocatalyst stability is highly needed, in order to develop continuous systems. In this work an extremophile enzyme, able to hydrolyze organophosphates, was immobilized on functionalized polymeric membranes to develop a continuous biocatalytic membrane reactor (BMR).

2. Methods

Commercial flat-sheet polymeric membranes of regenerated cellulose (Millipore), PVDF (GVS spa) and PES (GVS spa) were functionalized (Militano et al., 2016, Vitola et al 2016, Vitola et al 2018) in order to covalently bound three different mutants (called SacPox, SsoF and Sso-3M) from Sulfolobus acidocaldarius, Sulfolobus solfataricus (E. Porzio, 2007), kindly supplied by the Institute of Protein Biochemistry of the National Research Council (IBP-CNR). The obtained biocatalytic membranes were characterized by FT-IR, immunoelectron microscopy, enzyme catalytic activity and stability.The activity of the phosphotriesterase towards the pesticide paraoxon at 25 °C was

evaluated measuring the appearance of the reaction product (4-nitrophenol) by a spectrophotometer (405 nm).

3. Results and discussion

Among the different mutants with phosphotriesterase activity tested Sso3M showed the highest specific activity (10.0 ± 0.06 U/mg) in comparison to SsoF (0.65 ± 0.07 U/mg) and SacPox (0.34 ± 0.04 U/mg), respectively.

Sso3M showed the highest specific activity also when immobilized on hydrophilic membranes (PES and RC membranes) respect to hydrophobic (PVDF), giving the highest retained specific activity when immobilized on RC membranes.

The concentration of the immobilized enzyme amount which gives the highest specific activity and the best enzyme distribution on RC membranes (no enzyme aggregation observed by the in situ immunolocalization) is 0.17 (±0.03) mg/cm3. The conversion of the substrate at each passage through the biocatalytic membrane is improved up to 87%, when the residence time up to 0.96 min was increased. The stability of the enzyme in the continuous BMR was monitored for about 10 months and compared to the one of the free enzyme. The immobilized Sso3M showed high stability up to 10 months on the contrary the free enzyme is deactivated within two months

4. Conclusions

A continuous biocatalytic membrane reactor for the degradation of the pesticide paraoxon was developed. Under optimal conditions (residence time 0.96 min, amount of immobilized enzyme: 0.17 mg/cm3), the BMR has shown to detoxify about 90% of paraoxon (1 mM) at each passage through the biocatalytic membrane. Either in batch or in the continuous configuration, the immobilized enzyme showed higher stability than the free form up to 10 months.

Crystal Contact Engineering to Promote Technical Protein Crystallization

Phillip Nowotny*, Johannes Hermann, Dariusch Hekmat, Dirk Weuster-Botz

Technical University of Munich, Institute of Biochemical Engineering, Boltzmannstr. 15, 85748 Garching, Germany

**Corresponding author: p.nowotny@lrz.tum.de*

Highlights

- Crystal contact engineering effects faster crystallization of the enzyme *Lb*ADH
- *Lb*ADH variants crystallize at reduced concentration of crystallization agent PEG
- Both properties result in increased space-time yield and lowered process costs
- Enhanced crystallizability of *Lb*ADH variants can be explained on the atomic level

1. Introduction

Technical protein crystallization is an attractive alternative to preparative chromatography as a main purification step of proteins in biotechnological processes [1]. Recombinant insulin, being the most prominent example, has been industrially crystallized for several decades. However, only a few proteins are sufficiently well crystallizable and molecular processes during protein crystallization are barely understood. Crystal engineering has been investigated since the early 1990s and it has become a common method to optimize crystal size and diffraction quality for crystallographic purpose [2]. Our approach was to transfer and expand the knowledge of crystal engineering towards technical crystallization purposes on the basis of the enzyme *Lactobacillus brevis* alcohol dehydrogenase (*Lb*ADH) [3]. The objectives were to i) enhance its crystallization properties allowing for the use of technical crystallization by engineering the crystal contact patches and ii) to understand the underlying mechanisms on the atomic level.

2. Methods

*Lb*ADH variants were produced with *Escherichia coli* in shaking flasks or stirred-tank bioreactors and purified via affinity chromatography. After dialysis and protein concentration, crystallization was triggered by the addition of a crystallization buffer containing polyethylene glycol (PEG 550). µL-batch crystallization was monitored by automated microscopic imaging, mL-batch crystallization was monitored by measurements of the protein concentration in the supernatant and microscopy of the crystals. In parallel, the enzymatic activity and the purity of all mutants were assessed experimentally. X-ray diffraction was performed for structural analysis of relevant *Lb*ADH mutants.

3. Results and discussion

More than 50 *Lb*ADH variants were designed following deterministic approaches, produced and purified to equal purity grade and protein concentration. Crystallization in microbatch experiments under identical conditions were the foundation for tracing back distinct crystallization properties to single amino acid exchanges. Enzymatically active *Lb*ADH variants were generated with increased crystallization success rate which correlated with a larger amount of crystals, a reduced time till crystallization equilibrium and crystallizability under reduced concentration of crystallization agent PEG 550. X-ray diffraction analysis elucidated enhanced crystallizability of *Lb*ADH variants on the atomic level. Crystallization on a mL scale in stirred tanks revealed increased volumetric productivities and crystallization yield of *Lb*ADH variants (exemplarily shown by WT-*Lb*ADH and variant K32A, Figure 1) [4].

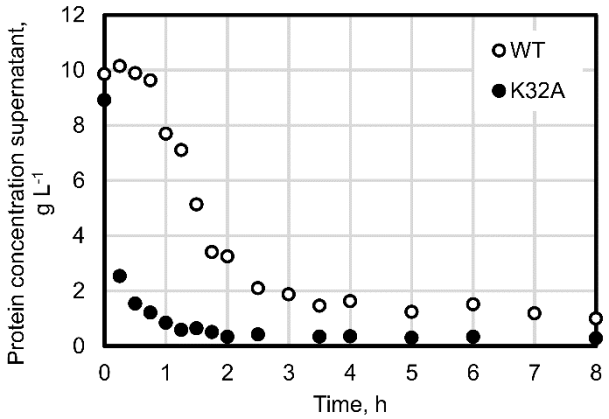

Figure 1. Crystallization kinetics of WT-*Lb*ADH (white) and mutant K32A (black) in a stirred tank crystallizer (V = 5 ml, initial protein concentration = 10 g L^{-1}, T = 20 °C) [4].

4. Conclusions

We have demonstrated for the first time that crystal contact engineering is a powerful tool to improve a protein's crystallizability for the use in technical crystallization. Single amino acid exchanges preserve enzymatic activities of engineered *Lb*ADH variants and lead to significantly enhanced crystallization space-time yields. Moreover, crystallization of *Lb*ADH variants takes place at concentrations of crystallization agent PEG 550 where the WT does not crystallize anymore. Both latter properties reduce process costs of technical large-scale protein crystallization, making it increasingly attractive for its integration into biotechnological downstream processes.

Evaluation of two-species binding model within anion-exchange membrane chromatography to predict pressure buildup during recovery of a virus

William Kelly[1*], Kelsey O'Donnell[1], Zuyi Huang[1]

Department of Chemical Engineering

Villanova University, 19085 USA

**William.j.kelly@villanova.edu*

Highlights

- Pressure drop across a membrane chromatography unit increases steadily during operation and that this increase is more significant if a higher amount of DNA is present in the feed to the membrane unit.
- A mathematical model was developed that accounts for the competition of DNA and virus for binding sites on the membrane surface, and predicts virus bound per channel length which correlates well with pressure rise.
- The model predicted quite well the experimental breakthrough curves (as well as the amount of virus loaded per membrane channel length) across a range of inlet DNA concentrations from 1 x 10^{-10} to 5 x 10^{-6} g/ml and a range of inlet virus concentration from 1-5 x 10^{-4} g/ml.

1. Introduction

Membrane chromatography is an emerging technology for its effective removal of host cell DNA, proteins, and other small macromolecules throughout downstream purification. Multiple vendors supply this single-use technology in several surface chemistry options. The main feature of chromatographic separations based on membranes is the absence of pore diffusion, which is the main transport resistance in conventional column chromatography. Using porous particles. With the membranes, the molecules move via convection through the pores (1).

2. Methods

The presented findings aim to determine the cause of constant pressure rise observed during the loading phase of a viral recovery process using Sartorius Sartobind Q anion exchange membranes. A mathematical model was developed, based on previous work with expanded bed adsorption of proteins (2). The membrane model accounts for the competition of DNA and virus for binding sites on the membrane surface as they flow convectively through a pores/channel. The adsorption isotherm was modelled as Langmuir-like.

3. Results and discussion

The mathematical model predicted the experimental breakthrough curves (as well as the amount of virus loaded per membrane channel length across a range of inlet DNA concentrations from 1 x 10^{-10} to 5 x 10^{-6} g/ml and a range of inlet virus concentration from 1-5 x 10^{-4} g/ml.

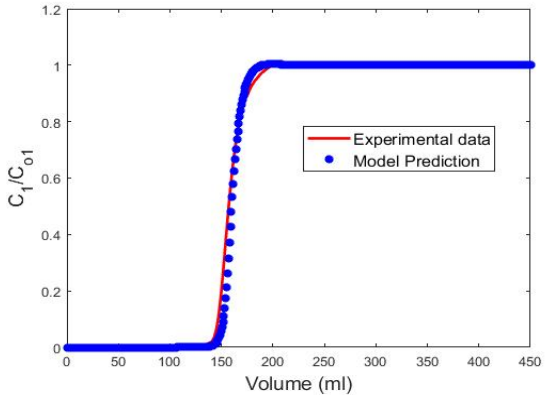

Figure 1. Breakthrough Results – Model versus experimental.

Initial Concentrations: C_{DNA} = 1 x 10^{-8} g/ml and C_{virus} = 3.1 x 10^{-4} g/ml

4. Conclusions

The model predicted quite well the experimental breakthrough curves. The model can be used to predict the time in a batch when the pressure drop across the column reaches a critical maximum limit, which might prompt operators to reduce the pressure drop by reducing flowrate or replacing the membrane.

Purification of macromolecules combined with a simultaneous BTC analysis on a single Akta system

Rok Ambrožič[1], Petra Modic[1], Gorazd Hribar[2], Aleš Podgornik[1]

1 University of Ljubljana, Faculty of Chemistry and Chemical Technology, Večna pot 113, 1000 Ljubljana, Slovenia

2 Lek d.d., Technical Development Biologics Mengeš, Kolodvorska 27, 1234 Mengeš, Slovenia

**Corresponding author: Rok.Ambrozic@fkkt.uni-lj.si*

Highlights

- Modified chromatographic system with on-line column outflow analysis was designed.
- Robust method enabled breakthrough curve (BTC) detection for different target molecules.
- The limit detection concentration was enhanced by increasing the injected mass.
- Different case studies with different process dynamics were used for validation.

1. Introduction

A preparative high-performance liquid chromatography (pHPLC) remains an extensively used technique for a downstream operation for commercially important bio macromolecules, such as proteins and nucleic acids. Since process time becoming more and more critical for biopharmaceutical manufacturing, fast and effective chromatographic methods are widely required. In this context, target molecule breakthrough point determination should be of a great interest, mainly due to high evaluation of the final product. Therefore, modified chromatographic system with on line examination of preparative column outflow, which enabled detection of target molecule breakthrough point, was developed. Different case study samples, such as i) monoclonal antibodies (mAb), ii) protein aggregates and iii) plasmid DNA (pDNA), were used to validated and verified the system with automotive software method.

2. Methods

All experiments were performed with ÄKTA Explorer (GE Healthcare Life Science, UK) modified HPLC chromatographic system which enabled on-line analysis of preparative column outflow by simultaneously injection outflow from preparative column on separate selective analytical column where target molecule(s) was/were analyzed. Cationic and/or anionic exchangers were used as chromatographic supporters (along with selective protein A membrane), dependent on the investigated case study (feed sample) and its characteristics.

3. Results and discussion

To validate modified system and its method, the sample of pure mAb was loaded on a CEX preparative column and its breakthrough curves were investigated by UV absorbance measurements (Figure 1 left). No noticeable differences between breakthrough profile determined

directly from measurements of UV absorbance from preparative column (blue line) and breakthrough profile determined with on-line detection by protein A analysis (red squares) was detected, meaning system and method were designed correctly. Furthermore, breakthrough curve of unpurified mAb was investigated by the same method (Figure 1 right) to determined breakthrough curve of target molecule (mAb) in heterogeneous mixture (real sample). Although UV absorbance signal directly from preparative column was completely occupied throughout the experiment and as such unusable, on-line detection by protein A membrane enabled clear detection of mAb breakthrough point.

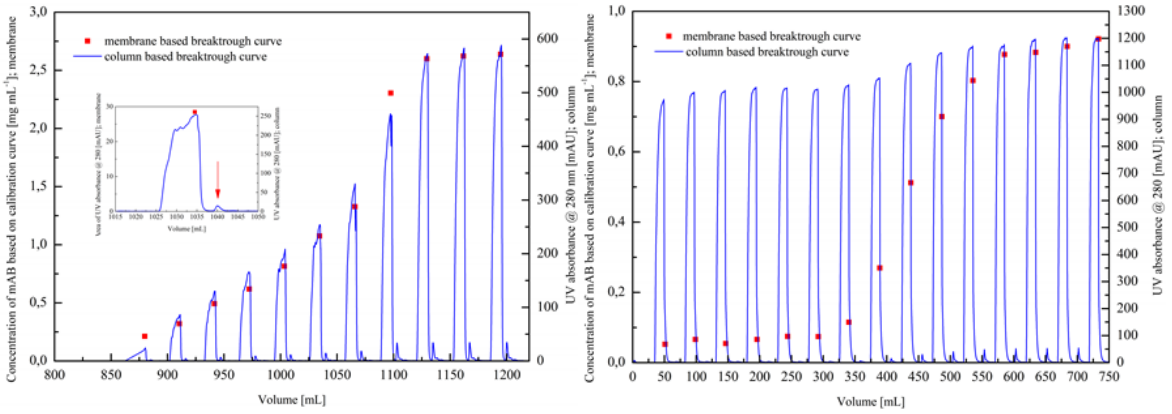

Figure 1. Protein A membrane (red squares) and CEX preparative column (blue line) based breakthrough curve of purified (left) and unpurified (right) mAb.

Additionally, modified HPLC system with the same analytical approach enabled efficient detection of protein aggregate, even below 1 % of total protein concentration. Since protein aggregates present a big concern in protein manufacturing, a fast and an efficient method for its detection should be widely required. Plasmid DNA was selected as a final case study, due to complex pDNA-RNA dynamics. However, excellent results with highly functional analysis for both target types of molecules were obtained without further modification of the system and/or method.

Finally, limit detection concentration was easily reduced by increasing the numbers of injection per each analyze step, what linearly increased injected mass and improved target molecule detection resolution. This simple, but extremely operative, solution was especially useful when target molecule concentration was below detection limit (in the early stages of breakthrough).

4. Conclusions

The modified HPLC system with automatize software method has proved to be very effective in detection of target bio macromolecules in preparative column outflow, even if the target concentration was below 1 % of feed concentration. Furthermore, system and method simple implemented into other pharmaceutical environments and its significant applicative potential should be enormous additional advantage for everyday use.

Highlights

- Adsorption properties of multimodal particle and membrane adsorbents were investigated.
- Interesting influence of Hofmeister ions on the binding capacity was observed.
- Single- and bi-component adsorption of proteins and DNA was studied.
- Desorption experiments revealed problems with reversibility of binding.

1. Introduction

Multimodal chromatographic adsorbents are novel materials with promising properties for downstream processing of therapeutic glycoproteins. This presentation summarizes the results of our research dealing with the properties of the salt-tolerant chromatographic membrane Sartobind STIC a several particle multimodal adsorbents with both cation- and anion-exchange ligands. The equilibrium properties of these materials were investigated for a number of model proteins and DNA. Moreover, their performance in the purification of recombinant human erythropoietin (rhEPO) from a cultivation broth produced by human embryonic kidney cells was examined.

2. Methods

The investigated adsorbents were MEP HyperCel, HEA HyperCel, and PPA HyperCel from Pall Corporation, Capto MMC, Capto MMC Impress from GE Healthcare, Eshmuno HCX from Merck, and Sartobind STIC from Sartorius Stedim Biotech. The compounds used for adsorption were bovine serum albumin, human serum albumin, ovalbumin, α-lactalbumin, cytoglobin, fetuin, lysozyme, and salmon DNA. rhEPO was produced by cultivation of human embryonic kidney cells 293 (HEK 293) [1]. Static adsorption experiments were carried out either in 96-well plates or in conventional shaken vessels. Flow experiments were carried out using the FPLC system ÄKTA Purifier (GE Healthcare, Uppsala, Sweden). The adsorbents were packed either in small laboratory columns or placed in a membrane module.

3. Results and discussion

One of the investigated aspects was the effect of buffer type on binding on multimodal adsorbents. It was found that no BSA could be bound onto Sartobind STIC from a polyvalent

phosphate buffer at all. On the contrary, salmon DNA binding was not affected by the buffer valency.

The effect of ions of Hofmeister series on the binding capacity was investigated for several adsorbents but most focus was on the performance of the salt-tolerant anion-exchange membrane Sartobind STIC and particle adsorbent with cation-exchange ligands Capto MMC. Eight different salts were examined ranging from strongly kosmotropic ones such as $(NH_4)_2SO_4$ to salts with strongly chaotropic ions such as Mg^{2+} or SCN^-. A typical upper limit of salt concentration was 2.5 M.

Very different behavior was observed. Kosmotropic salts had adverse effect on the adsorption capacity of BSA on Sartobind STIC. The protein was not adsorbed at all at the concentrations of about 0.1 M. On the contrary, the adsorption capacity of several proteins for Capto MMC was essentially unaffected up to the salt concentrations of 1-1.5 M. The binding of DNA on Sartobind STIC had however a different pattern. The binding capacity was more-or-less constant up to 0.6 M kosmotropic salts concentration and then gradually declined to zero at about 1.5 M.

Chaotropic salts had a rather negative effect on the adsorption capacity for Sartobind STIC and Capto MMC. In the case of Mg^{2+} ions, the polyvalent effect of this cation has been manifested. The effect of NaCl concentration was studied most carefully. All adsorbents exhibited salt tolerance when the adsorption capacity often did not change very much if the NaCl concentration was in the range 0–0.5 M. A rather high capacity was observed in many cases at the salt concentrations as high as 2–2.5 M. Differences in the salt concentration effect were observed among individual proteins were observed with respect to pH. This was more emphasized for the multimodal adsorbents with cation-exchange ligands where the electrostatic interactions become dominant for positively charged proteins.

The adsorption capacity of DNA on Sartobind STIC exhibited typically a maximum with the salt concentration. Bi-component binding of DNA and BSA showed that DNA was bound preferentially so the equilibrium adsorbed amounts of BSA were smaller than for single component isotherms. Multicomponent adsorption was studied also for the separation of rhEPO produced by cultivation of human embryonic kidney cells. Cation exchangers, both conventional and salt tolerant, were found to have the best selectivity for this separation which was also verified in column experiments.

4. Conclusions

This work presents the overview of our research activities on the equilibrium and performance properties of multimodal adsorbents.

Highlights

- This two-step purification delivers FGF-2 from *E. coli* with distinctive quality standards
- Polishing by HIC efficiently depletes a N-terminally degraded FGF-2 variant
- The full length product is recovered in the eluate with 100% yield
- HCP and dsDNA are depleted under their limit of quantification

1. Introduction

Fibroblast growth factor 2 (FGF-2) stimulates cell proliferation and differentiation via binding to the tyrosine kinase receptor and is an important therapeutics applied for tissue repair in regenerative medicine and for cancer treatment [1,2]. It is successfully produced by overexpression in the bacterial host *E. coli [3,4]*. During biopharmaceutical production a consistent product quality is of high importance. Typically, during capture the majority of process related impurities are depleted due to their properties which are highly differing from the product ones. In contrast, the polishing step is responsible to remove product variants of high similarity.

2. Methods

In the present study a two-step purification process for FGF-2 from clarified *E. coli* homogenate was developed. As capture step an ion exchange process was applied. The relative amounts of target product, host cell proteins (HCPs), dsDNA, endotoxin, monomer content, and high molecular weight impurities differed along the elution peak [4]. This information on the quality of the eluate is currently only available from time and labor intensive offline measurements. The holding step implemented for this purpose lead to degradation of FGF-2 generating product-related impurities. For robustness and quality assurance a polishing method based on HIC was integrated to assure the depletion of this process-related impurities and the separation of those product variants. The ion exchange eluate was purified using the HIC resin Toyopearl® Hexyl-650C. Its performance was compared to several other HIC resins regarding their impurity depletion.

3. Results and discussion

Toyopearl® Hexyl-650C performed superior compared to the other candidates. The product variants were effectively separated with a step yield of 100%. The HCP and dsDNA content after the HIC step was below the limit of quantification. Endotoxin content was depleted to 0.02 EU/µg FGF-2. The quantification of product variants was performed by an analytical ion exchange HPLC method.

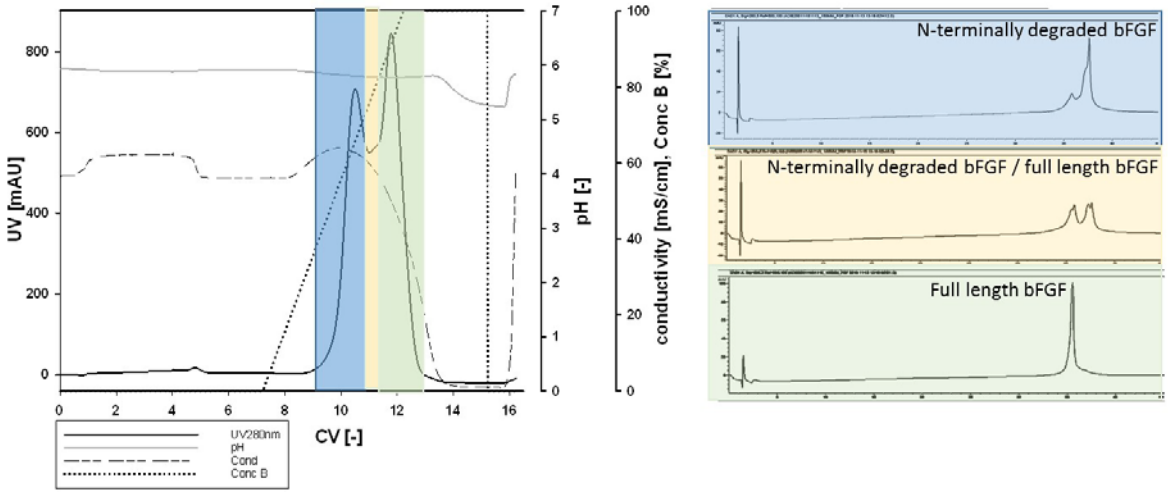

Figure 1. The HIC resin Toyopearl-Hexyl-650C (Tosoh, Japan) enabled the efficient separation of the N-terminally degraded product variant from the full length basic fibroblast growth factor: HIC chromatogram, elution was performed within 5CV with a linear gradient from 0 to 100% buffer B containing 10 mM Na-phosphate (left); Analysis of HIC eluate by IECX HPLC with gradient pH 7 – 10.5 (right)

4. Conclusions

The established polishing method by HIC enables the efficient depletion of the degraded product variant only differing in the loss of eight N terminal amino acids from the full length FGF-2. Toyopearl® Hexyl-650C resin separated the degraded product variant effectively while recovering the full length product with 100% yield. Implementing this polishing step into a two-step purification process started with a CIEX capture step a highly effective separation for FGF-2 was developed which meets distinctive quality standards defined by regulatory bodies. HCP and dsDNA were depleted under their LOQ.

Highlights

- Sea-urchin coelomocytes as biosensors for sea water contamination
- Anodic nanoporous alumina as adhesion substrate
- Long-term cultures in polylactic sampling chambers

1. Introduction

In this work we investigated the possibility of using living cells as stress sensing material in biosensors, in the light of the three Rs principle – Replacement, Reduction and Refinement [1]. This approach requires the necessity to cultivate them on biocompatible electrical conducting substrate and to insert the circuit into a culture chamber that must assure both the transport of oxygen and the diffusion of the medium containing the potential stressor to the cells, without modifying their response and the structure of the culture. To this aim we fabricated nano-patterned substrates of anodic porous alumina to be used for enhancing cell adhesion, and culture chambers made in polylactic acid. Sea-urchin cells (coelomocytes) were cultured on these substrates at different times of 1, 3 and 5 days in vitro. Since these cells are progenitors of immune cells in vertebrate systems (blood cells), they carry out similar functions. For this reason, although they can differ considerably from vertebrates, they have been proved to be very promising sentinels of environmental water quality [2], [3].

2. Methods

In order to assess the effect of pore size on the living cell adhesion, pores with different diameter in the range of 10 to 200 nm were prepared on the same substrates [4].

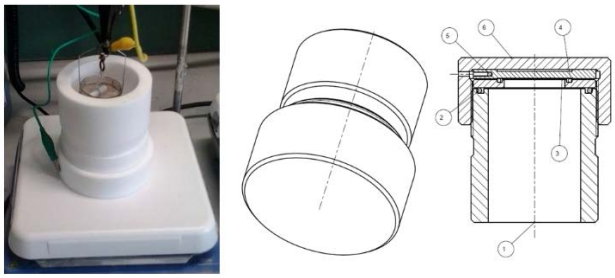

Figure 1. Anodization chamber

In the present version of the patterned substrates the living cell viability were assessed by examining both the presence and the nuclear status of the cells, via DAPI and IP staining, respectively.

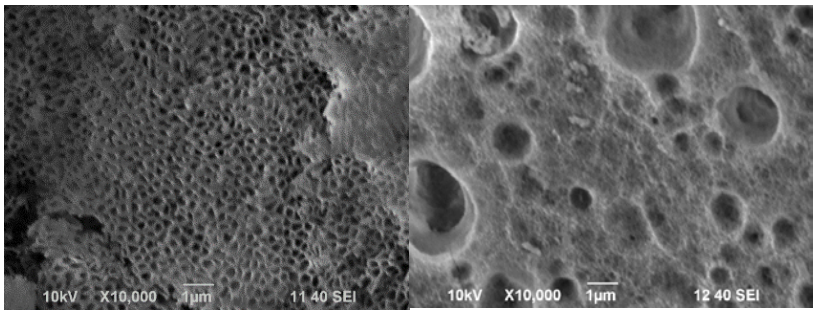

Figure 2. Different APA substrates

3. Results and discussion

All porous surfaces presented a higher number of adhering cells than different smooth controls of glass, polymer, and flat aluminum oxide without cell-adhesion promoting biomolecules. Coelomocytes readily adhered to the APA substrate up to 5 DIV: it can be observed that the nuclei are intact, and are all characterized by the same oval shape and size.

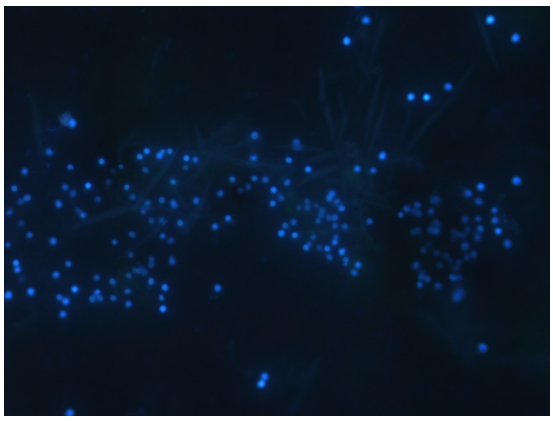

Figure 3. Culture cells on APA at DIV5, after staining with DAPI

4. Conclusions

The different pore size does not seem to have statistically significant effect on cell adhesion and this means that pore dimension can be optimized based on the need to realize an electrical read-out, to be carried out by impedance measurements.

Highlights

- Microfluidics are applied to the separation of biomolecules
- Protein-lipid A binding interaction is studied
- A recombinant protein has been successfully synthesized and characterized

1. Introduction

The interdisciplinary nature of microfluidics, MFs, as well as its multiple advantages, such as cost and reactants volume reduction, turn out attractive to medical sciences. This novelty has led to the development of bioanalytical devices focusing on different fields like clinical diagnosis, drug discovery or biohazard detection [1]. The favorable characteristics of MFs have paved the way to the design of high performance micro-magnetoforetic devices for the removal of trapped endotoxins from human blood based on the use of functionalized particles [2]. This approach could offer a paramount challenge for prevention, detection and removal of gram-negative bacterial sepsis, as it remains a significant cause of morbidity and mortality in hospitalized patients. Bacterial lipopolysaccharide (LPS) from G(-) is mainly composed of a glycosidic region and a lipidic region or Lipid A, which is the biological active fraction of the molecule. The interaction between Lipid A and different molecules such as antibiotics (PMB), isoenzymes like glucokinase ligand activators, binding proteins (LBP) and peptides as magainine have been subject of study due to the virulence of this kind of endotoxins. In this context, our work is now focalized on the analysis of the endotoxin selective sequestration by a recombinant protein and at the same time, we pursue a kinetic characterization of the lipid-protein interaction in order to contribute to the optimum design of the micro-device.

2. Methods

A separation system is intended to be implemented into a magnetophoretic microfluidic device where a biological fluid is contacted to a saline buffer in order to couple the endotoxin sequestration stage and the LPS-beads removal from the blood stream as depicted in Figure 1.

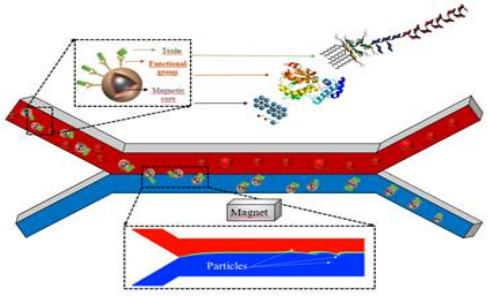

Figure 1. Magnetophoretic system for blood detoxification.

This sequestration stage needs a selective agent able to trap the lipid A. The functional molecule is a recombinant protein, expressed following the main strategies as vector design, host selection, and protein expression and purification [3]. Initially, a plasmid was designed and optimized for Escherichia coli and a histidine tag was added to bind the protein to Niquel carrying micro-beads. After the plasmid assembly, it was transformed into E. coli competent cells for protein overexpression at low temperature. The obtained soluble protein is loaded in 1mL HisTrap column, purified with affinity liquid chromatography techniques and finally concentrated. Then, it is bound to microbeads o/n to assure its complete functionalization. The sample is then centrifuged, the protein excess is removed and its concentration is measured to determine the beads adsorption capacity. Moreover, a fluorescent lipopolysaccharide conjugated with fluorescein isothiocyanate (FITC-LPS) stock solution of 1mg/mL is prepared and contacted to the protein-covered beads in order to analyze the selective binding of endotoxins. The fluorescent characteristic of LPS conjugates facilitates the quantification of the endotoxin removal and its quantification by fluorimetric techniques of samples supernatant.

3. Results and discussion

This work introduces a procedure to obtain a recombinant protein labelled with histidines as a quelating agent as a strategy to assure its binding to the divalent metallic ions of Ni2+ present in the micro-beads and optimizing its adsorption capacity. Preliminary studies have shown that 1mg of the protein binds to 5 µg of LPS, a promising protein activity, taking into account that septic patients show an endotoxin concentration around 300pg/mL. The specific binding takes place between the active site of the protein and the Lipid A of the lipopolysaccharide, but its mechanism needs to be deeply researched and defined with kinetic studies to precisely describe the lipid-protein interaction.

4. Conclusions

Focusing on the design of high performance microfluidic separation of G(-) bacterial lipopolysaccharide from human blood, we have addressed here the analysis of the ~~binding of~~binding of the Lipid A fraction to protein. With this purpose, we have developed a method that provides a soluble recombinant histidine tagged protein avoiding undesirable inclusion bodies. Preliminary studies demonstrate that 1 mg of our functional protein is able to sequestrate 5µg of LPS which constitutes promising results because average endotoxin levels in patients with sepsis are around 300 pg/mL. The encouraging data need further work focusing on the kinetic study of the interaction in order to contribute to biodevices microseparations and endotoxin detection and removal.

Production of Mannosylerythritol lipids (MEL) from vegetable oils: Exploring lipase application on substrate pretreatment

Petar Keković[1*], Nuno Faria[1], Frederico Ferreira[1]

1 iBB – Institute for Bioengineering and Biosciences, Department of Bioengineering, Instituto Superior Técnico, Avenida Rovisco Pais, 1049-001 Lisboa, Portugal

Highlights

- Free Fatty Acids (FFA) and Esters were used as a feed for production of MEL
- All ester-fed cultures, besides butyl esters, performed better than ones fed with oil
  Cultures fed with FFAs produced resulted in higher productivity and yields of MEL

1. Introduction

Mannosylerythritol lipids (MELs) are a group of extracellular glycolipid biosurfactants, known for their tensioactive versatility. High titers of MELs are obtained using vegetable oils as substrates for *M. antarticus*. However, a significant fraction of the bioproduced MEL is lost during downstream due to difficult separation from triglycerides [1]. Lipases are also produced by *M. antarticus* cultures, which break down the triglycerides that the vegetable oil consists of. Considering these two features of *M. antarticus*, three approaches are explored in this work, with the aim to increase MEL production and enable different downstream routes.: feeding the culture with vegetable oil, using oil partially broken down by lipases produced by *M. antarticus,* or transforming the triglycerides into alcohol esters, and adding them as a carbon source.

2. Methods

Cultures of 50 ml in 250 ml flasks were incubated at 27 °C, 250 rpm for 12 days. Glucose (40 g/l) was used as the initial source of carbon, while soybean oil, pretreated soybean oil and fatty acid alcohol esters (20 g/l) were added on day 4 to some flasks, at the start of the MEL production phase, following the previously established protocol for MEL production by using soybean oil [2]. Oil hydrolysis was performed using lipase-rich supernatant collected from cultures at day 7, and, for proof of concept, esterification was performed with commercially available purified CAL-B, with the addition of methanol, ethanol or butanol. The overview of the experimental plan is presented in Figure 1a.

3. Results and discussion

Lipase-rich supernatant (3 U/ml of activity), was mixed with soybean oil, and maintained at different conditions, with a three level variation of parameters, according to a Box-Behnken experimental design. The best performing conditions reached only 39% hydrolysis efficiency. The addition of 0.5% of emulsifiers, Xanthan and MEL, increased FFA concentrations, with the latter achieving 76% hydrolysis efficiency. Coherently, lipase-rich supernatant performed 15% better

than the commercial enzyme alone (39%), indicating possible positive contribution of the present MEL as an emulsifier, or the possitive effect of ions or cofactors on lipases [3].

The results show that *M. antaricus* was able to metabolize esters. Whether the cell directly uses esters as a carbon source , or they are hydrolyzed extracellularly, with the resulting FFA and alcohol being used as carbon sources, remains unknown. Higher MEL production was achieved with methyl and ethyl ester feeds compared to oil. Some negative effects of alcohol presence in early stages of the fermentation were observed for methanol and butanol, which corresponds to data found in literature on their toxicity to lipase activity [4][5]. The results for the approach where vegetable oil is partially hydrolyzed prior to fermentation are very promising, since availability of FFA in earlier stages of the fermentation seems to stimulate MEL production. MEL profiles indicate that the prehydrolysis step effectively reduced the fermentation period, and enabled reaching higher MEL concentrations compared to feeds with untreated oil. (Figure 1b)

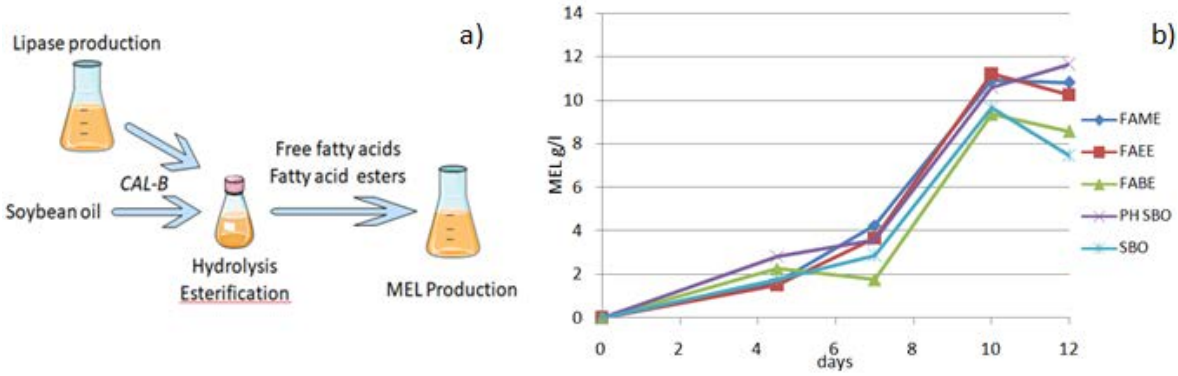

Figure 1. a) Experimental plan overview; b) Preliminary MEL production results. FAME - methyl esters; FAEE - ethyl esters, FABE - butyl esters; SBO - soybean oil; PH SBO - partially hydrolyzed soybean oil.

4. Conclusions

Feeds of prehydrolized and esterified oil increased MEL production efficiency by increasing MEL titres, reducing levels of residual tryglicerides in the broth, with the prospect of shortening the fermentation duration. This approach suggests a more efficient and potentially more sustainable alternative for MEL production when compared with the existing processes.

On the enzymatic oxidation of aniline, *p*-aminodiphenylamine (PADPA) or their mixtures by using an industrial laccase and vesicles as templates

Tomoyuki Fujisaki[1], Keita Kashima[1†], Peter Walde[2]

1 Department of Materials Chemistry and Bioengineering, National Institute of Technology, Oyama College, 771 Nakakuki, Oyama, Tochigi, 323-0806, Japan;

2 Department of Materials, ETH Zurich, Vladimir-Prelog-Weg 5, 8093 Zürich, Switzerland

†Corresponding author: keitakashima@oyama-ct.ac.jp

Highlights

- Aniline and PADPA were enzymatically oxidized with a commercial laccase and O_2
- The reaction products resemble the conductive polyaniline emeraldine salt form, PANI-ES
- The products have good stability for at least 28 days if stored at room temperature

1. Introduction

Polyaniline in its conductive emeraldine salt form (PANI-ES) is characterized by a good dispersibility in water phase, and by good thermal and radiation stability.[1] The enzymatic oxidation of aniline or the aniline dimer, *p*-aminodiphenylamine (PADPA), in the presence of dispersed anionic soft-interfaces in slightly acidic aqueous solution is an environmentally friendly process for obtaining PANI-ES. We previously reported about the enzymatic synthesis of PANI-ES-type products from PADPA oxidized with *Trametes versicolor* laccase (TvL)/O_2 as catalyst in aqueous pH = 3.5 solution at room temperature in the presence of anionic vesicles from sodium bis(2-ethylhexyl) sulfosuccinate (AOT) as reaction templates.[2-3] The focus of this previous work was on fundamental aspects of the reaction. For possible industrial applications, two points are important to consider: (i) the use of an industrial laccase which would decreases the production costs, and (ii) enabling the synthesis of PANI-ES from aniline (instead of PADPA), which is cheaper and chemically more stable than PADPA. In this study, the enzymatic oxidation of aniline, PADPA or their mixtures was investigated in the presence of AOT vesicles by using a laccase which is used in food industry. The formation of PANI-ES-type products (with their characteristic absorption bands around 1000 nm) was analyzed by *in situ* UV/visible absorption measurements.

2. Methods

The enzymatic oxidation of aniline, PADPA, or aniline/PADPA mixtures using laccase (Y120, from Amano Enzyme) was investigated. The concentrations of the laccase and the AOT vesicles were fixed at [laccase] = 0.207 µg/mL, [AOT] = 1.5 mM, in a 10 mL reaction volume. The reaction was carried out in 50 mL Schott glass bottles at pH = 3.5 by using an aqueous phosphate solution (0.1 M NaH_2PO_4 + H_3PO_4). The concentrations of the substrates in each reaction mixture were [aniline] = 2.0 mM, [PADPA] = 1.0 mM, or [aniline] = 0.6 mM + [PADPA] = 0.7 mM, respectively. The reaction mixture was withdrawn and poured into a quartz cuvette (l = 0.1 cm, V = 300 µL) at desired times (t = 1 min, 1 h, 4 h, 24 h, 2 days, 3 days, 4 days, 7 days, 14 days, 21 days, 28 days), and the UV/visible absorption spectrum was measured with a UV mini-1240, from SHIMADZU.

3. Results and discussion

Figure 1 shows the time course of the absorbance at λ = 1000 nm (A_{1000}) in each reaction with either aniline, PADPA, or an aniline/PADPA mixture. In the reaction with aniline only, the value of A_{1000} was clearly very low. In the reaction of [PADPA] = 1.0 mM, a major peak developed at λ ≈ 1000 nm which indicates formation of highly conductive PANI-ES. The value of A_{1000} in the reaction with PADPA reached a maximum value after t = 24 h, and then decreased after 7 days. In the reaction of [aniline] = 0.6 mM + [PADPA] = 0.7 mM, the major peak at λ ≈ 1000 nm appeared with almost the same intensity as in the case of the PADPA] = 1.0 mM system. Interestingly, A_{1000} of the reaction with the aniline/PADPA mixture kept a higher value for 28 days than the reaction with PADPA only. In the reactions with PADPA only and with the aniline/PADPA mixture, PANI-ES-type oxidative products were obtained. Especially, the reaction products obtained from the aniline/PADPA mixture showed good stability in aqueous solution.

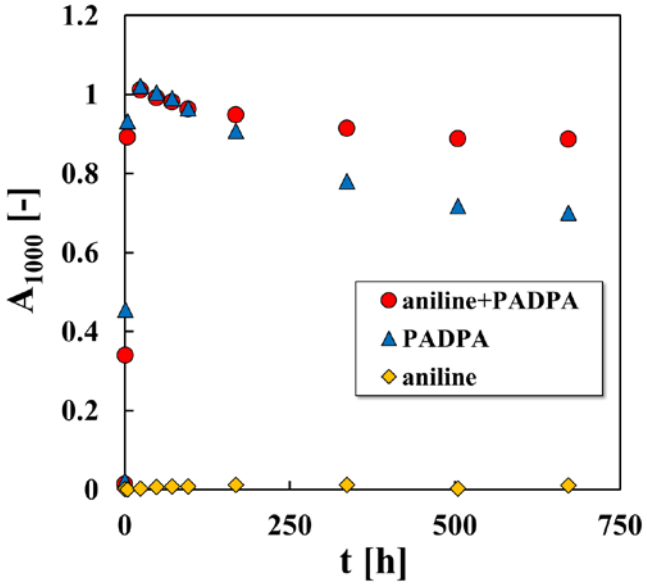

Figure 1. Comparison of the absorbance at λ = 1000 nm (A_{1000}) in three different reaction mixtures, pH = 3.5, [laccase] = 0.207 µg/mL, [AOT] = 1.5 mM. ● [aniline] = 0.6 mM + [PADPA] = 0.7 mM, ▲ [PADPA] = 1.0 mM, ◆ [Aniline] = 2.0 mM.

4. Conclusions

The industrial laccase/O_2-catalyzed oxidation of the investigated aniline/PADPA mixture ([aniline] = 0.6 mM + [PADPA] = 0.7 mM) in the presence of AOT vesicles as templates results in stable conductive PANI-ES-type products. This reaction is promising due to its reduced costs for both, enzyme and substrate, as compared to the previously investigated systems.[2-4]

Highlights

- DexMA/PAA systems were designed for applications in material science and biomedical field
- UV photo-crosslinking and thermal treatment were able to stabilize the systems in water
- FT-IR and DSC analysis showed the presence of chemical interactions between DexMA and PAA

1. Introduction

In the last decades, the use of polysaccharides has undergone a rapid progress in many different areas of material science and engineering including pharmaceuticals, biomedical use, food supplements, and cosmetics. The most widely used polysaccharides as biomaterials are alginate, chitosan, hyaluronan, gellan gum and dextran. Dextran (Dex), a bacterial-derived polysaccharide, consisting essentially of α-1,6 linked D-glucopyranose residues with a low percent of α-1,2-, α-1,3- or α-1,4-linked side chains, has received a great interest for column chromatography application, cell culture technology and drug delivery systems [1]. The elevated hydrophilicity of dextran imparts high resistance to protein adsorption, a fundamental requirement for use in implantable medical devices and drug or protein targeting carriers [2]. Layer-by-layer assembly can be considered a versatile tool for coating of implantable materials based on the use of polyelectrolytes such as polystyrene sulfonate, polyallylamine, chitosan and polyacrylic acid. In this work, the design, preparation and characterization of new materials based on dextran (DexMA) and polyacrylic acid (PAA) was reported in order to obtain a bioartificial material that combines polyelectrolyte properties with high protein surface and anti-fouling characteristics due to polysaccharide moieties.

2. Methods

Dextran derivatized with glycidyl methacrylate (DexMA) was performed according to a literature method [3] and was confirmed by FT-IR analysis. DexMA/PAA systems were prepared by a combination of UV photo-crosslinking and thermal treatment using different DexMA/PAA weight ratio: 100/0, 80/20, 60/40, 40/60, 20/80, 0/100. A morphological (SEM) and physico-chemical characterization (FT-IR, DSC, TGA) was performed on the systems, before and after crosslinking. Swelling and mass loss tests on the samples were also carried out.

3. Results and discussion

SEM images of the DexMA/PAA 60/40 system, before and after crosslinking (Figure 1), show a dense structure for untreated sample and a heterogeneous porosity for crosslinked sample. FT-IR analysis on the same samples (Figure 2) shows a decrease of the band intensity at 1000 cm^{-1}, due to the COC stretching of the pyranose ring, a reduction of bands at 3300 cm^{-1} and 1070 cm^{-1}, both due to hydroxyl groups of dextran, and the appearance of a peak at 1230 cm^{-1}, typical of a C-O ester stretching. These results indicate that the UV photo-crosslinking and thermal treatment lead to the breaking of the pyranose ring and the formation of an ester bond between PAA and DexMA.

DSC analysis, carried out on samples, showed a single glass transition temperature, confirming the presence of chemical interactions between DexMA and PAA.

TGA thermograms show characteristic degradative events of both components, and a mass loss event between 200°C and 300°C that could be ascribed to the breaking of glycosidic bonds caused by thermal treatment.

Stability in water was also tested for all samples. In particular swelling in water, swelling in saturated steam water and mass loss tests were performed. Mass loss tests showed a higher stability in water for DexMA/PAA samples after UV irradiations at 256 nm followed by thermal treatment. Swelling tests confirmed the presence of chemical interactions between the components and the efficacy of crosslinking. Concerning the trend of swelling ratio versus the composition of the DexMA/PAA mixtures, a minimum was observed for the DexMA/PAA 60/40 system.

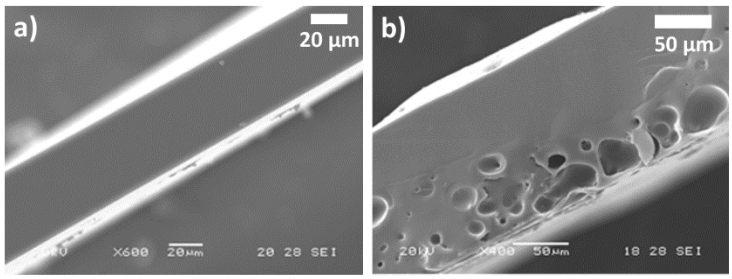

Figure 1. SEM images of untreated DexMA/PAA 60/40 (a) and UV and thermal treated DexMA/PAA 60/40 (b).

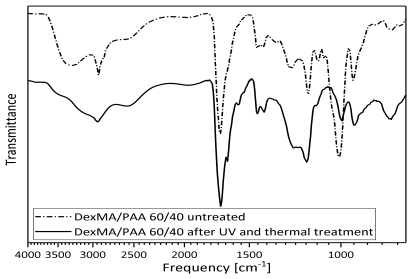

Figure 2. FT-IR of untreated and treated DexMA/PAA 60/40.

4. Conclusions

DexMA/PAA systems were prepared by using an innovative combination of crosslinking treatments thus making these materials attractive for use in many biomedical applications.

- Ethyl acetate production by yeasts was elucidated by discovering the "Eat" enzyme family.
- Eat enzymes are located in yeast mitochondria
- Expression of Eat1 in *E. coli* results in ethyl acetate production
- Costs of ethyl acetate production are expected to be lower than those of bioethanol

1. Introduction

This abstract will show our efforts to develop a process for the production of ethyl acetate.
Ethyl acetate is produced from fossil resources at 3.5 million tonnes at a total value of $3.7 billion in 2014. To reduce CO_2 emissions a biobased process is desired. Yeasts are able to produce high amounts of ethyl acetate from sugars and ethanol. The development of an efficient fermentation process was hampered because the key enzyme was unknown.

2. Methods

The Eat1 enzyme was identified by comparing the transcriptome of *Wickerhamomyces anomalus* under producing and non-producing conditions. A fusion protein of Eat1 and Gfp was made to show by light microscopy in which organelle Eat1 was expressed. The mitochondrial targeting sequence was identified using bioinformatics techniques. Eat1 was expressed in E. coli. Ethyl acetate production was optimized by knocking out byproduct formation, optimizing the expression level, removal of the targeting sequence, and in-situ product removal.

3. Results and discussion

We have identified this elusive enzyme. Eat1 is present in all yeasts known to produce ethyl acetate (figure 1, left). It has three activities: alcohol acetyl transferase converting ethanol and acetyl-CoA into ethyl acetate, esterase and thioesterase activity. The latter two activities have a negative effect on ethyl acetate production but were strongly suppressed when ethanol was present (Figure 1, middle)[1]. We have shown that the enzyme is located in the mitochondria, and we have identified the leader sequence responsible for mitochondrial targeting[2].

Expression of Eat1 in *E. coli* resulted in ethyl acetate production (figure 1, right)[1]. We have optimized anaerobic ethyl acetate production in *E. coli* by deleting LdhA and AckA, responsible for lactate and acetate production, respectively. This increased ethyl acetate production but also gave

rise to the accumulation of pyruvate, indicating the Eat1 activity was insufficient. Eat1 activity was improved by optimizing the induction level and by removing the mitochondrial targeting sequence. This reduced production of pyruvate but enhanced the production of acetate and ethanol. This appeared to be caused by the esterase activity of Eat1, hydrolysing ethyl acetate. By stripping the ethyl acetate from the broth, we decreased the time Eat1 could hydrolyse ethyl acetate, resulting in lower acetate and ethanol production. The final ethyl acetate yield obtained was 0.7 mol/mol, or 70% of the maximum pathway yield[3].

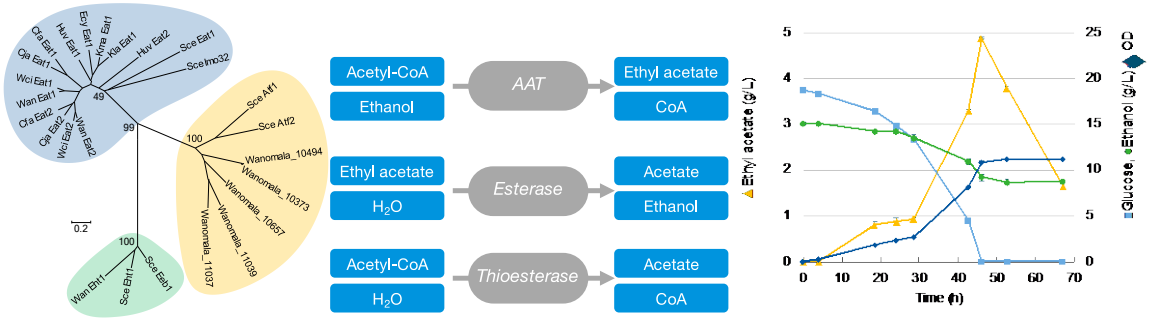

Figure 1. Left. The Eat family is a new alcohol acetyl transferase family, clearly distinct from the Atf and Eeb/Eht families. Middle. Eat1 from *W. anomalus* has three activities. Right. Expression of Eat1 from *W. anomalus* in *E. coli* results in ethyl acetate production.

4. Conclusions

By multilevel engineering – bioprospecting the key enzyme, optimizing its expressing, increasing its activity by protein engineering, knocking out byproduct formation and by applying in situ product recovery - we were able to efficiently produce ethyl acetate in *E. coli*. On paper, the production costs of ethyl acetate are lower than those of bioethanol.

Highlights

- Streptomycetes from the Atacama Desert are a good source of bioactive compounds.
- A genome-scale model for *Streptomyces* C34 was developed to study its metabolism.
- This genome-scale model is also used to optimize production.
- Microorganisms from the Atacama Desert inhibit important fungal pathogens.

1. Introduction

Today there is a tremendous need for new antibiotics and novel cytotoxic compounds against cancer cells to develop efficient alternative treatment to chemotherapy. We have searched for highly active Streptomyces strains in the driest desert in the world, the Atacama Desert in northern Chile. We have identified several new strains and found many novel antibiotics and anticancer agents ("Chaxamycins", "Chaxalactins" and "Atacamycins") from *Streptomyces* C34 and C38 [1-3]. With the high-quality genome sequence of *Streptomyces* C34 we identified the biosynthetic gene cluster of Chaxamycins and Chaxalactins showing the genomic potential of this strain to produce bioactive compounds [4,5]. Our aim is to improve the production of these novel compounds through metabolic engineering and to find new interesting bioactive specialised metabolites.

2. Methodology

To find metabolic engineering targets for increasing the production of Chaxamycins and Chaxalactins, we developed a genome-scale model of *Streptomyces leeuwenhoekii* C34 following standard methodology and we performed flux balance analyses. The selected overexpression targets were cloned under a constitutive strong promoter in an integrative plasmid.

The culture collection from the Atacama Desert was subjected to standard bioassays to find bioactive compounds against important fungal pathogens. The selected strains were subjected to chemical fractionation and HPLC-MS/MS analysis.

3. Results and discussion

The genome-scale model, *i*VR1007, has 1726 reactions including 239 for transport, reactions for secondary metabolite biosynthesis, 1463 metabolites and 1007 genes. The model was validated with experimental data of growth on 89, 54 and 23 sole carbon, nitrogen and phosphorous sources, respectively, and showed a high level of accuracy (82.5 %). We have included reactions for desferrioxamines, ectoine, Chaxamycins, Chaxalactins and for the hybrid polyketides/non-ribosomal peptide synthesized by the halogenase cluster. A detailed Metabolic Flux Balance Analysis was carried out in order to study the metabolic pathways of Chaxalactins, Chaxamycins and the product of the halogenase cluster, by recognizing overexpression targets and useful knock-out sites to increase production of these secondary metabolites [6]. Among the metabolic engineering targets found we have successfully overexpressed some of them and found that they indeed improve the production of the antibiotic compounds.

In parallel, we identified several strains belonging to the *Streptomyces* genera, that have antibiotic activity against *Botrytis cinerea, Fusarium oxysporum,* among other fungus of agroindustry importance. The strains that showed higher bioactivities were subjected to HPLC-MS/MS analysis. We are identifying novel compounds that could be responsible for the observed bioactivity.

Our recent results concerning these two topics showing the genomic potential for producing bioactive compounds of the microorganisms of the Atacama Desert and how to improve their compound production will be presented and discussed in this presentation.

4. Conclusions

The development of a genome-scale model for *S. leeuwenhoekii* C34 was useful for the identification of metabolic engineering targets that enhance the production of Chaxamycins and Chaxalactins.

The *Streptomyces* strains isolated from the Atacama Desert have antibiotic activity against important fungal pathogens.

Aromatics are amongst the most important bulk feedstocks for the chemical industry, however, no viable bioprocess exists today and production is still dependent on petro-chemistry. In order to develop p-hydroxybenzoic acid (PHBA) and p-amino benzoic acid (PABA) production in *Saccharomyces cerevisiae* we employed *in-silico* analysis for the prediction of suitable targets for strain improvement of the shikimate pathway [1]. A key reaction in metabolism was the knockout of pyruvate kinase, which is known to be non-viable on glucose. In addition, the knockout of competing pathways led to very poor growth and auxotrophic strains. To address these problems we have engineered dynamic regulation using a synthetic quorum sensing circuit in *Saccharomyces cerevisiae* [2]. The circuit activates gene expression at a high population density, and is linked with an RNA interference (RNAi) module to enable targeted gene silencing. The circuit was used to control flux through the shikimate pathway for the production of PHBA. Following this, strain and media optimization lead to production in the g/L range [3,4]. This is a starting point for future process development.

The quest for a cell factory for the production of recombinant proteins: *Pichia pastoris* Vs *Yarrowia lipolytica*.

Marie Vandermies, Chrispian Theron, Patrick Fickers*

Microbial Processes and Interactions, TERRA Teaching and Research Centre, University of Liège - Gembloux AgroBio Tech, Av de la Faculté, 2B. B-5030 Gembloux, Belgium

**Corresponding author: pfickers@uliege.be*

Highlights

- *P. pastoris* and *Y. lipolytica* were compared for the production of recombinant proteins
- Calb lipase was used as a case report
- Protein productivity was higher in *Y. lipolytica* despite a lower gene expression level
- The lower productivity in *P. pastoris* is due to proteasome degradation of CalB

1. Introduction

The production at industrial scale of recombinant proteins (rProt) is of increasing economic importance. Among the different microbial chassis that has been developed for that purpose, yeasts are regarded as the preferred option for the production of recombinant enzymes and therapeutic proteins. The main advantage of yeasts over bacterial systems such as *Escherichia coli* relies on the possibility to obtain posttranslational modified proteins in the culture supernatant at grams per liter. Historically, *Saccharomyces cerevisiae* has been used as the reference eukaryotic chassis, however it suffers several drawbacks such as low protein productivity, overflow metabolism or hyperglycosylation phenomenon. Moreover, it is less metabolically adapted to catabolize raw carbon and nitrogen sources that are nowadays increasingly considered as nutrients in bioprocesses. The non-conventional yeasts *Pichia pastoris* and *Yarrowia lipolytica* are considered as realistic alternatives to *S. cerevisiae* for rProt synthesis. They both combine advantages of growing at high cell density, to produce and secrete rProt at high yield and to have low nutritional requirements, allowing thus to grow them on raw materials or industrial byproducts. Although these two yeasts are well-established cell factories for rProt synthesis in industry, no direct comparison of their performances has been reported so far. Here, we report such a comparison using the CalB lipase from *Candida antartica* as a model protein.

2. Methods

The codon optimized gene sequence of CalB was cloned under the control of strong inducible promoters. For *Y. lipolytica*, the hybrid promoter pEYKA3B inducible by erythritol was used in combination with a EYK1*ko* recipient strain that is unable to metabolize erythritol. For *P. pastoris*, the widely used promoter pAOX1 was used in combination with a MutS recipient strain (methanol low consumption). The resulting strains were then grown in bioreactors in optimized conditions

and parameters such as cell growth, gene expression, carbon uptake rates and extracellular lipase activity were monitored over time.

3. Results and discussion

Y. lipolytica performances were by far superior in terms of cell growth rate and rProt synthesis. Compared to *P. pastoris,* it grew faster, at higher cell density and cells used carbon source more efficiently. The maximal lipase activities were equal respectively to 5540 and 1066 U/mgDCW for *Y. lipolytica* and *P. pastoris*, respectively, representing thus more than a 5-fold increase. Surprisingly, *P. pastoris* showed a significantly higher level (5-fold) of CalB gene expression as demonstrated by qRT-PCR. Several hypotheses has been formulated and tested to explain the reasons behind the observed differences. The lower protein productivity in *P. pastoris* was found related to the intracellular protein degradation by the proteasome complex.

4. Conclusions

From this study, *Y. lipolytica* appears a more efficient cell factory that is in addition not related to the utilization of flammable methanol as inducer.

The Characterization of the Central Carbon Metabolism of Arthrospira Platensis Brings Insights to Its Original Polysaccharides (PS) Composition.

M. Phélippé, G. Thouand, G. Cogne, O.Gonçalves*

GEPEA – UMR CNRS 6144 – U. Nantes, 31 bvd des université – 44600 SAINT NAZAIRE, FRANCE

Highlights

- Primary metabolite profiling using routine combined metabolomics approach
- The combined metabolomics approach consisted in using GC-MS and MFA
- *Arthrospira platensis* was cultivated in photobioreactor under various light conditions
- *Arthrospira platensis* EPS and PS fractions were modulated according to the incident light

1. Introduction

Micro-algae are photosynthetic micro-organisms that are able to produce at reduced cost high value products. To control this potential, the understanding of the photosynthetic and energetic metabolism of these micro-organisms at cellular and molecular level is often mandatory. Among the latest available approaches, the characterization and the analysis of the metabolic fluxes distribution is known to contribute accurately to a better understanding of the mobilized metabolic pathways and of the micro-organism behavior in response to environmental changes. For that purpose, metabolomics plays a key role since it enables to characterize these fluxes through high-throughput profiling of tremendous number of metabolites. Among the most cultivated photosynthetic micro-organisms, *Arthrospira platensis* is a cyanobacteria known to produce exopolysaccharides (EPS) and more particularly under light stress. Even though it is worldwide cultivated, only few major articles ([1],[2]) focused on the characterization of its central metabolism since Cogne [3]. Therefore, there is a lack of knowledge to understand the effect of environmental conditions on its energetic regulation metabolism. Knowing these mechanisms, would finally enable more efficient production of the specific PS or EPS.

In this study, the characterization of the carbon central metabolism of Arthrospira platensis cultivated in photobioreactor under growth with different light conditions and regarding EPS and PS production conditions was performed. For that purpose an original combined metabolomics approach was developed. It consisted in a profiling approach [4] allowing to quantifiy in routine the metabolites of the central carbon metabolism of the *Spirulina,* that was combined to a MFA calculation method used to estimate the dynamic of the metabolism thru the estimation of the biochemical reaction rates.

2. Methods

The central carbon metabolism of the *Spirulina* was characterized using the following GCMS analaysis workflow. It was combined to MFA calculation approach constrained by an accurate biochemical profiling approach. The results (absolute quantification and simulated reaction rate) were mapped on a extended central carbon metabolism map in order to check the influence of high light conditions on the PS and EPS fate and composition.

3. Results and discussion

The approach allowed assessing a better understanding of *Spirulina's* behavior facing high light environmental changes impacting more particularly its EPS and PS composition. Indeed, in the tested cultivation conditions (increasing light) it was possible to increase the amount of EPS, but also to modify its composition. The main observed differences concerned the amount of the uronic acids that was found to be drastically inferior to what was previously described [3]. The GCMS profiling of the carbon central metabolism extended to the elementary bricks constitutive of the protein, lipids and polysaccharides suggested more over that an alternative pathways for the uronic acid biosynthesis could be used. The Metabolic Flux Analysis data reinforced the observed hypothesis found using the low resolution metabolomic approach.

4. Conclusions

Finally in this study we were able to demonstrate that using routine low resolution metabolomics profiling approach, it was possible to bring insight to carbon fate regarding more particularly the PS and EPS fractions. Such a routine approach should be used in the next future to bring more informations of the *Spirulina*'s PS and EPS under differents cultivations conditions.

Highlights

- A new method to refine the results of Flux Balance Analysis (FBA) is presented.
- Predictions from Carbon-constrained FBA (ccFBA) are in good agreement with ^{13}C data
- ccFBA can improve our ability to predict reaction directionalities compared to FBA.

1. Introduction

Constraint based modelling methods, such as Flux Balance Analysis (FBA), have been extensively used to decipher complex, information rich -omics datasets in order to elicit system-wide behavioral patterns of cellular metabolism. FBA has been successfully used to gain insight in a wide range of applications, such as range of substrate utilization, product yields and to design metabolic engineering strategies to improve bioprocess performance [1]. A well-known challenge associated with large genome-scale metabolic networks (GEMs) is that they result in underdetermined problem formulations. Consequently, rather than single-point solutions, FBA and related methods examine ranges of reaction flux values that are consistent with the studied physiological conditions. The wider the reported flux ranges, the higher the uncertainty in the determination of basic reaction properties, limiting interpretability of and confidence in the results.

2. Methods

Herein we propose a new, computationally efficient approach that refines flux range predictions by introducing an additional set of constraints based on the elemental balance of carbon. Carbon constrained FBA (ccFBA) attempts to refine the feasible solution space, by constraining the permissible flux through intracellular reactions based on the amount of carbon taken up by the cell under the studied physiological conditions While at its core, ccFBA is a set of constraints based on the elemental balance of carbon, several aspects of cellular metabolism need to be taken into account.

3. Results and discussion

We compared carbon constrained FBA (ccFBA) with standard FBA using the latest CHO genome scale metabolic model (iCHO1766) [2] and were able to achieve significantly improved predictions for intracellular reactions. We showed that permissible flux ranges estimated by ccFVA contained the experimentally measured intracellular fluxes in the majority of cases and lead to quantitative predictions in the same order of magnitude as ^{13}C measurements. This can be attributed to ccFVA's ability to mitigate the impact of internal loops or futile cycles by constraining the amount of flux able to pass through any single reaction based on the amount of carbon entering the cell. Finally, when used in combination with random sampling, ccFVA substantially improved our ability to predict reaction directionalities compared to normal FVA.

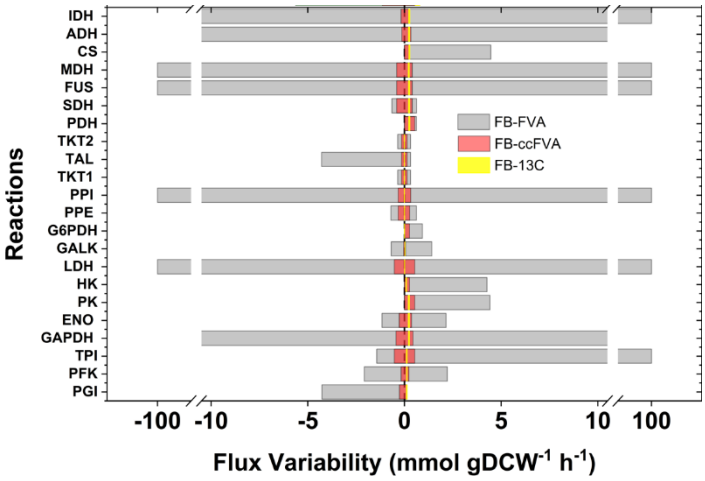

Figure 1. Comparison between FVA (grey bars), ccFVA (pink bars) and intracellular flux measurements (yellow bars) for central carbon metabolism (Glycolysis, TCA, PPP). Data from Templeton et al., 2017 [3]

4. Conclusions

ccFBA is an easy to use and computationally efficient method for reducing flux variability in and improving the accuracy of constrained-based metabolic networks. It can be used as a stand-alone method or as a complimentary tool to most other methods currently available for stoichiometric metabolic network analysis.

Light-induced promoter drives efficient over-expression of alternative nitrogenases in genetically modified *Rhodopseudomonas palustris*

Jan-Pierre du Toit[1], Robert Pott[1] *

1 Department of Process Engineering, Stellenbosch University, South Africa

**Corresponding author:* rpott@sun.ac.za

Highlights

- Volumetric biohydrogen production rate is limited by poor Mo nitrogenase enzyme activity
- V and Fe nitrogenase over-expression by insertion of efficient promoters to override control
- *PucBa* promoter shows promise for high-level, light-induced heterologous gene expression
- Potential of *R. palustris* as photobiological chassis organism is further advanced.

1. Introduction

Biohydrogen has long shown great promise as a clean energy source, produced from organic wastes by metabolically versatile anoxygenic photosynthetic bacteria such as *Rhodopseudomonas palustris*. Despite decades of investigation, feasibility of this potential bio-economy technology at large-scale remains limited by low volumetric hydrogen production rates [1].

The molybdenum (Mo) nitrogenase enzyme, the activity of which yields hydrogen as an obligate by-product, is driven by energy in the form of ATP derived from photosynthesis and electrons from organic substrates according to:

$$N_2 + 8H^+ + 8e^- + 16\ ATP \rightarrow 2NH_3 + H_2 + 16\ ADP$$

This complex, energetically expensive reaction results in a slow catalytic turnover, likely resulting in a bottleneck in the hydrogen production pathway [2]. Previous work on the temperature dependence of H_2 production supports this hypothesis: an increase in production rate was observed up to 40°C under equivalent light intensity, indicating availability of surplus reducing power to drive the reaction under thermodynamic conditions favouring higher enzyme catalysis rates. The energetic cost of nitrogenase activity means expression is tightly-repressed by availability of NH_3, limiting the potential for hydrogen production from organic waste waters containing a ubiquitous nitrogenous substrate [3].

R. palustris possesses two alternative nitrogenases with iron (Fe) and vanadium (V) cofactors, each evolving 3 and 9 H_2 per N_2 reduced respectively [4]. A prime target for addressing poor nitrogenase activity is thus presented, in overexpressing these isozymes via genetic modification.

Here we present the genetic modification of *R. palustris* by insertion of efficient promoters upstream of native nitrogenase gene operons in order to circumvent innate control mechanisms, and the characterisation of gene expression in the resultant strains.

2. Methods

Rhodopseudomonas palustris putative promoter sequences from LH2 protein (*pucBa*: light & anaerobic induced) or citrate synthase (*cisY*: constitutive expression) were inserted upstream of all 3 native nitrogenase gene operons by homologous recombination methods. Nitrogenase gene expression in the six resultant unmarked strains was quantified by RT-qPCR.

3. Results and discussion

Six strains of nitrogenase-overexpressing R. palustris were generated using an optimised protocol. Detailed quantification of transcript levels by RT-qPCR showed efficient upregulation of all genes in nitrogenase operons driven by puc promoter, between 8 to 12 Ct values higher than wild-type (up to ~4000-fold overexpression). Strains under control of cit promoter showed variable success with good upregulation of Vnf but not Anf, suggesting locus-dependent activity.

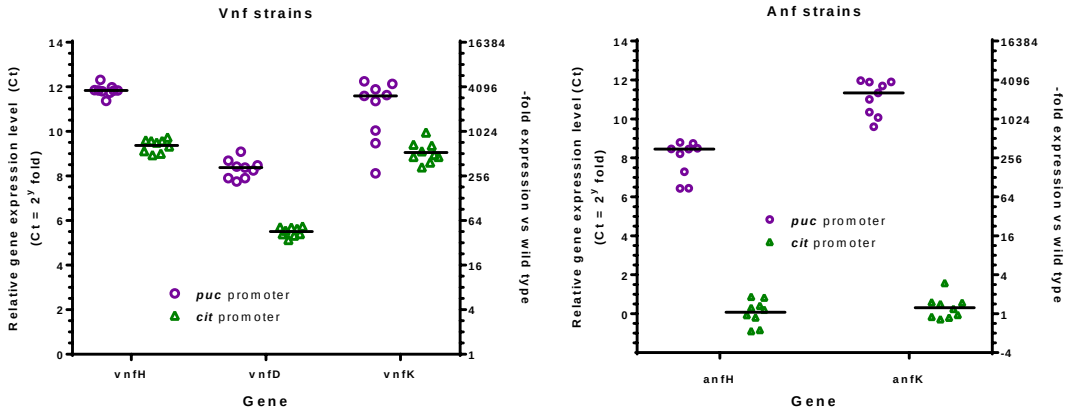

Figure 1. Quantification of gene expression from *R. palustris* vanadium (Vnf) and iron (Anf) nitrogenase operons

4. Conclusions

We present an efficient method for generating strains of *R. palustris* overexpressing complex native, multi subunit genes with a potential for heterologous gene expression. The *pucBa* promoter results in robust, light-induced gene expression useful for bioprocesses which exert high metabolic burden potentially compromising cell viability in absence of photosynthesis-derived energy. The overexpression of alternative nitrogenases will be confirmed by biohydrogen production studies as a direct *in vivo* measure of enzyme activity. In addition to advancing biohydrogen feasibility, the prospect of *R. palustris* as a biotechnological chassis organism is further developed.

Textile-Immobilized (Bio-) Catalysts.

Klaus Opwis[1], Katharina Courth[1], Thomas Mayer-Gall[1], Jochen S. Gutmann[1]

[1] *Deutsches Textilforschungszentrum Nord-West gGmbH, Adlerstr. 1, 47798 Krefeld, Germany*

**Corresponding author: opwis@dtnw.de*

Highlights

- Textiles were identified as new and innovative catalyst carrier materials.
- Various permanent immobilization strategies were developed successfully.
- Immobilization products are reusable at least 30 times.
- Results on textile-fixed organic catalysts promise huge economic success.

1. Introduction

The efficiency of most chemical processes is based on the use of catalysts. For many applications the catalysts are embedded in a solid matrix, which allows the recycling of the catalysts and the separation of the products. Such immobilizations offer the multiple or even permanent use. Common carrier materials are from polymeric or mineral nature. But their production and the charging with the catalysts are often complex and high-prized. In contrast, textile carrier materials made of cotton, polyamide or polyester are considerably inexpensive. The flexible construction of fabrics enables reactor constructions of arbitrary geometry and a quick removal of the catalyst without any residues after the reaction. Moreover, their open structure guarantees an optimal substrate turnover and the active surface is easily adjustable by the fiber diameter.

2. Methods

For the catalysts immobilization various fiber-specific wet chemical and photochemical processes were used [1-5]. The methods are summarized schematically in Figure 1. The (bio-) catalytic activity of the immobilized enzymes and organic catalysts were determined by typical enzymatic assays and model reactions.

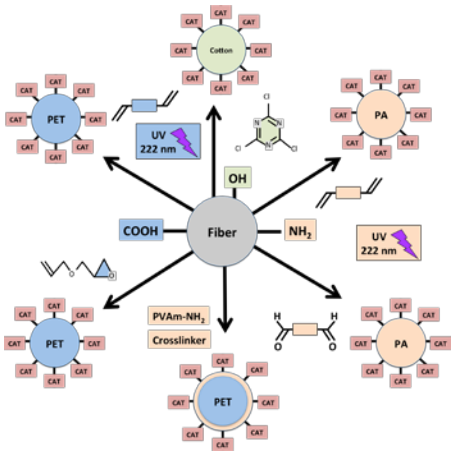

Figure 1. Catalase immobilized on Polyamide Fibers.

3. Results and discussion

We report various successful wet-chemical and photochemical techniques for the immobilization of different types of catalysts (enzymes, organic catalysts) on textile carrier materials. Figure 1 shows a SEM of textile-fixed catalase.

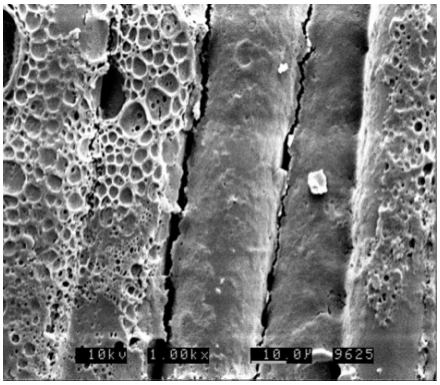

Figure 1. Catalase immobilized on Polyamide Fibers.

Beyond, we provide information on the (bio-) catalytic activity of the immobilized catalysts in repeated use, and explain various relevant applications, e.g., the use of immobilized peroxidases in the bleaching of whey from dairy processes (food industry) and the use of textile-fixed cinchona alkaloids for asymmetric syntheses of pharmaceutical products. For example, the desymmetrization of cyclic anhydrides runs for more than 250 cycles without a significant loss of its catalytic activity and an impressive enantiomeric ratio of 97:3.

4. Conclusions

In summary, we have identified low-cost textiles as alternative carrier materials for catalysts. With a low preparative and economic expense fabrics with a high load, a high catalytic activity and excellent permanence against desorption can be produced. Therefore, our textile-fixed catalysts represent a totally new tool for heterogeneous catalysis with widespread potential applications in pharmaceutics, chemistry and eco-friendly white biotechnology.

**Corresponding author: jochen.buechs@avt.rwth-aachen.de*

Highlights

- Prediction of residual substrate concentration without offline sampling
- Determination of the pectinolytic activity of *U. maydis* on polygalacturonic acid
- Mixed cultures increase metabolization rate of complex substrates

1. Introduction

The quantification of residual substrate is a major challenge during the microbial conversion of industrial organic waste streams. The pectin fraction of biomasses like sugar beet pulp is robust to acid hydrolysis. Enzymatic hydrolysis during microbial fermentations could thus help to convert complex substrates into fermentable sugars. Galacturonic acid - the main monomeric sugar in pectin - is an unusual carbon source during microbial fermentations. *Ustilago maydis* is well known as expression host for carbon activating enzymes (CAZymes) [1]. It is able to convert galacturonic acid [2]. Therefore, it was chosen as production host for polygalacturonases of intrinsic and heterologous origin.

2. Methods

U. maydis was cultivated in **R**espiration **A**ctivity **MO**nitoring **S**ystem (RAMOS) shake flasks for the online determination of oxygen transfer rate (OTR), carbon dioxide transfer rate (CTR) and respiratory quotient (RQ). The correlation of the consumed overall oxygen with the consumed substrate was demonstrated previously [2]. Production and secretion of endo- and exo-polygalacturonase in different strains was achieved by promoter exchange in the *U. maydis* genome or introduction of heterologous genes. The generated strains were screened for their potential to metabolize polygalacturonic acid, pectin or sugar beet pulp with or without addition of conventional enzyme cocktails.

3. Results and discussion

RAMOS cultivations demonstrated the metabolic activity of an *U. maydis* strain expressing a heterologous exo-polygalacturonase on polygalacturonic acid [2]. However, growth of the culture was limited to the enzymatic activity in the culture supernatant. A screening of three different

U. maydis strains expressing endo-polygalacturonases of intrinsic, bacterial or eukaryotic origin, respectively, was conducted in mixed cultivation with the exo-polygalacturonase expressing strain. Online monitoring of the metabolic activity revealed that the endo-polygalacturonase of eukaryotic origin showed the highest activity on polygalacturonic acid.

This mixed culture was subsequently cultivated on more complex substrates like pectin or sugar beet pulp. The limited metabolic activity demonstrated that additional pectinases are required for efficient conversion of those substrates. As proof of principle, the metabolic activity of *U. maydis* mixed cultures on pectin and sugar beet pulp was increased by addition of conventional enzyme cocktails. Finally, the potential of *U. maydis* to convert the main pectin sugars was demonstrated by cultivation in a minimal medium containing six different carbon sources.

4. Conclusions

A detailed overview of the respiration activity of *U. maydis* during growth on pectic substrates of different complexity was attained. The previously developed methodology for online determination of the residual substrate concentration was applied on a screening of mixed cultures expressing different endo-polygalacturonases. Limitations in the enzyme expression rate were overcome by addition of conventional enzyme cocktails demonstrating the capability of *U. maydis* to convert the main sugars from pectin.

Improving product specificity of whole-cell alkane oxidation in non-conventional media: A multivariate analysis approach

Frank Baganz[1]*, Johannes F Kolmar[1], Oliver Thum[2]

1 Advanced Centre for Biochemical Engineering, Department of Biochemical Engineering, University College London, Gower Street, London WC1E 6BT, United Kingdom; 2 Evonik Creavis GmbH, Paul-Baumann-Straße 1, 45772 Marl, Germany

Highlights

- Polarity of co-solvents determines product specificity.
- Accumulation of alcohol over acid using more polar solvents.
- PLS model showed defining factors are solubility parameters

1. Introduction

Two-liquid phase reaction media have long been used in bioconversions to supply or remove hydrophobic organic reaction substrates and products to reduce inhibitory and toxic effects on biocatalysts [1]. In case of the terminal oxyfunctionalisation of linear alkanes by the AlkBGT monooxygenase the excess alkane substrate is often used as a second phase to extract the alcohol, aldehyde and acid products [2]. However, the selection of other carrier phases or surfactants is complex due to the large amount of parameters that are involved, such as: biocompatibility, substrate bioavailability and product extraction selectivity.

This study investigates co-solvents of different polarities and structures as secondary solvents for the whole-cell alkane bio-oxidation by AlkBGT. Initially, the impact of six co-solvents at two concentrations is studied. Particular focus is on the overall product yield and specificity of the bio-oxidation of four linear alkane substrates. In order to efficiently screen this wide range of experimental conditions, a high-throughput microwell platform specifically customised for non-conventional media is used [3]. In a second step experimental data is combined with estimated physicochemical properties of the co-solvents in a multivariate Partial least squares projections to latent structures (PLS) regression analysis. This allows the identification of key properties of co-solvents that specifically affect the AlkBGT reaction in terms of product specificity and yields.

2. Methods

Materials and methods for whole cell bioconversion in customized microwell plates and analysis of the reaction products by gas chromatography has been described in detail in Kolmar et al 2018 [3]. For data analysis physicochemical properties i.e. Hansen and logP parameters were estimated for co-solvents and reaction substrate and products using COMSOquick software. PLS regression analysis was performed (SIMCA 13.0.3, Umetrics) for analysing multiple variables in one model.

3. Results and discussion

Partial least square regression showed that the defining factors for product specificity are the solubility properties of reaction substrate and product in the co-solvent, as measured by Hansen solubility parameters. Thus the polarity of co-solvents determines the accumulation of either alcohol or acid products. Whereas usually the acid product accumulates during the reaction, by choosing a more polar co-solvent the 1-alcohol product can be accumulated. Especially with Tergitol as co-solvent, a 3.2 fold improvement in 1-octanol yield to 2.4 g l^{-1} was achieved relative to the control reaction without co-solvents (Figure 1).

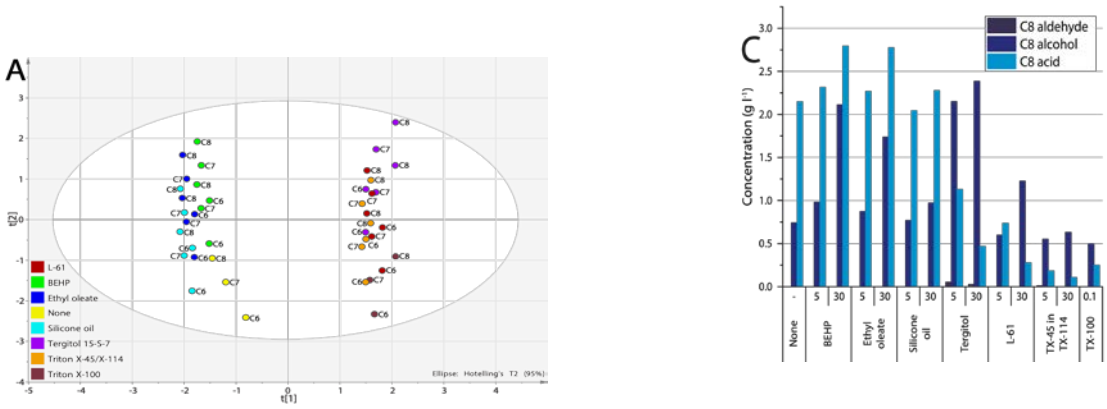

Figure 1. PLS model M2 score scatter plot of response data showing X-scores (t) of the first component along the x-axis and X-scores of the second along the y-axis (A) Co-solvent screening with octane substrate after 24h at 30°C and 250rpm, at varying co-solvent percentages in substrate indicated below x-axis (C).

4. Conclusions

The application of co-solvents is a promising strategy to influence whole-cell alkane oxidations. Further work needs to investigate efficient downstream processing options for the most promising candidates to fully leverage their advantages.

Increasing plasmid copy number of pTRKH3 in *Lactococcus lactis* for biopharmaceutical-grade pDNA production

Sofia Duarte[1], Maria Martins[1], Sílvia Andrade[1], Duarte Prazeres[1,2] and Gabriel Monteiro[1,2*]

1 IBB - Institute for Bioengineering and Biosciences, Instituto Superior Técnico, Universidade de Lisboa, Av. Rovisco Pais, 1049-001 Lisboa, Portugal; 2 Department of Bioengineering, Instituto Superior Técnico, Universidade de Lisboa, Av. Rovisco Pais, 1049-001 Lisboa, Portugal
**Corresponding author: gabmonteiro@tecnico.ulisboa.pt*

Highlights

- pTRKH3-b reached 215 copies in *L. lactis*, a 3.5-fold increase from the wild-type.
- pTRKH3-b had one additional RBS sequence and two additional start codons.
- pTRKH3-b encodes a mRNA secondary structure with the most negative ΔG value.
- pTRKH3-b showed an intermediate amount of transcriptional repressors.

1. Introduction

Pharmaceutical-grade plasmid DNA (pDNA) production in high quantities and in a cost-effective manner is a key point for several biotechnological and pharmaceutical applications, such as the production of DNA vaccines[1] and recombinant proteins and also for the use of food-grade bacteria in live mucosal vaccination.

Traditionally, pDNA is produced in *Escherichia coli*, but the use of this host shows a major drawback because lipopolysaccharides (LPS) may co-purify with pDNA, which raises several safety concerns and increase the manufacture cost[2].

Lactic acid bacteria (LAB), particularly *Lactococcus lactis* are a safer alternative host for pDNA manufacturing since they are naturally LPS-free and have a food-grade and Generally Recognized As Safe status[3]. In order to establish a cost effective *L. lactis*-based pDNA manufacturing platform it is imperative to engineer new high-copy number plasmids, since the highest copy number reported for the commonly used pAMβ1 replicon is around 100 copies, which is much lower than the 500-700 copies reported for *E. coli* pUC vectors[4].

2. Methods

In order to achieve different plasmid copy number (PCNs) in *L. lactis* LMG19460 cells, the RBS sequence of the *repDE* promoter of the pAMβ1 replication origin of the plasmid pTRKH3 was modified by site-directed mutagenesis.

L. lactis LMG19460 cells harbouring the non-modified pTRKH3 and the plasmids with the designed mutations were grown under previously optimized conditions. The PCN per cell was determined by real-time quantitative PCR and the data was analysed using a relative quantification method[5]. The translation initiation rates and consequently the predicted protein expression levels of each designed RBS sequences were evaluated using the RBS Calculator (https://salislab.net/software/, Salis Lab, Penn State University)[6,7]. The mRNA of the *repD* gene, along with the mRNA of its transcriptional repressors (*copF* and *CT-RNA*), were quantified by real-time qPCR, using the same method described above.

3. Results and discussion

The specific growth rates of cells containing the modified plasmids were not significantly ($p<0.05$) affected, suggesting that the modifications in the *repDE* RBS sequence of pTRKH3 do not influence negatively the overall cell metabolism.

With the exception of pTRKH3-a and pTRKH3-e, the average PCN of the modified plasmids at 10.5h of growth (i.e. late exponential/early stationary phase) were statistically higher ($p<0.05$ for pTRKH3-c and $p<0.01$ for pTRKH3-b, pTRKH3-d and pTRKH3-f) than the PCN obtained for the wild-type pTRKH3. The highest average PCN value was obtained for pTRKH3-b (215±38), representing a 3.5 fold increase over the wild-type plasmid (62±5) and much higher than the maximum of ~100 copies obtained for the pAMβ1 replicon in previous studies.

The pTRKH3-b plasmid has neither the most similar RBS to the 16S rRNA sequence nor the strongest RBS predicted by the Anderson library, but instead it was detected an unexpected 77 bp insertion, which led to the creation of an additional RBS sequence and two additional relevant start codons. Without that insertion, the mutant lost the ability to replicate with such a high PCN.

The *in silico* mRNA secondary structures analysis, using RNA folding software tools, predicted the pTRKH3-b mutant as the one having the most negative ΔG value, when compared with the remaining mutants and the parental plasmid, increasing the likelihood that the ribosome will bind to the mRNA and initiate translation of the replication initiation protein, leading ultimately to an increase in the PCN.

A principal component analysis performed with the mRNA quantification results showed that pTRKH3-b had an intermediate amount of CopF and CT-RNA repressors, which seems to allow the perfect balance between transcription initiation and its repression.

4. Conclusions

pTRKH3-b is a very promising high copy number shuttle plasmid that will contribute to bring LAB to the same level as *E. coli* as pDNA producers, with the additional advantage of being endotoxin free, which turns the process more profitable.

The main possible applications for this new plasmid is to use *L. lactis* as efficient producers of pharmaceutical-grade DNA vaccines and recombinant proteins, and as live mucosal vaccination vectors.

Recently, an effort is being made in our research group in order to engineer knockout *L. lactis* strains that could improve even more the quality and quantity of the pDNA produced.

Coarse Grained Modeling of Ribosome Availability In *E. Coli.*

Ayse Koruyucu[1], Andreas Kremling[1*]

[1] *Systems biotechnology, Technical University of Munich, Garching b München*

**Corresponding author: a.kremling@tum.de*

Highlights

- Kinetic model to describe ribosome abundance for a broad range of growth rates
- Integration of length distribution of individual protein as basis for the determination of active ribosomes
- Estimation of kinetic parameters for protein synthesis in dependence of free available ribosomes

1. Introduction

The set-up of mathematical models is still a challenging task in systems biology. Although experimental data from "omics"-technologies are frequently available, the number of unknown parameters which must be estimated is still high. Therefore, in systems biology, the development of one model type, so called coarse-grained models which have only a minor number of parameters, has attracted attention in last years. This is mainly based on the observation that the relationship between large proteome fractions linearly correlate with the growth rate and allows researchers to set up and validate simple, empirical mathematical models to describe these relationships. In this way, general design principles of cellular resource allocation can be postulated.

2. Methods

A pioneering role plays the group of Terence Hwa, California, U.S.A. which developed a holistic framework for the description of cellular bio-chemical reaction networks [1]. Although simple, these models are used to make predictions for different experimental conditions like additional load in form of foreign protein expression and altered kinetic parameters, for example, for different values of the translation velocity. A general drawback of empirical models is, that they are not based on equations that guarantee mass conservation; this is typically realized by setting up a mass balance equation and deducing equations for intracellular concentrations (typically, units like mol/g dry weight or mol/ l cell are used for components of the network. Kinetic expressions for synthesis and degradation are based on the state variables of the model and therefore contain "lumped" information. In coarse-grained models, the number of state variables is low (smaller than 5) and (in general) they are analytically solvable for quasi steady state: if the dynamic of the system is not in the focus, a set of algebraic equations results from setting time derivatives to zero. Finally, the solution space is analyzed by a variation, for example, of the growth rate and calculation of the steady state values of the state variables.

In the presented study, we focus on the synthesis of the overall proteome of the cell taking into account the availability of ribosomes and neglecting the pure metabolic substrate flux in form of

amino acids. The model takes into account geometric parameters like the length distribution of individual proteins, kinetic parameters for transcription/ translation, and the abundance distribution of proteins measured under different conditions.

3. Results and discussion

For the total protein *P* in the cell, a general differential equation in the form $\dot{P} = r_{syn} - \mu P$ with the total rate of protein synthesis $r_{syn}(n_{Rf})$ and the specific growth rate μ is used. The rate of synthesis depends on the free available ribosomes n_{Rf} in the cell. To count the active ribosome n_{Ra} for a distinct growth rate, we estimate the number of active RNA polymerases and, depending on the position of the RNA polymerase on the DNA strand, the number of ribosomes currently translating the mRNA. For a single transcription unit *j* one get according to [2]: $n_{Rj} = m_j \frac{(n_{Pj}+1)}{2\, d_R}$, with the length m_j of the transcription unit, n_{Pj}, the number of RNA polymerases, and d_R the distance between two ribosomes. This term can be reformulated to take into account the steady state number of the respective protein that depend on the selected growth rate. In this way, integrating over all proteins with individual length and the relationship for the total number of ribosomes, that is, the sum of active and free ribosome ($n_{Rt} = n_{Rf} + n_{Ra}$), we obtain a relationship for the total protein in steady state: $r_{syn}(n_{Rt} - n_{Ra}(P)) = \mu P$. We analyzed several possible kinetic expressions for the rate of synthesis r_{syn} and fit the model to available experimental data for the total number of ribosomes. Figure 1 shows the length distribution for the protein and the final fit for the total number of ribosomes.

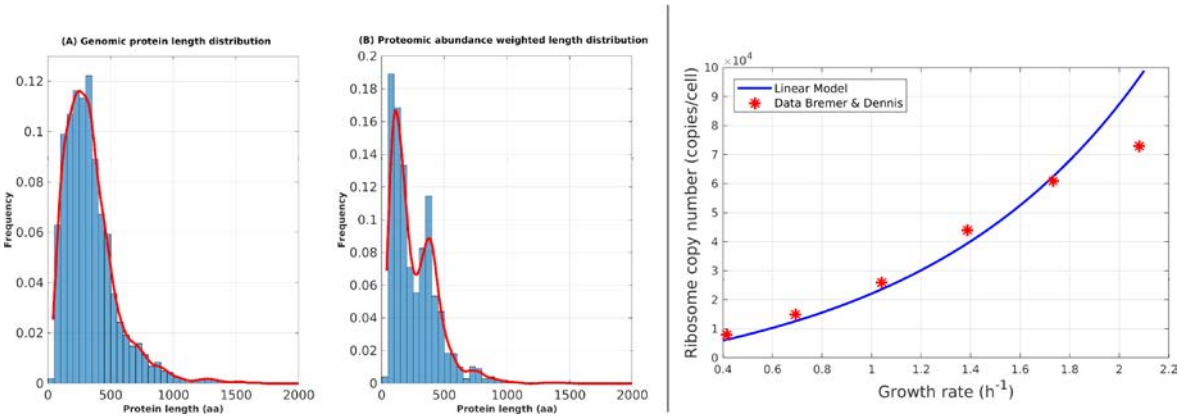

Figure 1. Left: (A) Protein length distribution with data from [3], (B) with steady state data weighted distribution. Right: Experimental data [4] and simulation comparison for the total number of ribosomes.

4. Conclusions

The model successfully describes experimental data for a broad range of the growth rate. Sensitive parameters of the model are the growth rate dependent velocities of the ribosomes and the RNA polymerase, as well as the total number of transcription units in the cell.

Highlights

- Different immobilization techniques have been applied to carbonic anhydrase.
- Whole cell catalyst bearing carbonic anhydrase has been developed.

1. Introduction

Post-combustion CO_2 capture strategy asks for novel processes avoiding the use of polluting solvents and aimed at CO_2 utilization. CO_2 absorption processes based on the enhancement of capture rate by the enzyme carbonic anhydrase (CA) (EC - 4.2.1.1) have been deeply investigated [1]. CA is able to catalyze the CO_2 hydration reaction and its thermophilic and halophilic forms are active into aqueous alkaline solvents [2]. In addition, the use of carbonate aq solvents and CA allows the exploitation of the bicarbonate enriched solvent for CO_2 utilization processes based on the cultivation of high value microalgae biomass [3, 4]. This contribution reports on recent efforts for the development of three techniques for the production of CA biocatalysts: two different CA immobilization techniques were developed and compared with a whole cell biocatalyst where CA is present on the outer membrane of engineered *Eschierichia coli* cells [5].

2. Methods

Thermostable CA was (Novozymes) and immobilized in the form of Cross Liked Enzyme Aggregates (CLEA) [6] and covalently attached on magnetic nanoparticles (MNP) [7]. Whole cell biocatalyst bearing CA on outer surface of cell membrane were prepared according to Del Prete *et al.* [5]. Kinetic characterization of CA based biocatalyst was performed through CO_2 absorption tests in a stirred cell lab scale bioreactor [6, 7].

3. Results and discussion

Figure 1 shows the immobilization yields (mass of immobilized enzyme/initial mass of enzyme) and the enzyme loadings (mass of enzyme/mass of biocatalyst) after preparation of CA CLEA and MNP with attached CA. CLEA shows remarkable improvement of these characteristics with respect to CA covalently attached on MNP. On the other hand, large CLEA size (low biocatalyst effectiveness) did

not allow kinetic characterization [6]. MNP and free CA apparent kinetics were fully characterized under industrially relevant conditions [7]. Whole cell biocatalyst showed active CA on its membrane [5] and its kinetic characterization is ongoing through CO_2 absorption tests used for CLEA and MNP characterization [6, 7].

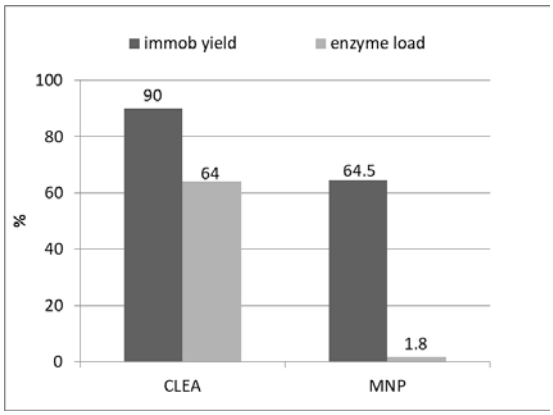

Figure 1. Comparison between CA immobilized on magnetic nanoparticles (MNP)and cross linked enzyme aggregates (CLEA).

4. Conclusions

Three technologies have been developed to produce CA-biocatalysts for the development of CO_2 capture processes oriented through aq phase CO_2 utilization [3, 4]. Table 1 reports pros and cons about each investigated biocatalyst. Among these, MNP biocatalyst is ready to further scale-up tests since assessed kinetic parameters have been used for an absorption column design study [8].

	Free CA/aggregates	CA on MNP	CLEA	Whole cell biocatalyst
Enzyme purification	+	+	+	-
Stability	-	+	+	Ongoing
Biocatalyst effectiveness	+/-	+	-	+
Kinetic parameters	+	+	-	Ongoing

Table 1 Comparison between possible strategies for CA use as promoter of enzymatic reactive absorption for CO_2 capture.

Highlights

- Enzymes immobilized on carbon nanotubes and mesoporous silica SBA15 maintained their regioselectivity towards N-acylation of lysine.
- Enzymatic N-acylation performances depended on immobilization materials.
- Functionalization of SBA15 with APTES improved enzyme loading and N-acylation performances

1. Introduction

N-acylation reactions allow the synthesis of amino acids/peptide derivatives, called lipo-amino acids/peptides belonging to the class of surfactants used in food and non-food applications for their good foaming and emulsion stabilization properties. Furthermore, as amino acids and peptides are molecules that may possess biological activities, the acylated derivatives of these molecules may also exhibit these bioactivities, making them detergents of choice in the cosmetic or pharmaceutical formulations. Industrially, the chemical reaction conditions are well known with the Schotten-Baumann reaction, but require the use of fatty acid chlorides in the presence of an organic cosolvent and generate effluents rich in salts. An alternative to this chemical route may be the use of hydrolytic enzymes to catalyse this reaction in aqueous or non-aqueous solvents depending on the enzyme. The use of lipases in non-aqueous media such as organic solvents or ionic liquids have already been reported [1] and aminoacylases in aqueous medium have also been described for the synthesis of acylated amino acids [2]. However to develop enzymatic processes to replace the chemical ones, the immobilization of the biocatalyst is required to improve its stability and allow its recycling. In this context, the aim of this work is to develop immobilization materials and conditions to improve enzymatic performances of both lipase in non-aqueous system or aminoacylases in aqueous medium for the synthesis of acylated amino acids.

2. Methods

The lipase B of *Candida antarctica* and aminoacylases from *Streptomyces ambofaciens* were immobilized either on SBA15 or on carbon nanotubes by physisorption or chemisorption. Preliminary functionalizations of SBA15 with APTES (from 10 up to 50 %) were performed. The synthesis of lauroyl-lysine was carried out with L-lysine (0.12 M) and Lauric acid (0.24 M) in 2 mL of

2-methyl-2-butanol previously dehydrated on 4 Å molecular sieves for CALB and in Tris-HCl 25 mM NaCl 50 mM (pH 8) for aminoacylases. The acylation reaction was performed in an agitated parallel system (Carousel 12 Plus Reaction Station™, Radleys) and is initiated by the addition of lipase B of *C. antarctica* immobilized on carbon nanotubes by physi- or chemisorption or by the addition of aminoacylases immobilized on SBA15. The quantity of supported enzymes was determined depending on the immobilization yield in order to add 1 mg of protein in the reaction medium.

3. Results and discussion

The synthesis of lauroyl-lysine was investigated using the lipase B of *Candida antarctica* immobilized on carbon nanotubes and aminoacylases immobilized on mesoporous silicate SBA15 functionalized with APTES. Both enzymes immobilized on carbon nanotubes or SBA15 maintained their regioselectivity towards N-acylation in α or ε position. By adsorption on SBA15, increased APTES concentration led to an improvement of aminoacylases loading up to 0.07 mg/mg material and increased N-acylation performances (Figure 1).

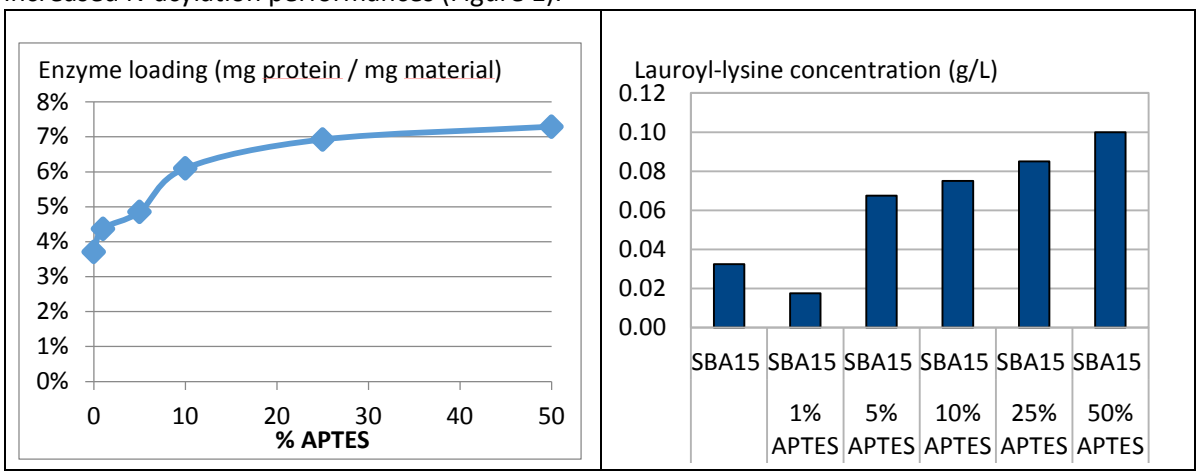

Figure 1. Aminoacylases loading enzyme on SBA15 functionalized with different APTES concentrations and lauroyl-lysine concentration obtained after 48h reaction.

Alternatively, the N-acylation of lysine was carried out with CALB immobilized on carbon nanotubes. Enzyme loading reached 0.16 mg/mg carbon nanotubes by direct adsorption whereas 0.25 mg/mg carbon nanotubes can be achieved by covalent bonding. However, the activity of CALB covalently immobilized on carbon nanotubes was 20 fold less than with Novozyme 435.

4. Conclusions

The regioselectivity of N-acylation was maintained whatever the enzyme and immobilization support. However, the performances of both enzymes depended on immobilization supports by adsorption or covalent bond on SBA15 or carbon nanotubes.

Highlights

- Optimization of culture conditions to produce active inclusion bodies
- Application of various high-throughput cultivation technologies
- Investigation of cultivation temperature using a mini reactor-based temperature profiling system

1. Introduction

It is of primary importance to develop new generic methods for simple and cost-efficient production of large amounts of stable enzymes to facilitate industrial applications. Although immobilization methods can improve enzyme stability, the additional processing steps are laborious and thus expensive. In contrast, catalytically active inclusion bodies (CatIBs) are in vivo, carrier-free enzyme aggregates that can be purified in a simple two-step purification process and retain beneficial features of conventional immobilization preparations. CatIBs can be produced in *E. coli* by the fusion of the target enzymes with certain aggregation tags [1, 2].

2. Methods

Active inclusion bodies, consisting of fluorescent reporter proteins or target enzymes, were produced with *E. coli* BL21(DE3) using the pET system. *E. coli* was cultivated in the Respiration Activity MOnitoring System (RAMOS) shake flasks for the online determination of the oxygen transfer rate (OTR). Additionally, different high-throughput online monitoring cultivation devices were used to measure scattered light (biomass, morphology) and fluorescence (product). A mini reactor-based temperature profiling system was used to investigate the impact of the cultivation temperature in a single experimental setup. To prepare IBs for activity determination, *E. coli* cells were lysed and insoluble cell fractions were isolated and washed. The activity of IBs was determined by fluorescence measurements or enzyme activity assays.

3. Results and discussion

First, the cultivation technologies were applied to develop a standard cultivation protocol. A streamlined methodology was developed combing the cultivation protocol, CatIB purification and the activity determination of CatIBs at µL-scale to facilitate process characterization and optimization. Subsequently, the impact of important cultivation parameters like medium composition, oxygen availability, temperature, and induction strength was investigated. Since the expression temperature strongly influenced the CatIB quality, a mini reactor-based high-throughput temperature profiling system was applied to study this effect in-depth. Results show that the cultivation temperature has to be adjusted carefully depending on the target protein and the chosen aggregation tag.

4. Conclusions

Various small-scale high-throughput technologies were applied to study CatIBs in depth. Results show that cultivation conditions have to be carefully adjusted for the production of active IBs. Furthermore, the results underline the great potential for industrial applications, as well as the necessity for further investigations.

Asymmetric reduction of (R)-carvone by cellular envelopes with an immobilized two enzyme system

Ingmar Polte[1*], Werner Lubitz[2], Dirk Weuster-Botz[1], Kathrin Castiglione[3]

1 Technical University of Munich, Institute of Biochemical Engineering, Garching, Germany; 2 BIRD-C GmbH. Vienna, Austria; 3 Friedrich-Alexander-Universität Erlangen-Nürnberg, Institute of Bioprocess Engineering, Erlangen, Germany

Highlights

- Analysis of undesired (2R,5R)-dihydrocarvone isomerization during whole cell-biotransformations
- One-step expression and immobilization of two enzymes in cellular envelopes of *Escherichia coli*
- 66 % reduced (2R,5R)-dihydrocarvone isomerization rates using cellular envelopes compared to whole cells
- The cellular envelope technology can be applied to reduce the effect of undesired side reactions mediated by the host cell metabolism.

1. Introduction

(2R,5R)-dihydrocarvone is a chiral building block which can be obtained by asymmetric reduction of the C-C double bond of (R)-carvone using ene-reductases. A purified ene-reductase from *Nostoc sp.* PCC 7120 (NostocER1) is capable of producing (2R,5R)-dihydrocarvone with a diastereomeric excess (de) ≥ 99 %. However, the application of whole cell biocatalysts expressing the cyanobacterial ene-reductase NostocER1 and a $NADP^+$-accepting formate dehydrogenase (FDH) mutant for internal cofactor regeneration led to a decreased de of 81.7% after 5 h which further dropped to the thermodynamic equilibrium of ~60% after 24 h [1]. The implementation of an *in situ* substrate feeding and product removal (SFPR) system based on polymeric adsorbent resins or ionic liquids could increase the achievable de in biotransformations with the whole cell biocatalysts up to 96.5 % [2], albeit the theoretical limit defined by the pure ene-reductase could not be reached. For different organisms than *Escherichia coli* it is suggested in literature that cytoplasmic components might catalyze the isomerization reaction of (2R,5R)-dihydrocarvone [4,5]. Therefore, in this contribution an inventive procedure for the one-step expression and immobilization of enzymes in cellular envelopes of *Escherichia coli* was applied to the two enzyme system comprising NostocER1 and FDH. The concept of cellular envelopes allows the construction of a biocatalyst lacking undesired catalytic interferences caused by host cell cytoplasmic components while keeping the economically beneficial low production and work-up costs of whole cell biocatalysts.

2. Methods

For the production of cellular envelopes, the two enzymes NostocER1 and FDH were fused on a genetic level to membrane anchorage domains, which allow a post-translational insertion into the

cytoplasmic membrane. In a second step the expression of protein E from phage ΦX174 led to the formation of lysis pores traversing both membranes of *Escherichia coli*. After cross-flow filtration to clean-up the released cytoplasmic components, cellular envelopes with a defined lysis pore and immobilized synthesis enzymes were obtained. Therewith, a biocatalyst with immobilized synthesis enzymes on the one hand but without potentially disturbing soluble host cell components on the other hand could be created.

3. Results and discussion

First it was proven that soluble cytoplasmic components of *Escherichia coli* can catalyze the undesired isomerization of (2R,5R)-dihydrocarvone to (2S,5R)-dihydrocarvone making it reasonable to apply the cellular envelope technology hereafter. Thus, seven different membrane anchorage domains were evaluated for the immobilization of NostocER1 in biotransformations with isolated membrane fractions. The highest activities and maintained stereo specificity were displayed for N- or C-terminal fusions of the hydrophobic transmembrane segment of the Vam3 protein from *S. cerevisiae* (Vam3p') and NostocER1. In these biotransformations FDH was membrane anchored via the C-terminal hydrophobic part of the Ubiquitin-conjugating enzyme 6 (UBC6) from *S. cerevisiae.* Subsequently, both configurations were employed in liter scale fed-batch processes for the production of cellular envelopes with membrane anchored NostocER1 and FDH. For both fusion types of Vam3p' to NostocER1 (N- and C-terminal) cellular envelopes could be prepared with high lysis yields of 99.93 and 97.25% after 27.5 and 29.7 h process time with maximal biomass concentrations of 12.83 and 10.72 g L^{-1}. During five subsequent washing steps of the cellular envelopes the protein concentration in solution as a measure of released cytoplasmic components in general was reduced to less than 4% (~80 µg mL^{-1}) of the starting value. In biotransformations the cellular envelopes displayed both NostocER1 and FDH activity and indeed (2R,5R)-dihydrocarvone isomerization rates were reduced up to 66% in comparison to whole cells.

4. Conclusions

The application of the one-step expression and immobilization procedure to the two enzyme system allowed the production of cellular envelopes with immobilized NostocER1 and FDH activity and high lysis yields. These cellular envelopes showed in biotransformations decreased (2R,5R)-dihydrocarvone isomerization rates compared to whole cell biocatalysts confirming the assumption that at least a part of the isomerization reaction is catalyzed by cytoplasmic compounds and that the cellular envelope technology can be used to reduce undesired side-reactions catalyzed by soluble host cell enzymes. To further investigate the remaining isomerization activity additional experiments regarding the completeness of the workup process should be considered.

Highlights

- *Trichoderma reesei* is sensitive to anaerobiosis
- Oxygen gradients in *T. reesei* cultures lead to a complex metabolic response
- Long exposure of *T.reesei* to anaerobiosis decrease the cellulases production

1. Introduction

Techno-economic evaluations of processes for ethanol production from lignocellulosic biomass show that reducing the cost of the cellulases used to hydrolyze the cellulose into glucose is a prerequisite to bring the ethanol cost to values close to the ethanol produced from starch. A very attractive option is to perform the production of enzymes on site in order to substitute expensive and pure carbon sources by lignocellulosic waste generated by the agri-food or forestry activity.

Industrial cellulases are mainly produced by an aerobic filamentous fungus, *Trichoderma reesei*, because of its high secretion capacity. Scaling-up this process is very challenging because of the complex links that exist between the process conditions, the morphology of this fungus and its productivity. Actually, the filamentous morphology induces an increase of the medium viscosity that strongly reduces the oxygen mass transfer rate. To ensure a sufficient rate, the power input has to be increased, which increase the fluid dynamic stresses on the mycelial structures. Carrying out fermentations with these microorganisms is complicated as the fungal morphology impacts process parameters, whereas process conditions affect in return the morphology and possibly the process productivity. Moreover, with increasing scale, the media experiences ever increasing spatial and temporal variations, especially in dissolved oxygen and sugar concentration compared to the bench scale. Scale-down techniques are a way of establishing at the bench scale the large scale behavior and their implications for the economics of the process. The goal of this work is to better understand and evaluate the impact of the upscaling on the physiology of *T. reesei*.

2. Methods

The effect of physical-chemical heterogeneities induced by the scale-up on the behavior of the microorganism are investigated using 2 scale-down approaches : a two-compartment system (2STR) and a single compartment system (1STR). The enzyme production follows a two-steps process: growth and production. The growth step is operated in batch mode in excess of sugar to

reach biomass concentrations of 15g/L. Cultures medium, preculture and operating conditions in growth step are similar to those reported in [1]. The production step is carried out in fed-batch mode. For the 2STR experiment, a 3.5L aerobic bioreactor (2.5L of culture medium) kept at 40% of dissolved oxygen saturation (pO_2) is connected to a 2.0L anaerobic bioreactor (0.5L of culture media) where the pO_2 is kept at 0% by injecting nitrogen. Two peristaltic pumps keep the broth circulating between the two bioreactors throughout the experiment. Two different cycling residence times in the anaerobic zone are tested by changing the volume of the bioreactors. For the 1STR experiment, cycling oscillations in the pO_2 (0-40%) are produced in a single 3.5L bioreactor by injecting a mix of air and nitrogen. For both scale down approaches, the temperature is 27°C and pH is 4.0 for all the experiments. The gas flow rate in the 3.5L bioreactors is constant and equal to 0.25 l/mn. A determination of the secreted proteins concentration is achieved on the medium filtrate by using the DCTM Protein Assay kit (Biorad, Hercules, United States of America) and is based on a range of bovine serum albumin (BSA, 0-1.5 gL-1) [2].

3. Results and discussion

As reported in figure 1.I & II, results indicated a decrease of 20% in the specific production rate and yield for longtime cycling exposures (15min) to anaerobic conditions in the 2STR experiments. This effect is quite low because heterogeneities of 15min are unlikely to occur in full-scale bioreactors. The comparison of the two different scale down approaches (2STR and 1STR) in figure 1.III showed very different results for the same characteristic times (3,4min) in the anaerobic zone. This indicates a) the sensitivity of *T. reesei* to anaerobiosis and b) the fact that the metabolic response is complex and not immediate because it depends on the distribution of the residence times of the microorganisms in the aerated or non-aerated zones.

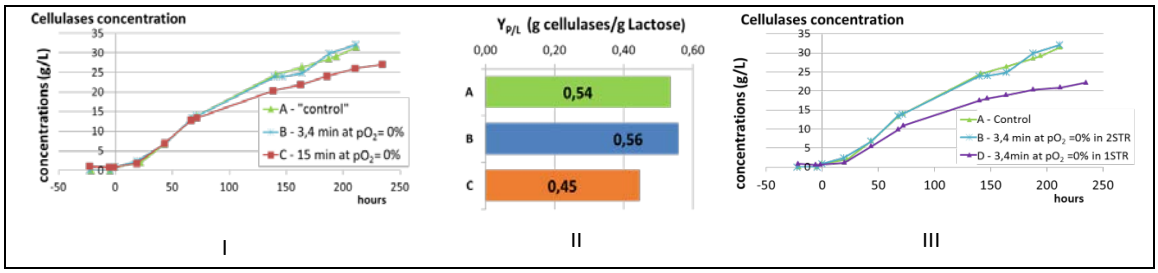

Figure 1. I & II) Comparison of cellulases production and yield (respectively) for three cultures in 2STR *:* A - control (no oxygen oscillations), B - 3,4 min and C - 15 min of cycling exposure to pO_2=0% ; **III)** Comparison of two different scale-down approaches for 3,4 min of cycling exposure to pO_2=0% : B - 2STR and D - 1STR

4. Conclusions

In this study, the effect of oxygen oscillations on enzyme production has been investigated during cultures of *T. reesei*. The possible low sensitivity of the fungus with respect to oxygen heterogeneities in production phase, opens perspectives in terms of technological choice on an industrial scale. However, its complex biological response to oxygen oscillations seems to be correlated with the distribution of the residence time in anaerobic zones inside large bioreactors.

A 5-Regime Kinetic Model for the Study of Heterogeneities in *Bacillus Licheniformis* Aerobic Fed-Batch Fermentation Processes.

Gisela Nadal-Rey[1], Sjef Cornelissen[2], Krist V. Gernaey[1,*]

1 Process and Systems Engineering Center (PROSYS), Department of Chemical and Biochemical Engineering, Technical University of Denmark, Building 229, 2800 Kgs. Lyngby, Denmark; 2 Novozymes A/S, Fermentation Pilot Plant, Krogshoejvej 36, 2880 Bagsvaerd, Denmark

**Corresponding author: kvg@kt.dtu.dk*

Highlights

- A 5-regime kinetic model for *Bacillus licheniformis* has been developed and validated
- Glucose and oxygen variations are considered for a differential cell performance
- The model can be used to assess the impact of gradients on aerobic fed-batch fermentation processes

1. Introduction

The combination of computational fluid dynamics (CFD) and microbial kinetic models is of great interest to investigate the occurrence and magnitude of gradients in process variables [1-3] in industrial-scale reactors, since detailed information of the fermentation environment can be generated. Nevertheless, coupling both models can become rather challenging due to the increased computational effort these types of simulations require. Therefore, it is important that simple, but accurate, kinetic models are developed for the study of heterogeneities.

In this work, a mechanistic model for the industrial workhorse *Bacillus licheniformis* [4] has been developed experimentally and validated. Its large-scale process consists of a high cell density aerobic fed-batch fermentation. Hence, the presence of sugar and oxygen gradients is likely to occur [5]. These gradients lead to the potential occurrence of five different metabolic regimes (acetate limited, fully oxidative, microaerobic and two overflow levels), depending on the concentrations of glucose and dissolved oxygen. With this kinetic model, the already well-established [1-3] CFD models can be extended and glucose and oxygen gradients in *B. licheniformis* fermentation processes can be investigated.

2. Methods

The model considers the different performance of *B. licheniformis* SJ4628 in five metabolic regimes depending on the concentration of glucose and oxygen in the fermentation broth (Figure 1). The switch between regimes is assumed to be instantaneous and based on critical concentrations of oxygen and glucose and on critical specific growth rates. Therefore, fermentations with varied concentrations of oxygen and glucose were performed to investigate the behaviour of *B. licheniformis* under different conditions.

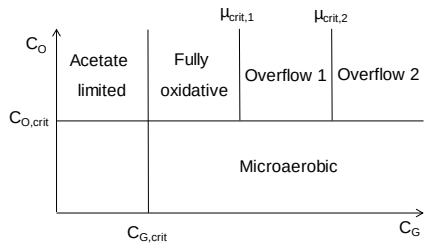

Figure 1. Scheme of the metabolic regimes of the kinetic model and the conditions at which the switch occurs.

The model describes growth with classical Monod kinetics and uses stoichiometric yield and maintenance coefficients to account for glucose, oxygen and acetate uptake and acetate production. More details regarding the equations setup will be given in this contribution.

3. Results and discussion

This work consists of the development and validation of a 5-regime kinetic model for *B. licheniformis* fermentation processes. The model takes into account the glucose and oxygen conditions at which the microorganism is grown, and uses different parameters and equations accordingly. Therefore, it resembles glucose and oxygen uptake in fully oxidative, overflow and microaerobic regimes, acetate re-assimilation under glucose-limiting conditions and acetate production under overflow and microaerobic conditions. Although all these different metabolic behaviors have already been described in literature [6], it is the first time that a 5-regime model with immediate metabolic switches has been experimentally developed and validated. Besides, it is also the first time that the growth, substrate uptake and acetate production kinetics of *B. licheniformis* have been investigated.

In this contribution, besides assessing the model uncertainty, the applications of this model to study glucose and oxygen gradients in fermentation processes will be discussed and exemplified. The implications of such gradients in industrial *B. licheniformis* fermentation processes will also be tackled.

4. Conclusions

With the execution of this work, it has been proven that the behaviour of *B. licheniformis* SJ4628 can be described with an unstructured mechanistic model including five different metabolic regimes. It has also been shown that the model is suitable for the study of glucose and oxygen gradients in industrial fermentation processes.

Highlights

- High throughput bioprocess development
- Automated exponential fed-batch
- Slow-release system
- Miniaturized cultivation with online signals
- Microtiter plate

1. Introduction

Tremendous developments in the field of metabolic engineering have strongly increased the throughput in the last decade. Through utilization of advanced techniques such as random mutagenesis and highly specific gene editing tools, large strain libraries can be generated in a very short time [1]. To identify the best strain candidates for in depth process characterization, these strains combined with a set of process parameters, have to be tested. Nonetheless, the number of mandatory experiments adds up to be very large [2]. Consequently, systems with increased cultivation throughput are in great demand. Therefore, micro bioreactor systems become a critical tool for accelerated bioprocess development. While most of these systems enable to screen batch cultivation, they lack the means to perform fed-batch processes, which are often the standard in industrial biotechnology. In this study, a novel approach for feedback-driven control of an enzymatic slow-release system is realized by combining a BioLector-based cultivation setup, a liquid handling system and a custom process control system, allowing for 48 parallel fed-batch cultivations in an automated and miniaturized manner.

2. Methods

BioLector cultivations, integrated in a liquid handling system were performed with a tailor made process control system. After an initial batch phase on free glucose as the sole carbon source, fed-batch cultivations were realized through the specific addition of enzyme. The amyloglucosidase is capable of releasing glucose monomers from a dissolved glucose polymer such as dextrin with a constant release rate. Through adaption of the amount of enzyme added, the substrate release rate and consequently the growth rate could be controlled.

3. Results and discussion

Through utilization of the online signals (biomass from backscatter, pH, DO, GFP) provided by the BioLector cultivation, the process can be feedback controlled. The quasi-continuous pH signal allowed for a single sided pH-control, where a small pulse of controlling agent was added to the cultivation well, when the pH dropped below a pre-defined threshold. This pH control was key to

success, since amyloglucosidase activity is very pH sensitive and initial experiments without pH control failed. The backscatter signal of the cultivation was used to calculate the online growth rate as previously described [3]. Once this processed signal fell below another threshold value (growth rate set point μ_{set}) a varying pulse of amyloglucosidase based on the current backscatter signal was added to the medium to increase the glucose release rate again and consequently keep a constant growth rate.

This technology allowed for highly reproducible exponential fed-batch cultivations with *C. glutamicum* in a modified CGXII medium. Four different growth rate set points were tested regarding reproducibility (Figure 1) and protein production with secreted GFP as a model protein. The lowest exponential growth rate set point resulted in an almost doubled GFP production in comparison to a batch process with the same amount of substrate. To test the applicability of this novel technology, exponential fed-batch cultivations with two other industrial relevant microorganisms, *E. coli* and *P. pastoris*, were conducted successfully.

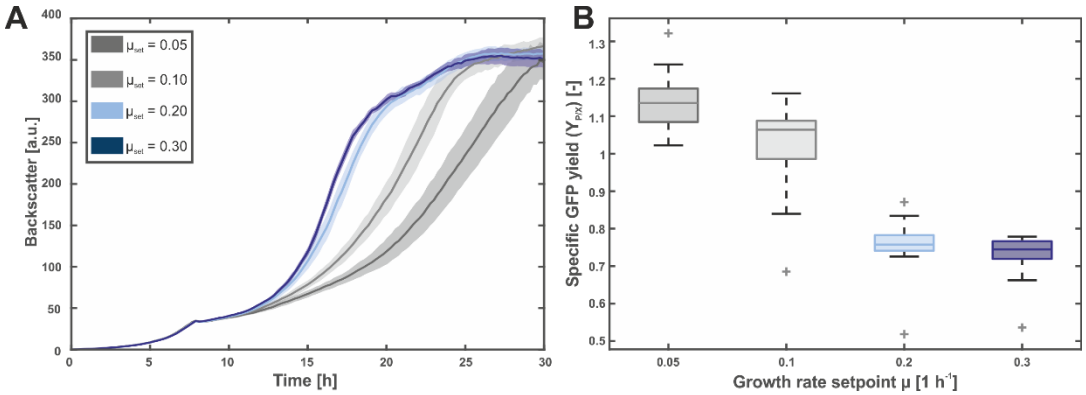

Figure 1. Backscatter curves (A) of *C. glutamicum* BioLector fed-batch cultivation and specific GFP yield (B) at the end of fed-batch cultivation.

4. Conclusions

In this study, a novel technology allowing for 48 parallel micro bioreactor fed-batch cultivation was developed. Via utilization of the online signals provided by the BioLector, a feedback controlled process was established, which showed high reproducibility for a given range of exponential growth range. This platform technology can be easily and cost effectively applied for screening purposes of up to 48 different cultivations.

Lipase-Catalyzed Solvent-Free Production of (Meth)Acrylate Monomers.

Wouter Van Hecke, Arjan Heeres, Yamini Satyawali, Karolien Vanbroekhoven

VITO (Flemish Institute for Technological Research) Boeretang 200 2400 Mol (Belgium)

**Corresponding author: wouter.vanhecke@vito.be*

Highlights

- (meth)acrylate esters were obtained at industrially appealing titers;
- nonlinear regression technique was applied to determine reaction rate constants;
- statistical inference was applied to the parameter estimates;
- second order kinetic model fits well with experimental results;

1 Introduction

Specialty or sensitive (meth)acrylate monomers are most often not available in the desired purity and quantity. Therefore, a milder and more sustainable manufacturing process is highly sought after [1]. To this end, lipases are known to catalyze ester synthesis at moderate conditions. Several of these have already been used to catalyse the production of (meth)acrylate esters with different alcohols in the presence of an inert organic solvent [1-3]. However, downstream processing could be simplified in solventless conditions [4, 5]. Hence, the first objective of this study was the solventless lipase catalysed transesterification of (meth)acrylates with various (bio-based) alcohols, enabling a more sustainable process for the production of specialty monomers. The second objective of this manuscript is to develop a generic kinetic model allowing simulation of the entire course of the solventless conversion based on nonlinear regression techniques.

2 Methods

2.1 Enzymes & chemicals

Novozym 435 (Novozymes, Bagsværd, Denmark) was used as catalyst in all tests. All organic alcohols and the methyl(meth)acrylate used for the transesterification had purities above 98% and were purchased from Sigma-Aldrich (Schnelldorf, Germany). A molecular sieve UOP Type 5Å (Sigma-Aldrich, Schnelldorf, Germany) was used to remove methanol.

2.2 Reaction conditions & nonlinear regression procedures

The lightest boiling substrate is added in molar excess to allow close to complete conversion of the highest boiling substrate and to avoid excessive temperatures in the subsequent distillation tower. Therefore, the conversions were only studied in reaction regimes using a molar excess of methyl (meth)acrylate. More detailed information on reaction conditions and the applied nonlinear regression procedures can be found in Heeres et al. [6].

3 Results and discussion

The ping-pong reaction mechanism seems to be the preferred model to describe lipase kinetics. A good fit with high R^2 values resulted from the selection of this mechanism. However, the large confidence intervals suggested overparameterization of the model. The use of a simpler second order rate equation yielded a more accurate model. Table 1 shows the results of the simulations. Higher reaction rate constants were systematically obtained for the transesterification of methyl acrylates, proving this to be a more accepted substrate than methyl methacrylate.

Table 1. The regressed second order reaction rate constants ranked in decreasing order. The lower and upper limit (LL and UL) of the 95% confidence intervals (CI) are also given.

Alcohol	Methyl ester	k_{cat} kg/(mol·h)	CI LL kg/(mol·h)	CI UL kg/(mol·h)
Tetrahydrofurfuryl alcohol	Methyl acrylate	1.69	1.26	1.71
Citronellol	Methyl acrylate	1.31	1.18	1.45
Furfuryl alcohol	Methyl acrylate	0.88	0.67	1.1
2-hexyl-1-decanol	Methyl acrylate	0.69	0.64	0.74
Methoxypropylphenol	Methyl acrylate	No reaction		
Isoeugenol	Methyl acrylate	No reaction		
4-methoxybenzyl alcohol	Methyl methacrylate	0.44	0.40	0.47
Furfuryl alcohol	Methyl methacrylate	0.36	0.25	0.48
Tetrahydrofurfuryl alcohol	Methyl methacrylate	0.35	0.31	0.38
Methoxypropylphenol	Methyl methacrylate	No reaction		
Isoeugenol	Methyl methacrylate	No reaction		

4. Conclusions and perspectives

Industrially appealing conversions and ester concentrations in solventless conditions were reached in this study. Progression curves were simultaneously used as input to estimate second order reaction rates and their confidence intervals based on nonlinear regression techniques. Larger scale production is currently under investigation for production of kg scale quantities.

Highlights

- The cloning and production of photosensitiser fusion enzymes was successful.
- Enzymes were produced soluble or as catalytically active inclusion bodies.
- The activity of the fusion enzymes was compared to the untagged enzymes.
- Photensitiser fusion enzymes show inactivation after light exposure.

1. Introduction

Cross-reactivity in complex enzyme cascades is a major challenge in the field of multi-step biocatalysis. To eliminate cross-reactivity in one-pot reaction systems, a novel strategy is followed: enzymes prone to side-reactivities are coupled to genetically encoded photosensitisers, which are able to produce reactive oxygen species upon irradiation with a distinct wavelength[1]. The resulting fusion enzymes can be added to the corresponding reaction step enabling the catalyst activity to be switched off after successful transformation. The three-step enzyme cascade starting from 3-hydroxy benzaldehyde and pyruvate to a trisubstituted tetrahydroisoquinoline has been chosen as a test system. This cascade encompasses a carboligation step, a transamination step and a final cyclisation[2]. It is a suitable target as in a one-pot reaction approach cross-reactivity especially of the transaminase occurs and dominant side-products are formed (Fig. 1), which has to be avoided.

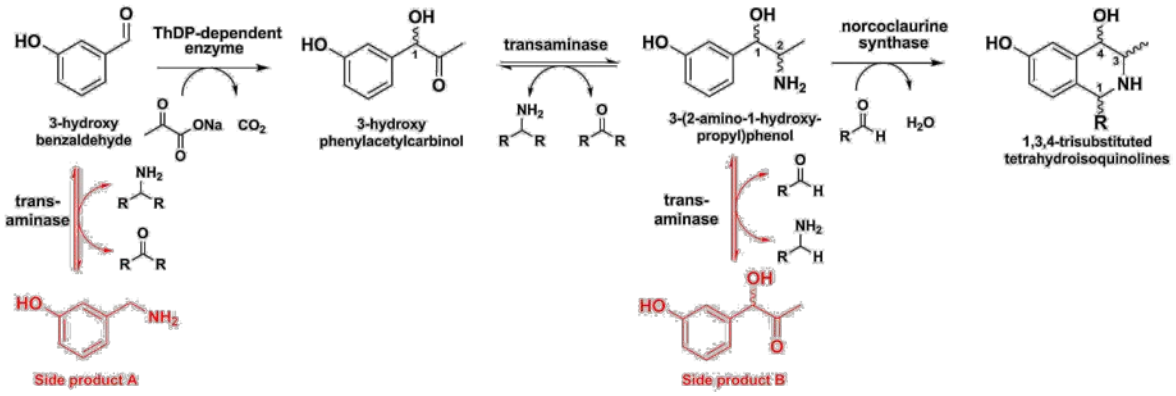

Figure 1. Three-step enzyme cascade starting from 3-hydroxy benzaldehyde and pyruvate to a trisubstituted tetrahydroisoquinoline. Possible side products are implied.

2. Methods

The flavin-binding fluorescent protein from *Bacillus subtilis* was genetically coupled to the pyruvate decarboxylase variant E469G/W543H from *Acetobacter pasteurianus* (Fp-*Ap*PDC-2v) and to the *Chromobacter violaceum* transaminase (Fp-*Cv*2025). The untagged enzymes as well as the fusion enzymes were produced in *Escherichia coli* BL21(DE3). The protein solubility was checked via SDS-PAGE and the proteins were purified using an ÄKTA chromatography system. The activity of the *Cv*2025 variants was measured spectrophotometrically for the reaction from alpha-methylbenzylamine to acetophenone. The activity of the *Ap*PDC-2v variants was determined via HPLC for the reaction from 3-hydroxybenzaldehyde to (S)-3-hydroxyphenylacetylcarbinol.

3. Results and discussion

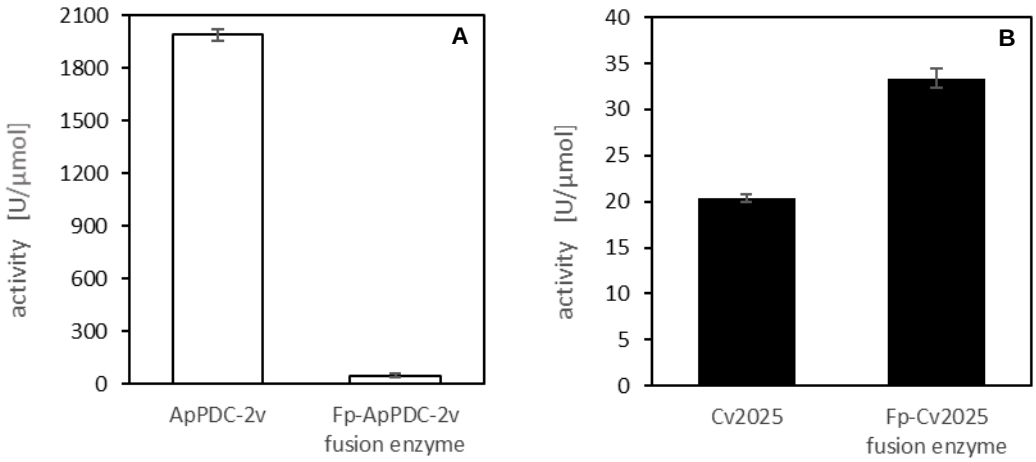

Figure 2. Activities of the photosensitiser fusion variants of *Ap*PDC-2v (A) and *Cv*2025 (B) compared to the respective untagged enzymes.

The Fp-*Ap*PDC-2v shows only 2.5 % of activity compared to the untagged enzyme, while the activity of the Fp-*Cv*2025 is even 30 % higher. The lower activity of Fp-*Ap*PDC-2v is likely to be caused by the structural properties of this enzyme because it is produced as catalytically active inclusion body. Depending on the structure of the untagged enzyme, multimeric photosensitisers seem to mediate the formation of a multi-enzyme network.

Furthermore, a light experiment with Fp-*Cv*2025 revealed, that 10 min of light exposure is sufficient to inactivate the enzyme completely.

4. Conclusions

The characterisation of two photosensitiser fusion enzymes was completed regarding their production and activity. Light experiments have shown that the photosensitiser tags are able to facilitate a fast inactivation of the fusion enzymes. Enzyme inactivation will now be analysed in detail.

Highlights

- 1. FRET-peptide system was a strong tool for screening catalytic antibodies (antigenases).
- 2. Several antigenases to cleave FRET-Tau peptides were found in this study.
- 3. Each antigenase exhibited a little different feature in the cleavage of the Tau peptide.
- 4. Antigenases against Tau-peptide are involved in human antibody genes.

1. Introduction

Most common cause of dementia among older adults is Alzheimer's disease (AD). In the disease, two kinds of molecules, amyloid β peptide (Aβ) and Tau protein, are considered as the main factors relating with the cause of the disease by the accumulation with neurofibrillary tangles (NFT) or phosphorylated filamentous tau protein, which works as proteinopathies on the brain.

Antigenases (catalytic antibodies) capable of hydrolyzing peptides and proteins (antigenase) are potentially useful agents for therapeutics, through the specific elimination of pathogenic peptides and the essential proteins in microorganisms. Actually, antigenases such as HIV envelope glycoprotein, helicobacter pylori urease, influenza viruses, and amyloid β (Aβ) have been developed in a last few decades.

In this study, Tau protein was targeted in order to make the antigenases capable of enzymatically degrading the protein. For this objective, we designed and synthesized a substrate based on Förster resonance energy transfer (FRET) to efficiently find out the desired antigenases from our protein bank, in which hundreds of human antibody light chains possessing a catalytic triad–like structure are stored as the protein.

2. Methods

The fluorescence-quenched substrates were synthesized by conventional Fmoc SPPS using Rink amide resin. The structure of the substrate was confirmed by ESI-MS after purification by HPLC. After a human antibody light chain gene inserted into pET20b (+), it was transformed into *E. coli* and induced by IPTG. After recovering the soluble fraction of the culture supernatant, it was purified by Ni-NTA chromatography, cation exchange chromatography or size exclusion chromatography. Catalytic activity was measured using synthetic substrates of FRET-Tau (391-408) at C-terminal side and FRET-Tau (19-30) at N-terminal side.

3. Results and discussion

The number of the stored light chains in our protein bank reached to hundreds. Thus, we screened the antigenases capable of cleaving the Tau peptides using the synthesized FRET-Tau peptide substrates. As the results, two antigenases (C1 & C2) to cleave the FRET-Tau (391-408) peptide at C-terminal side were found in 111 light chains examined. On the other hand, one antigenase (N1) to hydrolyze the FRET-Tau (19-30) peptide at N-terminal side was obtained in 96 light chains examined. The C1 antigenase cut the peptide bond between Val399-Ser400 (Fig. 1) and C2 between Gly401-Asp492. The two antigenases showed different enzymatic feature. Regarding the N1 antigenase, the peptide bond between Asp22 and Arg30 was cleaved. It is interesting that there were several antigenases capable of cleaving several sites of Tau protein in the protein bank of antibody light chains, which were prepared from human antibody library. This suggests that the catalytic antibody light chains against Tau molecule can naturally be produced.

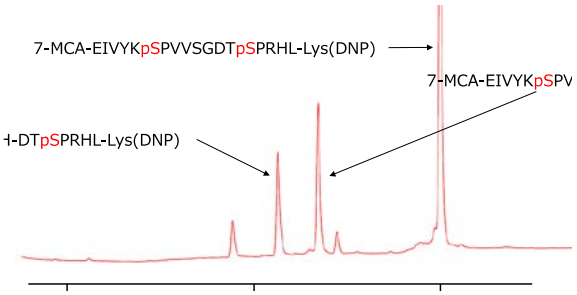

Figure 1. HPLC chromatogram for the products after the reaction of Tau peptide at C-terminal side and C1 antigenase. The peptide bond between Gly401 and Asp402 was digested by C1 antigenase.

4. Conclusions

We found several antigenases capable of cleaving Tau peptides. C1 & C2 antigenases digested the C-terminal (391-408) side peptides. N1 antigenase hydrolyzed the N-terminal side peptide (19-30). These antigenases were present in human antibody genes.

1 LISBP (CNRS 5504 - INRA 792 – INSA), Toulouse, FRANCE; 2 PIHM-UMET (INRA 638), Lille, France, 3 IRH Ingénieur Conseil, Ludres, France; 4 Aqualabo, Caudan, France, 5 LMDC, Toulouse, France

**Corresponding author: boukazia@insa-toulouse.fr*

Highlights

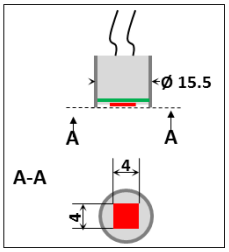
- *In-situ* fouling sensor based on MEMS technology and thermal excitation.
- Steady Permanent and Periodic Thermal Regimes are compared.
- Responses are scrutinized versus fouling magnitude and thermal properties.

1. Introduction

In industrial (bio)process, undesirable components impact efficiency [1; 2]. Monitoring and quantification of (bio)fouling through *in-situ* and local sensors constitute scientific and technological challenges. In present work, a prototype fouling sensor based on MicroElectroMechanical System (MEMS) technology and thermal pulse analysis method (INRA patent FR2885694) has been developed and produced by Aqualabo Company (France). Steady permanent Thermal Regime (STR) and Periodic Thermal Regime (PTR) were investigated and compared to theory to extract fouling properties (thickness, thermal conductivity and diffusivity)

2. Methods

Studied sensor is based on hotwire method with powered and regulated Joule effect [1]. Hot wire and fluid temperatures are continuously recorded. According to heat conduction's law, temperature difference ($\Delta\theta$) evolves as linear function with heat flux (φ) and thermal resistance (R_{th}) in STR mode (Eq.1). In PTR mode (Eq.2), sinusoidal excitation is imposed and $\Delta\theta$ evolves as a function of φ and fouling nature [3]. Mean temperature difference, $\overline{\Delta\theta_{PTR}}$, amplitude, A and phase lag, $\Delta\Phi$ enable to determine thermal resistance and diffusivity of deposit. Considering both excitation modes, deposit thermal properties can be extracted and compared with theory.



$$\Delta\theta_{STR} = \varphi.\left(\frac{1}{h}+\frac{th_d}{\lambda_d}\right) = \varphi.Rth \qquad \text{Eq.1}$$

$$\Delta\theta_{PTR}(x,t) = \Delta\theta_P(x,t) + \Delta\theta_C(x) = A.cos(\omega t + \Delta\phi) + Rth.\overline{\varphi} \quad \text{Eq.2}$$

$$\text{where } A = Rth.A_{\varphi}.exp\left(-\sqrt{\frac{\omega}{2a}}x\right) \text{ Eq.3, and } \Delta\phi = -\sqrt{\frac{\omega}{2a}}x \text{ Eq.4}$$

$$\text{With } Rth_d = \frac{th_d}{\lambda_d} \text{ Eq.5}$$

Sensor structure includes a plan square MEMS (red line) stuck on a printed circuit board (PCB, *th*=800µm, green wire) and encapsulated in a stainless steel cylinder (grey wires) filled with an electrical insulation resin. MEMS surface is in direct contact with fluid (bulk). Sensor was tested in

a 5L mixing reactor (fluid: water, *Re*=2.2E06 and 20±1°C). Multiple PVC scotch layers (TESA® 53948, *th*=130µm, ρ_d=1300 kg.m^{-3} [4]) were used to generate fouling. Thermal conductivity and heat capacity were measured at λ=0.115 W.m^{-1}.K^{-1} and *Cp*=1025 J.K^{-1}.kg^{-1} (NEOTIM FP2C), thus thermal diffusivity, $a=\lambda/(\rho.Cp)$=8.63E-08 m².s^{-1}. Experiments were performed in clean (reference) and fouled (up to 5 layers) conditions. In STR, five successive heat flux steps were applied (0.2 to 7.5 kW.m^{-2}, 30min/step). In PTR, a mean heat flux, $\overline{\varphi}$=4700W/m² with an amplitude A_φ=4100W/m² was applied. Spectral response was investigated for 8 frequencies (0.001 to 0.2Hz).

3. Results and discussion

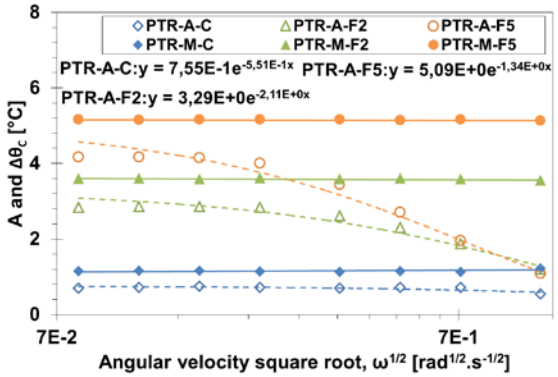


Figure 1 *A* and $\Delta\theta_C$ spectrum in clean (C) and fouled conditions (F2: 2 layers,F5: 5 layers)

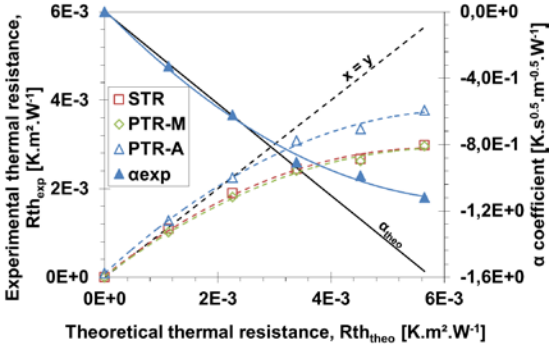

Figure 2 Rth_{exp} (dotted lines) and α coefficient ($-th_d/2.a^{0.5}$) (solids lines) versus Rth_{theo}.

In STR, heat resistances were determined by linearization of thermal responses, $\Delta\theta_{STR}$. In PTR (Figure 1), mean temperature difference (PTR-M) and thermal amplitude (PTR-A) were used to extract heat resistance depending of fouling conditions. Thermal properties were calculated with efficient heat flux identified in STR. Deviation between nominal and efficient flux can be attributed to edge effects due to packaging. Figure 2 compares the evolution of calculated heat resistances (Eq. 1, 2, 3) with theoretical fouling heat resistance (Eq.5). For low thermal resistance, experimental and theoretical values are close. Non-linear evolution of thermal resistances (beyond 3.4 K.m².W^{-1}) indicates the upper sensor limit of detection (LOD). PTR-A response shows better fair values than STR and PTR-M responses. Later inflexion is also noted with α coefficient evolution and confirms the upper LOD observed in STR, PTR-M and PTR-A thermal resistance study. Considering linearity area, thermal diffusivity measured is equal to 9.30E-08 m².s^{-1}.

4. Conclusions

In STR and PTR modes, thermal resistance responses are similar and match with theoretical values. The thermal diffusivity according to literature can be extracted through spectral analysis. Both methods give different upper LOD, at *Rth*=3.6E-03 and 5.5E-03K.m².W^{-1} for STR and PTR respectively. In PTR, LOD is equivalent to a dense biofouling (λ_d=0.6 W.m^{-1}.K^{-1}) of 3.4mm.

Highlights

- Microbioreactor enables high throughput clone screening
- Microbioreactor enables fermentation process parameter screening
- Fab expression causes lysis after a specific timespan

1. Introduction

We selected Antigen binding fragments (Fabs) as model proteins to evaluate the potential of a microbioreactor system. For this class of molecules a broad range of possible combinations of genetic constructs (host, leader sequence, promoters, mono- or bicistronic constructs, order of heavy and light chain sequences, UTR sequence etc.) is intensively discussed and consequently Fabs are optimally suited to answer this question. Fabs are single monovalent binding arms of IgG molecules, composed of a light and a heavy chain connected by disulphide bonds. As they are distinctive smaller in molecular size than full antibodies, they get producible in *E. coli* which makes it an attractive alternative to mammalian cell culture [1-3].
In the course of this work the main focus was laid on the applicability of a microbioreactor for clone and condition screening and transferability of results to bench top fed batch fermentation processes. The main challenge is to screen a high amount of clones in the shortest possible time, getting significant and reliable data.

2. Methods

We selected four different Fabs (BIBH1, BIWA4, CIM and FabX) with identical constant domains. For translocation to the periplasm a post-translational (ompA) and a co-translational (dsbA) leader sequence were used. *E. coli* BL21(DE3) and *E. coli* HMS174(DE3) were transformed via genome integration resulting in a total number of 16 clones.
For a first screening of the expression systems a microtiter fed batch like cultivation in a BioLector® system was used. After a growth phase of 16 hours we induced the systems with 0.5 mM IPTG and after a 9 hours production phase samples for the determination of intracellular Fab concentration by ELISA were taken.
In a next step we performed fed batch cultivations with all clones in a DASGIP® cultivation system. After a batch phase at 37 °C with a final biomass of approximately 10 gCDM/L a C-limited feed phase

was started with a growth rate of 0.1 h^{-1} at 30 °C. After approximately 0.5 doublings recombinant protein expression was induced for another two doublings. Induction level was kept constant at 2 µmol IPTG/g CDM.

3. Results and discussion

During BioLector ® cultivation Cell growth was not affected by leader/Fab combinations but yield of correctly folded Fab ranged from 0 to 12.5 mg/gCDM. In general K12 clones showed higher specific Fab titers but lower biomass yields than BL21 clones. The microbioreactor fed batch like cultivations with the selected set of host/leader/Fab combinations resulted in a broad range of variations in terms of Fab yields.

During bench top experiments we end up with exactly the same clone ranking in terms of specific Fab yield. However we also observed lower specific yields in the benchtop bioreactor setup which can mainly be assigned to the significantly higher growth rate in the production phase. In addition the production period was longer and approximately 8 hours past induction adverse effects on cell growth were observed. Fab was not only found in the cell fraction but also in the supernatant and DNA quantification in the fermentation supernatant showed that Fab release was caused by lysis which is also highly negatively correlated with the final cell mass that was obtained. The most significant influence on growth was seen for Fabx clones if the Fab was expressed.

4. Conclusions

Summarizing we could show that the microbioreactor system is a well suited HTP tool for clone and condition screening. Results generated in this platform can directly be transferred to benchtop fed batch bioreactor cultivations as long as limitations of the HTP system are adequately included in interpretations.

Efficient synthesis of chiral amino alcohol using 2-step enzyme cascades in repetitive batch mode

Kevin Mack[1,2]*, Vanessa Erdmann[1], Dörte Rother[1,2]

[1] IBG-1: Biotechnology, Forschungszentrum Jülich GmbH; [2] Aachen Biology and Biotechnology, RWTH Aachen University

*Corresponding author: ke.mack@fz-juelich.de

Highlights

- Novel amino alcohol products from cheap bulk chemicals.
- Excellent conversions in combination with excellent *ee* and *de* values.
- Improved specific space-time yield by enzyme immobilization.

1. Introduction

Vicinal amino alcohols can be applied as active pharmaceutical ingredients and key building blocks in industrial applications. Due to their multiple chiral centers, asymmetric synthesis is challenging. Here we present a sequential 2-step enzymatic reaction (**figure 1**) targeting the selective synthesis of three of four stereoisomers of the building block 1-amino-1-phenylpropan-2-ol (APP).

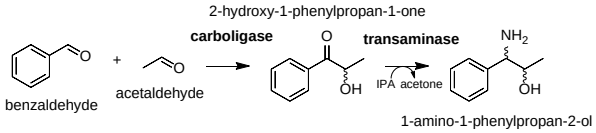

Figure 1: Atom- and step efficient two-step reaction setup for the asymmetric synthesis of all APP isomers.

For the first cascade step, either a benzaldehyde lyase (BAL) or a benzoylformate decarboxylase (BFD) is used.[1,2] This gives access to the intermediate 2-hydroxy-1-phenylpropan-1-one (HPP). The second step to APP is carried out using transaminases. The product APP was produced with excellent sereoselectivity and conversion. For further optimization, the reaction was set up with immobilized enzymes. HaloTag® and EziG™ immobilization methods were chosen and showed similar good results with improved specific space time yields (sSTY).

2. Methods

Conversion of products and intermediates were analyzed by high performance liquid chromatography and a supercritical fluid chromatography. Transaminase activity was determined in a photometer[3]. HaloTag® immobilization was carried out as described [4], the immobilization protocol on EziG™ was developed during this Project.

3. Results and discussion

For the first cascade step of the (*R*)-selective carboligase from *Pseudomonas fluorescens* (*Pf*BAL) or a (*S*)-selective carboligase from *Pseudomonas putida* (*Pp*BFD) is applied.[1,2] This gives access to the intermediate HPP. The second step to APP is carried out with either a transaminase from *Bacillus megaterium* (*Bm*TA) or *Arthrobacter* sp. (*As*TA). The complete cascade was demonstrated in 1 mL scale and scaled up to 30 mL reaction volume. Both scales showed good conversions of 93%-98% and *ee* of 97%-99% as well as *de* of 92%-99% in all three possible cases. To cut on process cost by reusing the catalyst, three different enzyme formulations were compared to each other. The example *Bm*TA showed that HaloTag® immobilization enabled 75% remaining activity while the free enzyme and the EziG™ immobilization had 100% activity. For optimal reaction design and to determine sSTY (free enzyme 0.12 g/(l*h)), the full 2-step reaction to (1*R*,2*S*)-APP was set up with HaloTag®[4] (1.20 g/(l*h)) as well as EziG™[5] (3.77 g/(l*h)) immobilized enzymes in repetitive batch mode and compared.(**figure 2**)

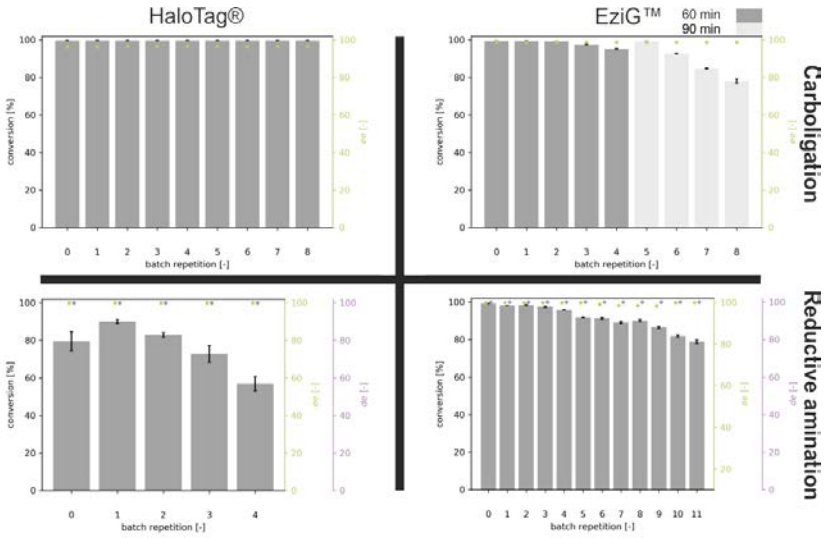

Figure 2: Repetitive batch reaction with HaloTag® and EziG™ towards (1*S*,2*R*)-APP. 60-90 min carboligation with *Pp*BFD var. and 24-72 h Transamination with *Bm*TA

4. Conclusions

The 2-step reaction was displayed with high conversions in combination with excellent *ee* as well as *de* values with purified enzymes. sSTY of the reaction could be improved by immobilizing and reusing the enzyme. In addition to the improved sSTY, the EziG™ carrier was tested for reusability, which could be a crucial step for an ecologic and economic reaction setup and passed the testing with very good results. The concepts presented here will be further expanded to similar products and enzymes to make complex enzymatic and chemo enzymatic cascades feasible with high sSTY in larger scales.

Development of algorisms to introduce a catalytic function into normal antibodies.

Emi HIfumi[1], Yuko Akiyoshi[1], Taizo Uda[2]

1 Research Promotion Institute, Oita University, Oita 870-1192, Japan; 2 Nano-tech Lab, ISIT, Fukuoka 819-0388 Japan

**Corresponding author: e-hifumi@oita-u.ac.jp*

Highlights

- 1. Amino acids of Thr-Arg at 29th and 30th in CDR1 can exhibit a catalytic function.
- 2. Deletion of Pro95 in CDR3 contributes to exhibit a catalytic function.
- 3. Several catalytic antibodies to cleave of Amyloid-beta (Aβ) were found.
- 4. Several algorisms how to make catalytic antibodies from normal antibody are developed.

1. Introduction

Catalytic antibodies capable of hydrolyzing the targeting peptides and proteins are potentially useful agents for therapeutics, through the specific elimination of pathogenic peptides and the essential proteins in microorganisms. Over the course of the last few decades, several groups have reported catalytic antibodies hydrolyzing antigens such as HIV envelop glycoprotein, helicobacter pylori urease, rabies virus, influenza virus and amyloid β peptide (Aβ). However, it is not easy to find out the catalytic antibody from a huge number of normal (non-catalytic) antibodies. It has been desired that the development of an algorism how to easily and effectively introduce a catalytic function into the antibodies. Therefore, for these ten years, the authors have devoted to prepare a protein bank of human antibody light chains having a catalytic triad-like structure. The light chains were cloned from human antibody library and highly purified after the expression in *E. coli* f. The number of the stored light chains has reached to several hundreds. Therefore, in this study, the screening whether or not the stored light chains can possess a catalytic activity for a synthetic substrate, Arg-pNA, and FRET-Amyloid-beta (Aβ), was carried out to obtain important information about the algorism.

2. Methods

The fluorescence-quenched substrates were synthesized by conventional Fmoc SPPS using Rink amide resin. The structure of the substrate was confirmed by ESI-MS after purification by HPLC. After a human antibody light chain gene inserted into pET20b (+), it was transformed into *E. coli* and induced by IPTG. After recovering the soluble fraction of the culture supernatant, it was purified by Ni-NTA chromatography, cation exchange chromatography or size exclusion chromatography. Catalytic activity was measured using synthetic substrates Arg(R)-pNA and FRET-Amyloid-beta (Aβ).

3. Results and discussion

The authors screened the catalytic activity for more than 100 light chains stored in the above protein bank. Out of them, #7wt and #7TR light chains showed interesting results. The former showed the low activity to cleave synthetic substrate Arg-pNA. In contrast, the latter light chain showed the high catalytic activity to cleave the substrate. For FRET-Aβ (26-33) substrate, the former light chain did not decompose at all but the latter did. The difference of both light chains is in the amino acids at 29th and 30th position in CDR1. The former is Gly-Tyr and the latter Thr-Arg. By being replaced with Thr-Arg, the antibody light chain can gain the catalytic function. Interestingly, #7TR light chain could cleave not only FRET-Aβ (26-33) peptide but also Aβ41 of the full size molecule.

In addition, we found other unique human antibody light chains, S35 and S38. The amino acid sequence of both light chains is identical except for Pro95 in CDR3. S35 has the Pro95 residue but S38 deleted the amino acid. The former did not decompose Arg-pNA at all. In contrast, the latter showed high decomposition activity (Fig. 1).

These results are noteworthy, because it enables for us to design a catalytic antibody from the non-catalytic antibody on molecular basis.

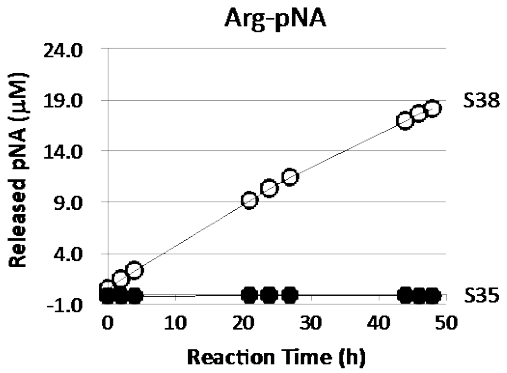

Figure 1. Cleavage reaction of a synthetic substrate, Arg-pNA

4. Conclusions

On molecular basis, several algorisms how to make a catalytic antibody from the general antibody are found.

Highlights

- Investigation of mechanical properties of cross-linked enzyme crystals
- Enhancement of crystal stability due to cross-linking immobilization
- Changing of mechanical properties of protein crystals through protein engineering
- Determination of correlation between crystal structure and cross-linking progress

1. Introduction

Due to their highly selective reactions, safety and sustainability, industrial use of particular biocatalysts, like protein enzyme crystals has been expanded to many manufacturing sectors including the pharmaceutical production. The catalytic activity of those particles correlates with particle size and must maintain as high as possible during enzyme-catalyzed reactions. Hence, the knowledge of mechanical properties is necessary to avoid particles breakage by downstream processing and thereby, changing or loss of the catalytic activity. Mechanical properties of protein enzyme crystals depend on the structure of individual protein molecules, packing density, as well as the conformation within a 3-dimensional structure of protein particles. In recent years, there has been an increasing interest in the improvement of protein performance using immobilization method or due to protein engineering, which aims at the modification of protein sequence, and hence, its structure, in order to create enzymes with improved functional properties.

2. Methods

The purpose of this study was to enhance mechanical stability of protein crystals due to cross-linking immobilization method on the one hand and additional protein engineering for intensified cross-linking on the other hand. For this reason, halohydrin dehalogenase wild type (HheG) was crystallized as model protein, cross-linked using glutaraldehyde and mechanical tested in liquid environment with the aid of an atomic force microscopy (AFM), as described previously[1]. Those measurements allowed investigation of hardness and Young's modulus of prismatic and basal crystal faces of hexagonal crystal's prism depending on the cross-linking duration time. Moreover, a breakage behaviour of cross-linked enzyme crystals, compared to the native crystals is examined using micro-compression tests. In the second step, additional lysine residuals, which can form covalent bonds with the glutaraldehyde-linker, were introduced on the halohydrin dehalogenase wild type (HheG) surface. Then, mutated HheG protein were crystallized, cross-linked and mechanical tested in nanoscale using AFM-based nanoindentation technique again. Due to exchanging of amino acid residuals, increased cross-linking and hence, higher mechanical stability of enzyme crystals was expected.

3. Results and discussion

One of the most significant findings to emerge from this study is that the cross-linking reaction takes place in the first 24-hours. In this time both, hardness as well as Young's modulus increase almost threefold, compared to the reaction time of 4 hours and stay constant at ca. 11.5 MPa (prismatic face) and 500 MPa, respectively. The second major finding was the evaluation of 30%-higher mechanical stability for the basal face. The evidence of this study suggest an anisotropic behavior within the three-dimensional crystal lattice, which was subsequent analyzed using a mathematical model. The applied model enables quantification of theoretical bonds for cross-linking within a supercell and qualitative visualization of potential cross-linking bridges within the crystal structure. The results show that the measured anisotropy might be caused by different direction-dependent amount of bonds on the one hand, and distinct channel orientation within the crystals on the other hand. Interestingly, because of the protein engineering both, hardness and Young's modulus slightly decreased, compared to the mechanical properties of wild type crystals (see Figure 1). However, the statistical consideration of the results showed a significant reduction of the distribution width, indicating an improved crystal packing density with less flaws.

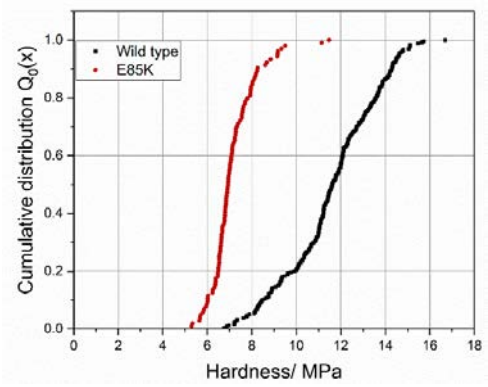

Figure 1. Hardness distribution of HheG wild type and mutant protein crystals. Note that the mean value of mutant HheG crystals decreases by ca. 40%, compared to the wild type crystals.

Additionally, the results of the micro-compression tests show considerable higher mechanical stability against normal forces for cross-linked HheG wild type crystals, compared to the native crystals.

4. Conclusions

The present study was designed to enhance mechanical stability of enzyme crystals due to cross-linking immobilization and protein engineering. Using AFM-nanoindentation technique, we were able to investigate small changes in the mechanical properties, like hardness and Young's modulus on distinct crystal faces dependent on the cross-linking duration time. Due to explanation of measured phenomena using a mathematical model, which bases on the crystal structure, this project provides an important opportunity to advance the understanding of the structure - properties correlation of protein particles and creates fundamentals for future studies on desired formulation of reinforced catalytic active crystalline biocatalysts.

Highlights

- Cultivation of *P. ostreatus* on the waste plant biomass for enzymes production.
- The highest enzyme activities were detected after 8th day of fungi cultivation.
- Stabilization of extracellular enzymes from *P. ostreatus* was done using CLEA method.

1. Introduction

Forest and agricultural waste can be a major development and ecological opportunity and can serve as a substrate for medicinal mushrooms cultivation such as *Pleurotus ostreatus*, which can be easily cultivated by everyone. It can successfully grow on a wide range of waste lignocellulosic material [1,2]. *P. ostreatus* is a woody fungus that acts as a saprophyte. It is involved in a process of degradation of hemicellulose, cellulose and lignin. The enzymes laccase and cellulase, which are part of the lignocellulolytic enzyme system, contribute to this degradation. Various substrates affect the activity of the thus obtained enzymes from *P. ostreatus*. The utilization of the waste biomass from forestry and agriculture for the cultivation of *P. ostreatus* mushrooms in order to obtain different enzymes can be integrated to waste management and the development of the bio-economy. Produced enzymes from *P. ostreatus* could be used as nutritional supplements or they can be immobilized as an enzyme cocktail, e.g. laccase and cellulase in the form of cross-linked enzyme aggregates (CLEA) (without a carrier) to improve the enzyme stability. Immobilization of enzymes allows the recycling of these biocatalysts, which is otherwise almost impossible and can improve their stability. In addition, the cost of the biocatalyst could be reduced due to easily separation of biocatalyst from the reaction mixture. Immobilization in the form of CLEA allows the use of so called crude enzymes and therefore, it is not necessary to use a pre-purified enzyme, which reduces processing costs and is interesting for industrial use [3]. The cultivation of *P. ostreatus* fungi on a solid medium (wheat bran) was performed. The activity of laccase and cellulase from fungi extracts after different cultivation time was studied. The optimal time for *P. ostreatus* cultivation to obtain the highest specific activity of laccase and cellulase was determined. The immobilization of extracellular enzymes produced by *P. ostreatus* in the form of CLEA was done and their activity was also studied.

2. Methods

Cultivation of *P. ostreatus*

P. ostreatus was cultivated on wheat bran at 27 °C and at different period of time.

Enzyme extraction from *P. ostreatus*

After defined growing time of *P. ostreatus,* extracellular enzyme extraction with 0.05 M sodium citrate buffer was performed.

Preparation of CLEA

Preparation of CLEA laccase was performed in two steps: precipitation with different solvents (acetone, ethanol etc.) and cross-linking using glutaraldehyde (GA) at different concentrations.

Determination of laccase and cellulase activity

Laccase activity was determined at 420 nm using 2,2-azino-bis(3-etilbenz-tiazolin-6-sulfonat) as a substrate and cellulase activity was defined at 340 nm with a UV-Vis spectrophotometer using the method with Sigmacell solution as a substrate.

3. Results and discussion

After 8th and 14th day of fungi cultivation, enzyme extraction was carried out to determine the activity of the selected enzymes. The optimal incubation time was 8 days, since the activities at that time were the highest. Specific activity of cellulase was 6.3166 U/$mg_{protein}$ and of laccase was 6.7280 U/$mg_{protein}$ (Figure 1). The obtained enzymes extract was used for CLEA preparation. The optimal precipitation reagent was found to be acetone, since highest specific activity of laccase and cellulase was obtained after precipitation in that solvent. With the increase in GA concentration from 1% (v/v) to 8% (v/v) an increase in immobilization efficiency and in specific activity of cellulase and laccase were determined.

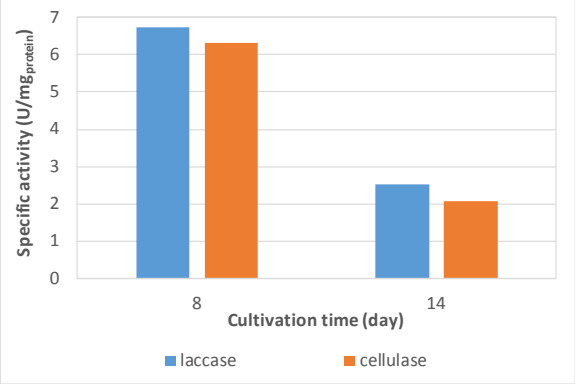

Figure 1. Influence of cultivation time of *P. ostreatus* on laccase and cellulase specific activity.

4. Conclusions

Cultivation of *P. ostreatus* was successfully performed on solid medium using wheat bran as a substrate. The activities of extracellular laccase and cellulase were the highest after 8th day of *P. ostreatus* cultivation. Extracted extracellular enzymes from *P. ostreatus* were immobilized in the form of CLEA for possible application in industrial cascade bioprocesses.

Highlights

- Protein aggregation has been recently described as a native and regulated process.
- The *E. coli* sirtuin CobB was purified as a dimer and as a large-oligomer.
- The oligomer showed a higher thermostability than the dimer.
- The dimer and large-oligomer showed similar enzymatic and substrate-binding parameters.

1. Introduction

Escherichia coli (*E. coli*) is a Gram-negative bacterium widely employed in biology and biotechnology as a model microorganism to produce high-value compounds such as proteins or drugs with a great commercial interest (1,2). Recombinant protein overexpression in *E. coli* still is the most used strategy for protein production. However, many difficulties can difficult protein expression and purification, such as low expression, protein toxicity, difficult purification steps or inclusion bodies formation (3). To solve these drawbacks, new purification strategies are being developed (4). Protein inclusion bodies are insoluble protein aggregates which are formed when protein aggregates are large enough. However, proteins can form soluble large-aggregates in response to diverse conditions, such as heat shock, other environmental stress conditions or a fast and high expression of recombinant proteins (5). Moreover, protein aggregation has been recently described as a native and regulated process in bacteria, yeast and mammalian cells (6).

2. Methods

In this study, the overexpression and purification of a soluble large-oligomer *E. coli* CobB protein is presented. Native electrophoresis, HPLC size-exclusion chromatography, enzymatic characterization, Differential Scanning Calorimetry (DSC) and Isothermal Titration Calorimetry (ITC) were carried out to evaluate and compare the two protein conformations.

3. Results and discussion

The results showed that the *E. coli* sirtuin CobB, highly conserved since prokaryotes to humans, was purified in two different conformations: a dimer and a large-oligomer. The two protein conformations were time-stable and an equilibrium between them was not observed. Moreover, the large-oligomer conformation showed an enzymatic activity and a binding constant for Acs

(Acetyl-CoA synthetase) protein similar to the dimer. Finally, the oligomer showed a higher thermostability, with a melting temperature almost 15 degrees higher.

4. Conclusions

The results of this work emphasize the importance of protein large-oligomer conformations for their use in biotechnology as a strategy to carry out processes with extreme conditions (7).

Development of an optimal process for the production of a light-coloured and highly soluble sunflower protein isolate

Sara Albe Slabi[1, 2], Christelle Mathé[1], Mélody Basselin[1], Arnaud Aymes[1], Olivier Galet[2] and Romain Kapel[1*]

Highlights

- The optimal extraction conditions were found at pH 7.0 and 0.5 mol·L^{-1} NaCl
- Saline ultrafiltration present an original process for sunflower purification that results in highly-purified protein product (around 100 %/dm)
- The established alternative process for sunflower protein production yields in light-coloured and highly soluble isolate (> 75 % at pH 7)

1. Introduction

The growing world population sets a new challenge for food industry because of increased demand for proteins. Sunflower (*Helianthus annuus* L.) is the fourth most important oilseed with production exceeding 47 million tons in 2016 [1]. The solid residue co-produced after oil extraction process (meal) is a valuable source of proteins (30-50 %/dm). Sunflower proteins (helianthinins and SFAs) are considered very promising for human nutrition thanks to many potential nutrition and functional benefits. However, during solid/liquid extraction phenolic complexation to proteins take place resulting in an unsuitable green colour of protein products [2]. Furthermore, a conventional purification of sunflower proteins is carried out by acidic precipitation. This leads to a poor solubility of protein products and an important loss of sunflower albumins [3]. Therefore, the main objective of this work was to propose an optimal process for sunflower protein extraction and an alternative protein purification by ultrafiltration that yields in light-coloured and highly soluble isolate.

2. Methods

In the first part of the work a 3^2 design of experiments was used to investigated the influence of NaCl concertation (0-0.5 mol.L^{-1}) in the range of pH (6-9) on extraction yield, protein composition (helianthinin, SFAs) and phenolic contamination. Then, to select the most appropriated conditions for protein extraction a multi-objective optimization strategy with incorporated constraints in algorithms was applied. Finally, the best scenario for protein purification by ultrafiltration was

established. For this purpose, retention coefficient of target compounds was determined and modelling a protein purity with overall balance of matter was carried out. The solubility of protein isolate obtained using optimized process was characterized.

3. Results and discussion

The response surface revealed a positive, synergic impact of pH and ionic strength on protein extraction yield and helianthinin extractability. Irreversible phenol-protein interactions revealed dramatically increased with extraction pH. Interestingly, a protective effect of NaCl was also shown. Thus, the objective of the multi-objectives optimization was to maximize extraction yield of protein (≥ 45 %) and the content of helianthinins (≥ 65 %) while minimizing phenolic contamination of helianthinins (≤ 8 %) and SFA (≤ 25 %). Based on these results the solid/liquid extraction at pH 7.0 and 0.5 mol·L^{-1} NaCl was found to be the best trade-off between all competing criteria (Fig. 1a). The proteins extracted under optimal conditions were subsequently purified by ultrafiltration using an original protocol with saline diafiltration step (0.5 mol·L^{-1} NaCl). The developed process resulted in excellent separation of sunflower proteins and free phenolic compounds (≥ 95 % after 6 DV) and satisfying purification yield (> 70 %). Consequently, a light-coloured proteins with a high-purity (99.9 %/dm) was obtained (Fig. 1b). Additionally, the solubility of protein isolate (≥ 75 % at pH 7, Fig. 1c) was considerably improved comparing to those purified by acidic precipitation (< 10 % at pH 7) [3].

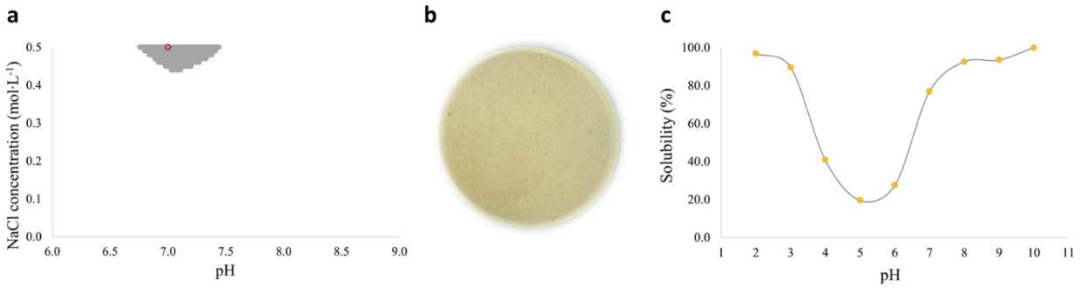

Figure 1. Non-dominated responses (grey points) of multi-objective optimization of protein extraction and the selected optimal condition (red-framed) (**a**). The coulour (**b**) and the solubility of purified proteins as a function of pH (**c**).

4. Conclusions

The obtained response surfaces allowed selecting the optimal extraction conditions found at pH 7.0 and 0.5 mol·L^{-1} NaCl. The further protein purification by ultrafiltration yielded in colour-light and highly soluble protein isolate. Thus, the proposed alternative process for preparation of sunflower proteins could be an answer for sustainable valorization of sunflower meal in food industry.

Mechanical stress during scale up to membrane aerated stirred bioreactors for rebeccamycin production in filamentous *Lentzea aerocolonigenes*

Kathrin Pommerehne[1,3], Nadine Wurzler[1,3], Marcel Schrader[2,3], Arno Kwade[2,3], Rainer Krull*[1,3]

1 Institute of Biochemical Engineering; 2 Institute for Particle Technology; 3 Center of Pharmaceutical Engineering, TU Braunschweig, Germany

**Corresponding author: r.krull@tu-braunschweig.de*

Highlights

- Filamentous *L. aerocolonigenes* produces the antitumor antibiotic rebeccamycin.
- Particle-induced mechanical stress on *L. aerocolonigenes* increases rebeccamycin titers.
- Simulations can be used to characterize the optimal mechanical stress.
- Membrane aerated bioreactor cultivations result in comparable rebeccamycin titers.

1. Introduction

Filamentous microorganisms represent the majority of natural producers of antibiotics and other active pharmaceutical ingredients (APIs). *Lentzea aerocolonigenes* is a filamentous actinomycete producing the antitumor antibiotic rebeccamycin. The microorganism exhibits a complex morphology ranging from freely dispersed mycelia to dense pellets [1]. The morphology is linked to the product formation and can be controlled by e.g., inoculum concentration and viability, pH, medium composition, hydromechanical stress, addition of inorganic salts or particles [2]. Rebeccamycin formation in *L. aerocolonigenes* was increased by the adjustment of mechanical stress induced by glass particles in shake flask scale [3]. Regarding a scale up from shake flasks to a laboratory scale stirred bioreactor the induced mechanical stress is an important factor.

2. Methods

Cultivations of *L. aerocolonigenes* were conducted in 250 mL shake flasks with 4 baffles and 50 mL filling volume. Glass particles were added for adjustment of the induced mechanical stress. The flasks were incubated on an orbital shaker at 120 min^{-1} (50 mm amplitude) at 28 °C for 10 days.

A scale up to a stirred bioreactor (Applikon, The Netherlands; 6 blade Rushton turbine) with 1.2 L filling volume was performed. Aeration in this bioreactor was conducted via an oxygen permeable silicone membrane (0.2 mm thickness; Reichelt Chemietechnik, Germany). Stirrer speed was set to 400 min^{-1} and pure oxygen was used for aeration (aeration rate 0.2 L min^{-1}).

3. Results and discussion

The influence of mechanical stress on cultivations of *L. aerocolonigenes* in shake flasks was investigated using glass beads in different sizes and concentrations. The highest rebeccamycin concentration of 70 mg L^{-1} after 10 days of cultivation was achieved with 100 g L^{-1} glass beads of

969 µm diameter compared to an unsupplemented control (rebeccamycin concentration after 10 days of cultivation with 5 mg L^{-1}) (**Fig. 1**).

A stirred bioreactor usually generates higher mechanical stress than a shake flask. Therefore this parameter is important to consider during scale up, especially since product formation is influenced. As conventional bubble aeration and agitation induce mechanical stress, a bubble free membrane aeration was chosen to reduce the influencing variables. A first membrane aerated cultivation without glass beads resulted in a rebeccamycin titer of 12 mg L^{-1} after 6 days of cultivation which is comparable to a regular unsupplemented shake flask cultivation (**Fig. 2**).

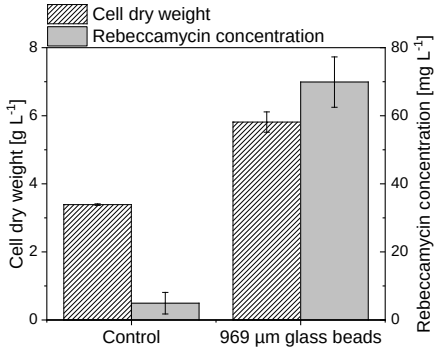

Figure 1. Cell dry weight concentration and rebeccamycin concentration of shake flasks cultivations without and with 100 g L^{-1} glass beads after 10 days of cultivation.

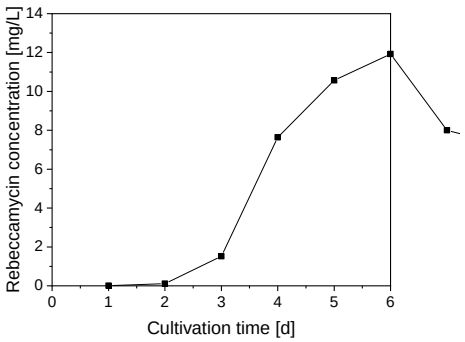

Figure 2. Rebeccamycin concentration of a silicone membrane aerated bioreactor cultivation without glass particles at an agitation rate of 400 min^{-1}.

Coupled CFD-DEM simulations have already been conducted to characterize the induced mechanical stress in shake flasks with glass particles. A similar simulation of the membrane aerated stirred bioreactor will allow a comparison of the induced mechanical stress and thereby an adjustment to the optimal stress found in shake flasks.

4. Conclusions

Rebeccamycin production in *L. aerocolonigenes* is increased by setting an appropriate mechanical stress by glass bead addition in shake flask scale. This knowledge can be used for scale up. A first membrane aerated stirred bioreactor cultivation led to a comparable rebeccamycin titer as in unsupplemented shake flask cultivations. Further adaption of mechanical stress by stirrer speed and geometry as well as the addition of glass beads could lead to even higher rebeccamycin titers.

Highlights

- Low shear forces favor the preservation of macromorphology in *S. clavuligerus.*
- High shear forces promote mycelia thinning and clavulanic acid accumulation.
- Oxygen uptake and clavulanic acid production are affected by mycelia aggregation

1. Introduction

Streptomyces clavuligerus (*S. clavuligerus*) is a Gram-positive filamentous bacterium notable for producing clavulanic acid (CA), which is a potent inhibitor of β-lactamases enzymes that confer resistance to bacteria against β-lactam antibiotics. CA is traditionally produced in stirred tank reactors (STR); nevertheless, the impact of bioreactor geometry on cell performance and CA production has not been completely understood. The present study aims at performing a comparative analysis of the metabolic response of *S. clavuligerus* to low shear stress in 2-D rocking-motion single-use bioreactor and at high mechanical shear stress in STR.

2. Methods

Cultivations of *S. clavuligerus* DSM 41826 in chemically defined media [1] were conducted by duplicate cultivations in a 15 L STR (Techfors S, Infors AG, Bottmingen, Switzerland) and in a 20 L 2-D rocking-motion single-use bioreactor CELL-tainer® (CT) (CELL-tainer Biotech BV, Winterswijk, The Netherlands). Cultivations were operated in batch mode (5 L) during the first 37 h, followed by fed-batch operation (35 mL/h) during 77 h. Cell dry weight (CDW), CA and metabolites quantifications were performed as described by Ramirez-Malule [1]. Mycelia samples were photographed in a Nikon Eclipse Ti2 inverted microscope (Nikon Instruments Inc., Amsterdam, The Netherlands) at 40x and further processed in ImageJ software (U.S. National Institutes of Health, Maryland, USA).

3. Results and discussion

In Figure 1, microscopy images (Figures 1a-1c) and biomass concentration developments of *S. clavuligerus* (Figure 1e) for the STR and CT cultivations are presented. In CT cultivations, the calculated specific growth rate (μ_{max}) and maximum biomass concentration were 0.068 h^{-1} and 10 g/L, respectively. A similar μ_{max} (0.069 h^{-1}), but higher maximum biomass concentration (14.5 g/L) were obtained in STR cultivations. The increase of agitation rate from 300 to 500 rpm in STR caused a decrease in mycelia thickness of 22.5% during the cultivation time (Figure 1e) as consequence of

high shear forces. In contrast, the lower shear forces in CT reactor did not cause hyphal fragmentation leading to more aggregated and thicker mycelia. The mycelial thickness in CT increased 30.6% (Figure 1e) during the same time of cultivation and comparable values of dissolved oxygen in the CT reactor. The higher biomass production observed in STR (Figure 1e) was attributed to the generation of a considerable number of mycelial fragments capable to growth and reproduce [2,3].

CA production is promoted by phosphate limiting conditions [1,4]; although the latter condition was reached in STR and CT reactors, CA release was lower in CT cultivations. The maximum specific CA concentrations were 33.44 mg/g CDW and 14.3 mg/g CDW in the STR and CT cultivations, respectively. In this regard, a reduction in oxygen uptake was observed in CT cultivations due to aggregation and clumping of mycelia. Oxygen uptake has a key role in the secondary metabolism of *S.clavuligerus*, since several oxidation steps reactions require molecular oxygen to occur. Thus, CA accumulation was further enhanced by the high shear stress and hyphal fragmentation that prevent the adhesion of filaments and limitations to oxygen diffusion. These results suggest that environmental conditions in CT reactor promoted a different carbon flux distribution as a consequence of less relative stress conditions, leading to a lower activity of secondary metabolism and hence, lower CA accumulation [4].

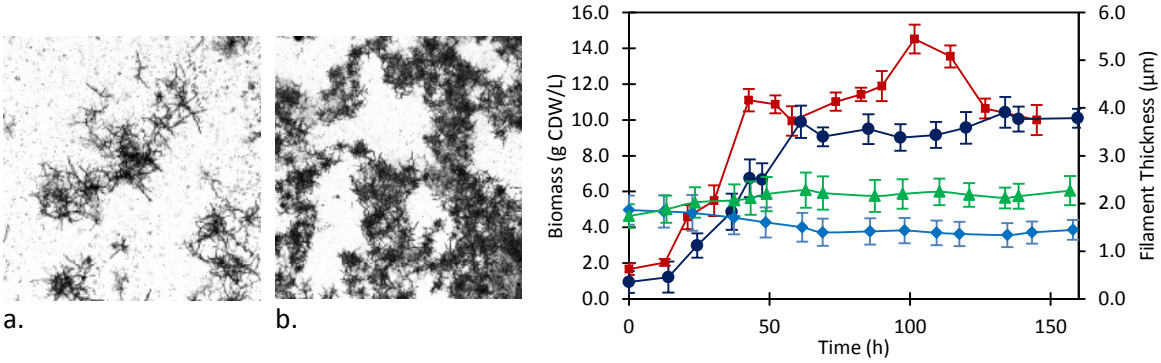

Figure 1. Morphological response of *S. clavuligerus* in STR and CT: a. STR (143 h); b. CT (139 h); e. Time course of biomass in STR (squares) and CT (circles) and mycelia thickness in STR (diamonds) and CT (triangles).

4. Conclusions

Low shear forces did not lead to significant hyphal fragmentation or lysis, on the contrary, it promoted mycelial thickening and branching in *S. clavuligerus*. Hence, the 2-D rocking-wave pattern of agitation favored the preservation of macromorphology in this filamentous organism.

Oxygen plays a key role in enhancing the CA productivity, thus the hyphal fragmentation during the exponential phase and moderate cellular stress seem to be critical for attaining high CA titers.

Highlights

- Spiral impeller enhances mixing and homogeneity due to bidirectional fluid flow
- Spiral impeller improve mass transfer efficiency by increasing surface renewal rate
- Achieved mass-transfer $k_L a$ of 16 hr^{-1} with cell density exceeding 4x10^6 cells/mL
- Achieved high ACE protein expression of 465 mU/mL

1. Introduction

Mammalian cells are often the preferred choice for expressing recombinant proteins because of their superior cellular machinery for post-translational modifications. However, they are very shear-sensitive and prone to hydrodynamic shear as they do not have a cell wall. Increasing demand for the production of large quantities of recombinant protein has driven the development of new bioreactor designs and processes, but small changes in the microenvironment during fermentation can produce heterogeneity in protein structure and varying biological activity [1]. This leads to inter- and intra- batch variation and inconsistent yields and product quality. Liquid shear forces from stirring, bubble formation and direct sparging have drastic effects on the overall cell growth and productivity of the fermentation batch. There is a growing need for a bioreactor design suitable for a wide variety of cell-lines to produce biologics at the lowest cost and with minimum risk. Therefore, a horizontal tubular bioreactor (HTB) with a spiral impeller was designed and fabricated for the propagation of mammalian cells at CeBER. The engineering characterization of the HTB was presented [2] and in continuation of this work, the HTB was further evaluated by growing CHO-K1 cells expressing angiotensin-converting enzyme (ACE) to assess its suitability for the growth of mammalian cells.

2. Methods

The HTB batch was run at 3.0 L capacity which is around 70 % of the total capacity of the bioreactor. Initially, 2.0 L complete serum-free medium (SFM4CHO +4 mM stable glutamine + 0.1 % Poloxamer 188) was charged into the bioreactor for sterility check for 48 h following which the bioreactor was seeded with CHO cells expressing somatic ACE with initial cell density of 0.3 x 10^6 cells/mL. Periodic sampling was done after every 24 h for the determination of cell density, viability percentage and for the spent media analysis. Termination of the batch was carried out when the percentage

viability dropped below 85 %. The bioreactor was operated at a speed of 150 rpm, at the set temperature of 37 °C, pH maintained in the range of 7.0-7.2 during growth phase and reduced to 6.85 - 6.95 after 5th day of protein expression and the air flow rate was kept at 0.2 LPM to maintain the 40 - 50 % of saturation of air. ACE activity was determined by a fluorimetric assay [3]. Spent media was analyzed for glucose consumption and lactate production using HPLC, ammonium ion by a calorimetric method [4] and osmolality with a SLAMED 800 CL Osmometer.

3. Results and discussion

The bioreactor batches were taken at a speed of 150 rpm to avoid hydrodynamic shear to the cells. The cell density achieved was 4.2 x 10^6 cell/mL (Figure 1 a). It is also evident from the cell density and the morphology of the cells that the bioreactor conditions were conducive for cell growth and exerted low shear conditions which result in prolonged longevity of the culture. The ACE maximum ACE activity was 465 mU/mL. The mobility of the proteins on SDS PAGE, using a polyclonal antibody to identify ACE, corresponded to that of purified somatic ACE (Figure 1 b). The glucose concentration decreased over time and the lactate production increased as expected but lactate did not exceed 3.0 g/L. The ammonia concentration and osmolality were 200-250 µg/mL and 300-380 mOsmol/kg respectively, presumably due to the base addition and lactate production during the batch run.

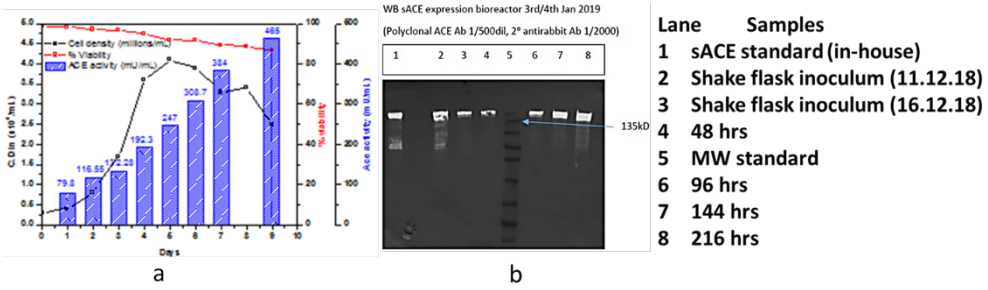

Figure 1. sACE protein expression (a) w.r.t. CHO growth profile in HTB (b) Cell medium was resolved by SDS PAGE and analysed by Western blotting with a sACE polyclonal antibody.

4. Conclusions

Hydrodynamic conditions of the bioreactor are dictated by the aeration-agitation regimen. The horizontal tubular bioreactor with spiral impeller has an edge over traditional STR bioreactor where rising bubbles and high impeller speeds damage the cells while maintaining a high cell density. HTB with spiral impeller is a combination of surface aeration and impeller mixing with enhanced surface renewal rates which resulted in cell density of more than 4 x 10^6 cells/mL with extended longevity. It could be predicted that in fed-batch mode, target cell densities of more than 10 x 10^6 cells/mL is achievable based the obtained ($k_L a$) value of 16 hr^{-1} for this reactor.

Microstructuring of Bioreactor surfaces with fine Particle Impacts for influencing Biofilm Growth

Paul Breuninger[1*], Daniel Kleine[2], Roland Ulber[2], Sergiy Antonyuk[1]

[1] *Institute of Particle Process Engineering; Technische Universität Kaiserslautern, Kaiserslautern, Germany*

[2] *Institute of Bioprocess Engineering, Technische Universität Kaiserslautern, Kaiserslautern, Germany*

**Corresponding author: Paul.Breuninger@mv.uni-kl.de*

Highlights

- Surface modification of bioreactor substrates by fine particle impacts
- Distinction between elevations and indentations of the surface by adaption of the process parameters
- An Influence on the structure and growth of biofilms was observed
- Results can be used to design certain bioreactor surfaces

1. Introduction

The present study describes a process for microstructuring industrially relevant surfaces of titanium (ASTM grade 2) by fine particle impacts to create a specific micromorphology in the same size of biocells. This influences the cultivation of biocells, for example in bioreactors [1], which affects the composition and productivity of the biofilms formed.

2. Methods

Titanium surfaces have been microstructured by a cold spray setup. The particles dispersed in a nitrogen stream are accelerated to supersonic velocities (up to 900 m/s) and sprayed on a substrate. When the particles exceed a critical impact force, they bond firmly to the surface and create an elevation. If the impact force is less than this limit, the particles rebound and leave a crater. Within this study both phenomena were used to create microstructured surfaces. Titania particles (size between 0.8 and 1.5 µm) were cold sprayed on the titanium surface and created a strong bonding on the surface. This produced a surface with elevations of about 1 µm in size. In addition, titanium surfaces (grade 2) were created with crater structures only. The produces surfaces were cultivated with Lactococcus lactis biofilms in a custom built flow cell. Optical coherence tomography (OCT) was used to observe biofilm formation and morphology.

4. Results and discussion

SEM and Scanning probe microscopy showed a statistical distributed surface morphology, with a roughness of 40% higher than reference substrates (Sq = 200 nm). Renewed roughness measurements after ultrasonic examinations showed a strong adhesion of the particles to the surface, without any change of the roughness. Microscope images of the statistically distributed indentations show depths up to 2 microns and width up to 15 microns. Morphologically different regions of one biofilm were identified by using OCT analysis. These regions consist of either

compact homogeneous biofilm or complex mushroom structures and can be related to the microstructure of the substrate.

4. Conclusions

A statistical distributed microstructure can be applied on the surface of technical substrates by the presented method. By selecting the process parameters it can be distinguished between elevations and indentations of the surface. An influence on the biofilm structure and the growth could be observed. These findings can be used to produce special surfaces for bioreactors.

Obtaining fermented beverages from vegetables and seeds using a commercial lactic culture

Martha Cuenca[1], Milenka Cerda[2], Débora Pizarro[2]

1 Assistant Professor, Program of Chemical Engineering, Unviersidad de Cartagena, Av del Consulado No 48-152, Cartagena, Colombia; 2 External consultants, Escuela de Ingeniería Química, Pontificia Universidad Católica de Valparaíso, Av Brasil 2162, Valparaíso, Chile

Highlights

- Probiotics sources for common people are expensive in Latin America
- Vegetables consumption in Latin America is low
- Seeds and grains can be useful to prepare fermented beverages
- Blends of vegetable purees and seeds extracts can be a cheaper source of probiotics

1. Introduction

Nowadays there is an increasing interest of people to replace consumption of dairy products, not only for health reasons, like lactose intolerance, but also for ethical reasons, as vegans. Vegetable beverages are now a reality, and their studies are focused on beverages from soybean. In case of other legumes, cereals and vegetables, there is not enough information about their products or how the process to obtain them is performed. That is why the use of this engineering is proposed, to obtain fermented beverages through lactic fermentation of vegetable beverages of quinoa and canary seed, considering the addition of carrot and pumpkin puree.

2. Methods

Quinoa (*Chenopodium quinoa*), canary seed (*Phalaris canariensis*), carrots (*Daucus carota*) and pumpkins (*Cucurbita maxima)* were purchased at the local market in Valparaiso, Chile. A Commercial culture Choozit® MY 800 LYO (Dupont), which contains three types of microorganisms: *Streptococcus thermophilus, Lactobacillus delbueckii subsp. lactis* and *Lactobacillus delbueckii subsp. bulgaricus*, was used as fermenting agent. All fermentation tests were done in triplicate, and the culture was added directly to the mixtures according to the manufacturer's dosage instructions.

Preparation of quinoa and canary seed beverages and vegetables purees

It was performed according to methodologies reported by Cuenca and Benavides to obtain soymilk [1,2]

Lactic fermentation of beverages, purees and blends

Lactic culture was added for all cases according to the manufacturer's dosage instructions (0.016 g/kg). 1 kg of beverage, puree or blend was fermented at 42ºC in triplicate using three home yogurt makers (Blanik, model BYM019, 220V, 50-60 Hz, 20W, China) for 5 hours.

Analytical analysis

pH and total acidity measurements, expressed as percentage of lactic acid (% w/v) (methods 981.12 and method 950.15, AOAC, 1998) [3]

Total reducing sugars

Initial and final total reducing sugars were measured by the 3,5 Dinitrosalicyclic Acid Method (DNS) [4]

3. Results and discussion

Table 1 presents different blends evaluated during lactic fermentation, and Figure 1 presents variation of blends F1, F2, F3 and F4 during 5 fermentation hours for pH (a) and Total Acidity (b).

Table 1. Different blends used for evaluating lactic fermentation (% w/w)

Beverages blend	Quinoa beverage	Canary seed beverage	Purees blend	Carrot puree	Pumpkin puree	Formulation	Quinoa beverage	Canary seed beverage	Carrot puree	Pumpkin puree
B1	100%	0%	P1	100%	0%	F1	16%	64%	8%	12%
B2	80%	20%	P2	80%	20%	F2	12%	48%	16%	24%
B3	60%	40%	P3	60%	40%	F3	8%	32%	24%	36%
B4	40%	60%	P4	40%	60%	F4	4%	16%	32%	48%
B5	20%	80%	P5	20%	80%					
B6	0%	100%	P6	0%	100%					

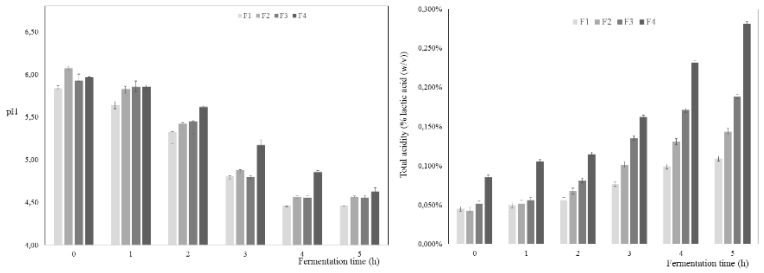

Figure 1. pH (a) and Total Acidity (b) Variation of different blends with quinoa, canary seed, carrot and pumpkin

Through these studies it was determined that despite not being a process as productive as the lactic fermentation of cow's milk, it is possible to carry out the fermentation of the different substrates studied. It was selected F4, which contains an 80% of purees and 20% of vegetable bevereages, presenting values consistently better than other blends, achieving a productivity of 0.563 $g*l^{-1}*h^{-1}$. Final product 1.1 x 10^5 $CFU*ml^{-1}$ of lactic acid bacteria, which is one order of magnitude less than what is required to be named a probiotic, if it has characteristics that would make it an adequate food for consumption.

4. Conclusions

It is possible to obtain vegetable fermented blends that can be a potential source of lactic acid bacteria to people that cannot access to cheap probiotic sources. It remains to study specific parameters of the process, such as its viscosity, and the effect that temperature has on the process. A greater dosage of lactic acid bacteria culture can improve microorganism's count in the final product to be consider a good source of probiotics.

New technological strategies to preserve the pasty-making confectionery food through biological material packaging.

Teresa De Pilli

Department of Science of Agriculture, Food and Environment – University of Foggia

Via Napoli, 25 Foggia (Italy)

**Corresponding author: teresa.depilli@unifg.it*

Highlights

- Edible film slows down the water migration of stored product, decelerating the staling.
- Prevention of growth of mold without use preservative substances like alcohol.
- Low fat content without compromise the sensorial properties of products during shelf life.

1. Introduction

Today the consumption of high amounts of fat is one of the main nutritional problems and it is considered one of the causes of serious health problems such as coronary heart disease and obesity. The foods that mainly contribute to intake of fats, above all in the case of the children, are the confectionary products. Nevertheless, the fats cannot be easily replaced in these kinds of products since they deeply influence their sensorial characteristics. In fact, fat provides to flavour, mouth feel, appearance, palatability, texture and lubricity. Moreover, soft pastries are generally filled with creams with high content of fat rich in saturated fatty acids. A complex set of conditions determines bakery product shelf life, which complicates efforts to extend the "life" of these foods. In fact, when stored at room temperatures, soft bakery product crumb undergoes a progressive deterioration of quality commonly known as staling that involves: hardening and toughening of the crumb; appearance of crumbliness and finally, moisture loss by evaporation. Moreover, during storage of bakery products can occur the development of molds, above all for the products preserved at room temperature and ordinary atmosphere. Ethanol is considered to reduce staling by acting as a plasticizer in the protein network of dough and it is able to inhibit the growth of microorganism. Alcohol give a typical smell when the packet is opened that it is not appreciated by consumers because of aromatic changes of food being in the packaging. In addition, this preservative, although perfectly safe, is more and more criticised above all for food devoted to the children because could be toxic for theirs also at low concentration. A possible solution to these technological drawbacks could be the use an edible biological material packaging applied directly on bakery products that would be able to preserve hygienic and quality characteristics of these kinds of food during shelf life.

The aim of this research was to study an innovative edible film that allows realizing pastry-making confectionery food with low fatty fraction without addition of additive and preservative ingredients, which is able, also, to keep its hygienic and sensorial properties during storage at room temperature and ordinary atmosphere.

2. Methods

Sponge cakes filled with sweet cream, coated with edible coating [1] or not and produced without the addition of preservative and additive substances, were stored at room temperature for 85 days and packaged in plastic bags under ordinary atmosphere. Ten samples were taken every 17 days to evaluate the chemical and mechanical characteristics changes of samples during storage. The

moisture and activity water (a_w) were carried out on crust, crumb and cream while the determination of hardness and the microbiological analyses were evaluated on the whole samples and the apparent viscosity on the filling cream. All analyses were replicated at least three times. The variation of analytical indexes during storage was calculated subtracting the values at the end of storage from the that measured at the start. A positive variation meant an increase of values of analytical index during storage while a negative value meant the decrease one.

3. Results and discussion

The moisture content and a_w values of crust increased during storage while those of crumb and cream decrease for both type of samples even if more moderately for samples with coating. (Table 1). Moreover, samples with edible film did not present mold growth during storage while samples without coating showed a mold concentration like $1.4*10^4$ FCU/g at the end of storage. The hardness of bakery products and apparent viscosity of cream increased during storage, even if samples coated with edible film showed an increase of hardness and viscosity of cream lower than products without coating (Table 2).

		Moisture (%)		aw	
		No coating	*Coating*	*No coating*	*Coating*
Crust	Start storage	8,21	10,47	0,657	0,677
	End storage	19,16	13,05	0,795	0,744
	Variation	***10,95***	***2,58***	***0,138***	***0,067***
Crumb	Start storage	19,05	17,46	0,836	0,76
	End storage	16,46	16,46	0,805	0,748
	Variation	***-2,59***	***-1***	***-0,031***	***-0,012***
Cream	Start storage	50,73	36,8	0,964	0,81
	End storage	18,18	15,9	0,805	0,746
	Variation	***-32,55***	***-20,9***	***-0,159***	***-0,064***

Table 1. Moisture and a_w variation of samples coated or no with edible film during storage.

		Hardness (N)			Viscosity (mPa)	
		No coating	*Coating*		*No coating*	*Coating*
Bakery	Start storage	23,73	35,83	***Cream***	263	388
products	End storage	43,82	48,66		404	416
	Variation	***20,09***	***12,83***		***141***	***28***

Table 2. Hardness and viscosity variation of samples coated or no with edible film during storage.

4. Conclusions

The presence of edible film is able to slow down the water migration inside product and the water evaporation outside food that cause its staling. Moreover, the edible film studied showed a good barrier to water vapor transmission and oxygen transmission. These gas barrier properties prevent the grown of mold without use preservative substances like alcohol, sulphurous anhydride, salts of sorbic acids, etc. The main innovation and advantageous characteristics of this edible film is relating to principal ingredients used to produce it, which are constituted by natural ingredients.

Highlights

- Tucumã pulp has a high content of β-carotene.
- Vacuum packaging and freezing keeps the tucumã nutritional properties for 30 days.
- Antioxidant activity remained preserved for 2 months in frozen samples of tucumã pulp.

1. Introduction

The Amazon region has different fruits often consumed by local population which present high economic potential [1]. The tucumã, also known as tucumã of the Amazonas, tucumã-açu e jabarana [2] is an example of tropical fruit, derived from the palm tree *Astrocaryum aculeatum* (Arecaceae), which presents significant biotechnological potential. It is characterized as slightly acidic, low sugar, high in β-carotene and high energy fruit [3]. Once the pulp is obtained, it must be consumed within one day at room temperature, or within a week under refrigeration [4]. Since the pulp storage has been performed inappropriately in most of the commercial establishments in Manaus, our objective with this work was to study the conservation of the antioxidant activity and the nutritional properties of tucumã pulp *in natura*, using vacuum packaging.

2. Methods

The tucumã was collected in a rural property located in Rio Preto da Eva, Amazonas (2°37'31.8"S 59°44'52.6"W). The tucumã pulp was obtained according to Flor et al. [5] and stored into polyethylene bags (200 g of pulp per bag) under vacuum. The packs were stored under freezing (18°C) and cooling temperature (5°C). During 150 days, the content of moisture, ash, pH, acidity, ethereal extract, energy, and microbiological growth (coliforms and Salmonella), were verified according to the methodologies describes by the Adolfo Lutz Institute [6]. Antioxidant activity was measured using DPPH• radical scavenging method [7].

3. Results and discussion

It was found that the values of moisture, ash and pH are retained by the use of vacuum packaging, in freezing or cooling temperatures for 5 months; acidity is conserved in vacuum packages only in the freezer for 10 days; the ethereal extract values are maintained for 3 months under freezing temperature and for 1 month when cooled; and the energy value contained in the pulp is kept for 2 months under freezing and for 10 days under cooling. The presence of coliforms and Salmonella

were not detected during 5 months of storage for both frozen and cooled samples; and the antioxidant activity remained preserved for 2 months in frozen samples (Figure 1A), but was not maintained in refrigerated samples (Figure 1B).

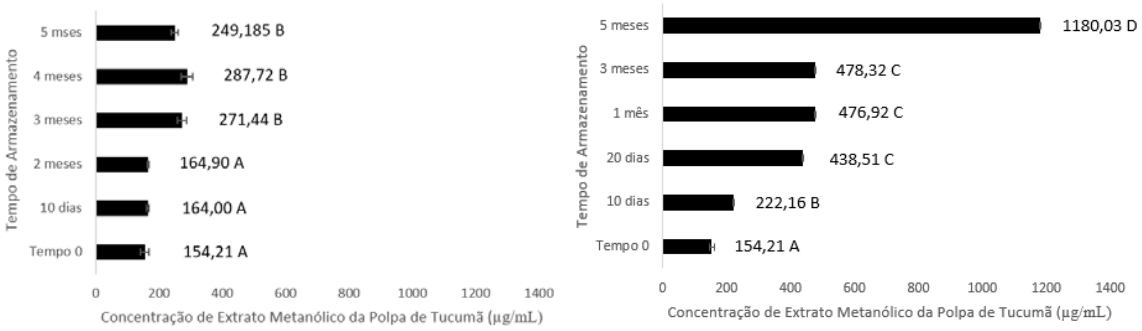

Figure 1. Efficient concentration at 50% (EC_{50}) of tucumã pulp stored in vacuum packaging under cooling (A) and freezing (B) temperature.

The maintenance of antioxidant activity of fruit pulps using freezing temperature was also verified by Freire et al. [8] The authors stored acerola pulp (*Malpighia emarginata*) at -18°C and the antioxidant activity was kept for 3 months. Manach et al. [9] affirmed that the concentration of phenolic compounds that are responsible for the antioxidant activity may be affected by factors such as processing, storage, as well as by environmental factors. It has been observed in the tucumã pulp the presence of different flavonoids, such as rutin and quercetin, as well as tanins, like galic acid, caffeic acid and chlorogenic acid [10].

4. Conclusions

Through this study we found that the use of vacuum packaging, associated with freezing, provides the conservation of the main nutritional properties of tucumã pulp in natura, for 30 days of storage, a simple procedure that can be used by local food suppliers.

**Corresponding author: theresa.scharl@acib.at*

Highlights

- Online monitoring in downstream processing.
- Real-time prediction of critical quality attributes.
- Machine learning application on large data from biotechnology.
- Pooling algorithm for material collection of an antibody capture process.

1. Introduction

It is state of the art in biopharmaceutical industry to monitor chromatographic processes by standard detectors and probes such as UV/VIS, pH and conductivity. Quality attributes such as product quantity and purity (e.g. dsDNA content, host cell protein concentration and high molecular mass impurities) can only be obtained by collecting and analysing fractions after each unit operation. In our project we have developed an online monitoring system for downstream processes, which is based on an array of online sensors. ATR-FTIR spectrometer, a fluorescence detector as well as a multi angle light scattering detector and a refractive index detector were implemented as additional sensors.

2. Methods

In order to use all available online signals in real time a powerful database environment is needed. Here we use an evon database (https://en.evon-automation.com/xamcontrol/) to store all the data that is measured by the sensors. A quantitative protein A run takes several hours. For the implemented sensors more than 18.000 online signals are measured in a time grid of one second yielding a huge amount of data. For further data usage efficient storage, time alignment and data pre-processing are crucial. In a first step several antibody capture runs were conducted where online signals of all available sensors were measured during the whole run. In addition, fractions were collected where quality attributes were analysed. In the next step all available online and offline data were processed using the statistical computing environment R [1].

3. Results and discussion

Several machine learning methods (e.g., partial least squares, random forests, generalised additive models) were used to find a relation between the measured offline variables such as product concentration or dsDNA content and the available online variables. Structured additive regression models in combination with boosting as a variable selection tool were found to be a useful modelling technique [2]. These prediction models allow online pooling decisions replacing time and labor-intensive laboratory measurements (Figure 1).

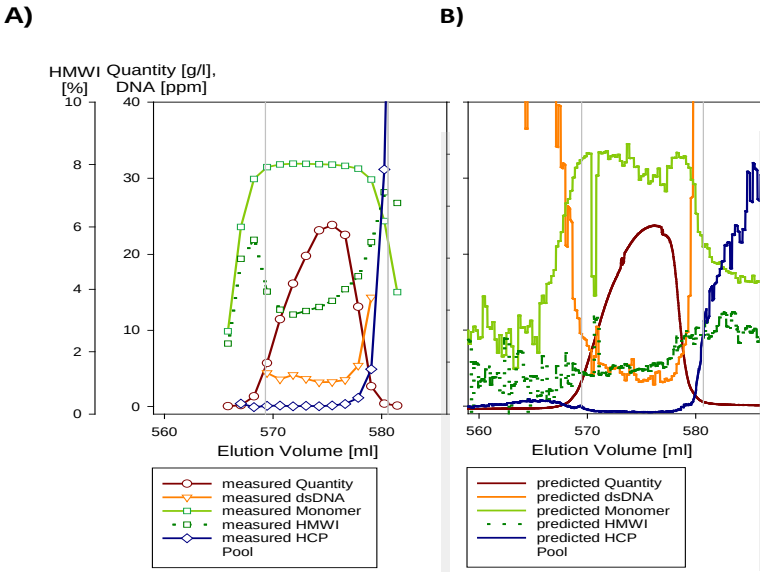

Figure 1. Measured (A) and predicted (B) quality attributes of an antibody capture run.

4. Conclusions

Prediction models solely based on online signals were set up providing real-time predictions. These models can be directly applied in real-time inside the database during a new chromatographic run to predict the quality attributes of a product solely based on the online variables measured. From the quality perspective it is also in accordance with FDA's recommendation. It is requested to include on-line sensors to improve the constant quality of the product.

Highlights

- Adaptive, nonlinear model predictive controller
- Optimization of aerobic *Saccharomyces cerevisiae* cultivations
- Implementation of a NMPC with a commercial process control system

1. Introduction

The Open Loop Feedback Optimal (OLFO) controller belongs to the class of adaptive nonlinear model predictive controllers [1]. The controller consists of a model parameter identification part and an optimization part. Model parameters are estimated frequently on the basis of available online and offline data. The updated model parameters are passed on to the optimization part, where process trajectories like substrate feeding profiles are calculated. Based on the process of yeast cultivation, the controller was tested in virtual and real experiments.

2. Methods

For the implementation of the OLFO controller two communicating WinErs-projects (IB Schoop GmbH) were created and executed simultaneously. Project 1 is a conventional process control project for controlling the bioreactors Biostat B (2 L) and Biostat C (20 L) (B. Braun). Project 2 contains the OLFO controller. The required parameter estimators and process optimizers were realized in WinErs via available packages. In our work the *Saccharomyces cerevisiae* cultivation model was integrated in form of a C-eStIM – WinErs – Interface – *.dll [2]. The basis for model development were several batch and fed-batch cultivations of *S. cerevisiae*. The OLFO project received the required state variables from the current process. These data were used to adapt the parameters and initial states of the deposited yeast culture model. Based on this, the glucose feed rates were calculated to achieve a maximum biomass density in the further course of the process. The calculated feed rates were transferred to the process control system (project 1).

3. Results and discussion

Figure 1 shows the result of a virtual yeast cultivation using the OLFO controller. The controller can adapt the parameterization of the used process model to fit the data of the cultivation process and map the trend.

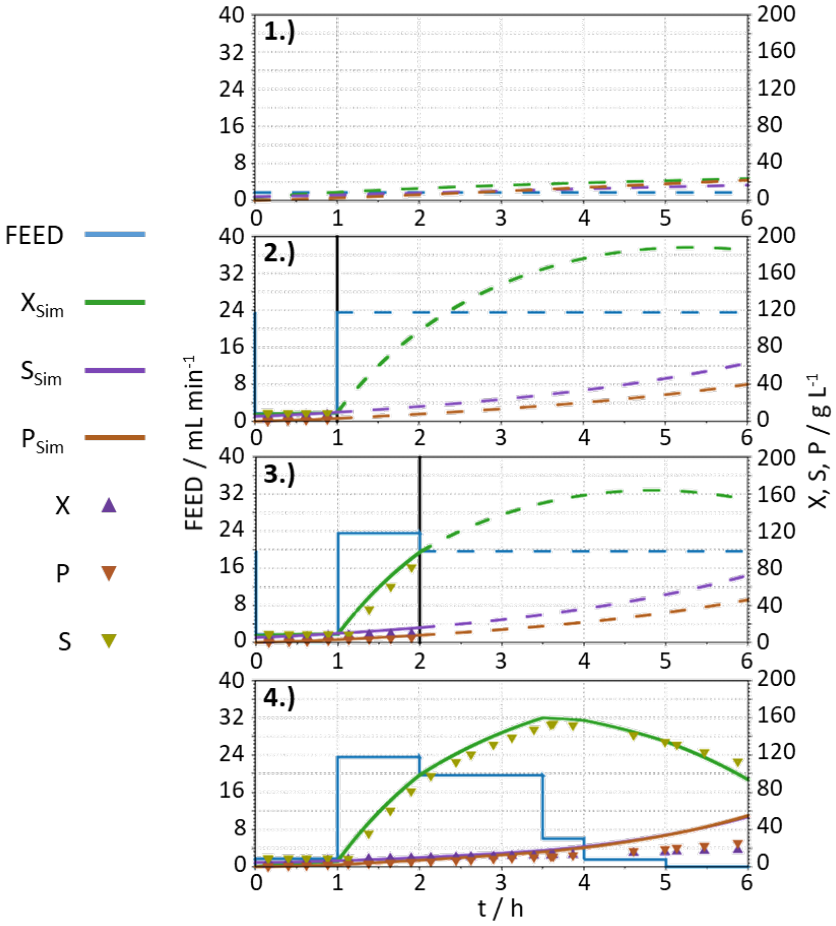

Figure 1. Demonstration of the OLFO controller working principle using a virtual bioreactor [3]. Dashed lines show the predicted trend for feed and concentration of the model utilized by the OLFO Controller.

Furthermore, fed-batch cultivation experiments were carried out in stirred tank reactors (STR). The transfer of the OLFO controller to real experiments was successful. The potential of the OLFO strategy is clearly visible. In subsequent works the OLFO controller will be used to optimize the cultivation process.

4. Conclusions

Our yeast cultivation experiments show, that even fairly simple mathematical models may successfully be used within the OLFO controller and lead to an increase in biomass production. The tool is now available for the systematic optimization of aerobic microbial cultivations.

Development of an Automated Perfusion Bioreactor 'Ambr® 250 Perfusion'.

Barney Zoro, Asma Ahmad, Alison Rees-Manley,Tom Jeffery

Sartorius Stedim Biotech

**Corresponding author:* barney.zoro@sartorius.com

In recent years a strong trend towards intensified and continuous biopharmaceutical processing has gathered momentum, enabled by key cell culture technologies such as ATF and TFF. However, small-scale application has been limited to traditional benchtop bioreactor formats that are manually intensive, relatively low throughput and costly to operate. Automated high throughput, single-use, mini bioreactor systems with new capabilities to support perfusion culture, including new ambr 15 capability and the novel 'ambr 250 perfusion', can facilitate and significantly accelerate an industry wide transition to intensified and continuous perfusion cell culture processes.

Working in close collaboration with biopharm industry development partners, the design of the 'ambr 250 high throughput' bioreactor system has been modified to include hardware, software and single use components required to operate up to 24 parallel bioreactors with ATF or TFF cell retention modes. Iterative prototype testing with biopharm industry development partners has resulted in a novel ambr 250 system design, shown to be capable of operating for extended culture durations and supporting high cell densities.

Technical description and cell culture results presented for 'ambr 250 perfusion' outline system capability for intensified cell culture applications. Case studies will be presented on the utility of new ambr 15 system features for perfusion mimic applications, together with a range of industry case studies and novel performance data for the new 'ambr 250 perfusion' system. As previously established with ambr 250 for fed-batch processes, 'ambr 250 perfusion' has the potential to provide the biopharm industry with a step change in perfusion process development capacity, enabling implementation of DoE based approaches for perfusion process optimization and characterization.

A wind tunnel method to develop products for controlled delivery of volatiles: experimental apparatus and mathematical model.

Fernando Bernardo*, Rita Chim, Mara Braga

CIEPQPF, Department of Chemical Engineering, University of Coimbra
Rua Sílvio Lima, Pólo II, Pinhal de Marrocos, 3030-790 Coimbra-Portugal

Highlights

- Method to test/develop products that release volatile active ingredients
- Application to a product releasing an insect attractant compound
- Method semi-validated with first set of assays; further validation is needed
- Useful to assess different product concepts and optimize formulation

1. Introduction

The release of a volatile active ingredient (AI) is a key functionality in a wide range of products, including personal care products, home fragrance products and insecticides. The method here presented was motivated by the development of a product releasing an AI that strongly attracts a particular insect (the beetle Monochamus galloprovincialis), known to be the main vector of the pinewood nematode, which in turn is responsible for the pine wilt disease [1]. The product should be active for several days (or even weeks) and up to a certain distance from the source. Product testing will be done in three stages: lab tests without insects, lab tests with insects and finally field tests (in the pine forest).

The method here described applies to the first stage tests where the goal is to evaluate AI concentration in the surrounding air resulting from a given product formulation, as a function of time and distance from the product. For that purpose, the product is tested in a wind tunnel and AI concentration measured downstream of the product. Complementarily, a mathematical model of AI transport is setup and solved, aiming at producing useful estimates to plan further tests and thus accelerate product optimization. The results from this stage, together with the known threshold concentration (above which attraction effect is significant), will be used to design the second stage tests, where the insect response will be monitored in a larger wind tunnel system.

2. Methods

Figure 1 shows a sketch of the cylindrical wind tunnel. The product is placed on the tunnel axis, 1 meter away from the entrance, where the air fan is located. In the base case here considered, the product is a small porous cylinder composed of an inert polymer (polycaprolactone) loaded with AI (α-pinene). The concentration of AI is measured through adsorption fibres that are first exposed to the flowing air until saturation (which is fast), and then analysed by SPME-GC-MS (details of the procedure and its calibration are not here described). The duration of this analysis only allows the use of four fibres at a time. The four selected positions P, in cylindrical coordinates (z,r), are: P1(0.25,0.085), P1'(0.25,0.035), P2(0.50,0.085) and P3(0.75,0.085) (values in meters; the

product is at the origin (0,0)). The concentration in these four points is measured at different times after the beginning of the assay.

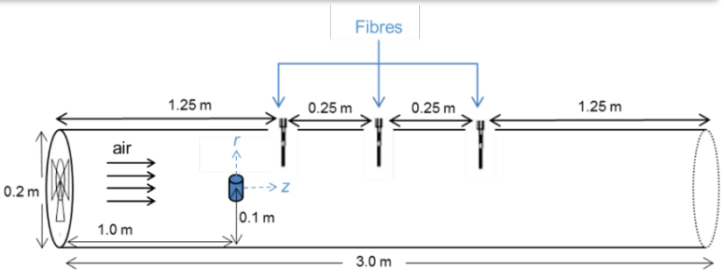

Figure 1. Wind tunnel.

The AI transport model comprises two components: A) release from the cylindrical product (internal diffusion with effective coefficient Di, partitioning at the air/product interface with coef. K, convective transfer to the surrounding air); B) axial and radial dispersion along the tunnel (coefs. Dz and Dr), and axial advection with the cross-section mean velocity (u). Model A has a well-known analytical solution, available in classical textbooks. Model B (with the source at z=0 approximated to a disk) also has analytical solution [2], but we have derived an equivalent one, using simpler methods. The dynamics of transport B is much faster than that of transport A (a few tens of seconds compared with several days). A pseudo-steady-state is then assumed for transport B, resulting in an overall model A+B for which we have derived an analytical solution (and this is a new contribution). The main model parameters are the ones above mentioned (Di, K, Dz, Dr and u). Di was previously determined based on AI release tests under quiescent air, and for the base case here considered is $(0.72\pm0.21)\times10^{-9}$ m^2/s. Initial estimates for the other parameters are: K_0=330 (from AI vapour pressure and Flory-Huggins model), u_0=0.38 m/s (from the fan specifications), Dz_0=0.026 and Dr_0= 0.00017 m2/s (for fully developed turbulent flow in a pipe).

3. Results and conclusions

Figure 2 shows experimental results and the best fit of the model, obtained with $K=23K_0$, $u=1.9u_0$, $Dz=0.12Dz_0$ and $Dr=8.0Dr_0$. The fit is good for points P1 and P1', and not so good for further away points P2 and P3. The model still needs to be improved in order to produce reliable estimates of low concentrations far from the source (e.g., the air flowrate should be directly measured, thus revealing the true value of u). After these improvements, we believe the model may provide valuable guidance in product development (e.g., making predictions for other AIs and for alternative product formulations).

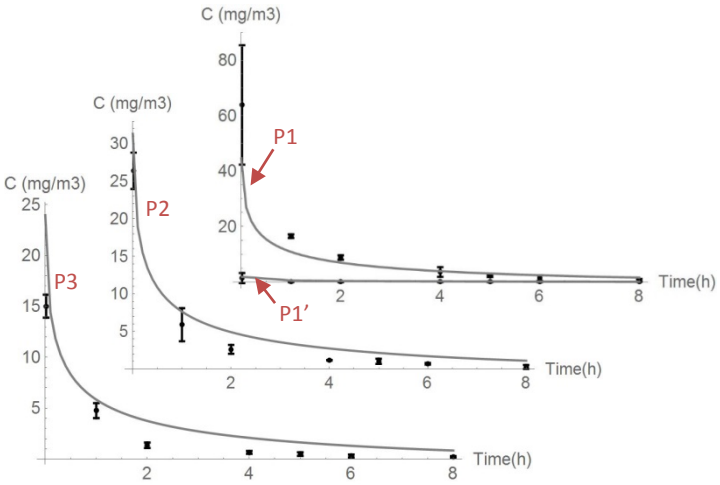

Figure 2. Measured AI concentrations (discrete points) and model predictions (continuous curves).

Highlights

- Workflow for knowledge-based bioprocess development.
- Combination of mathematical modeling and statistical Design of Experiments.
- Reducing the number of experiments for process design.

1. Introduction

The development of biotechnological processes is still mainly based on one-factor-at-a-time approaches. This increases the time for process development and simultaneously limits the obtained knowledge. As an alternative, Design of Experiments (DoE) tools can be used for the evaluation of multiple variable impacts simultaneously. However, conventional DoE frequently leads to a high number of time-consuming and costly experiments.

In this study, a model-assisted DoE (mDoE) concept is introduced for a knowledge-based process design with a reduced number of experiments. The main part of mDoE is a mathematical process model, which incorporates the prior knowledge and known mechanistic relationships [1]. The combination of the process model with conventional DoE methods enables the knowledge-based reduction of the experimental space. This method is exemplarily shown for the optimization of the initial glucose and glutamine concentration (batch) and the development of a bolus fed-batch strategy (4 parameters) for the cultivation of antibody-producing CHO cells.

2. Methods

For mDoE, data of first cultivations based on literature or prior knowledge (e.g. former studies) is generated. It is used to model biomass growth, metabolic activity and product formation during the process. Models of different complexity may be utilized, describing e.g. phenomenological relationships and effects [2], structured biomass compartments [3], or segregated population dynamics [4]. After process modeling, conventional DoEs are planned and the factor combinations are exported. The planned processes are simulated instead experimentally performed and the DoEs are evaluated using statistical methods. A response-surface model is estimated and a constraint-based optimization of the experimental space is conducted. This loop (see Figure 1) can be repeated several times to reduce the number of experiments further. Finally, a reduced number of cultivations is performed in the optimized experimental space.

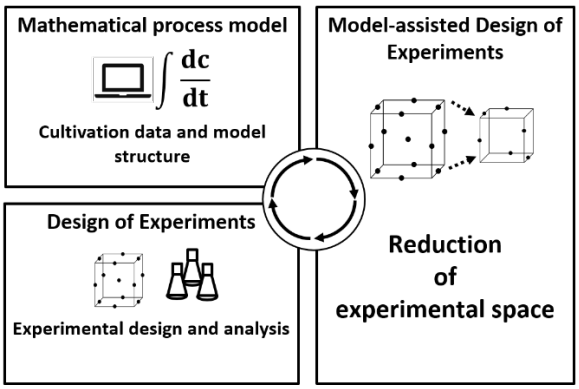

Figure 1. Scheme of the method for mDoE.

3. Results and discussion

The parameters of a mathematical process model [2] were estimated based on data of four first experiments for each application (batch and fed-batch). Conventional DoEs with broadly distributed factor boundary values were planned and the responses were simulated. The experimental spaces were evaluated and the factor boundary values were adapted. Experiments were conducted within the reduced experimental spaces and the results compared to the simulated DoEs. The same optimal conditions were found for both, simulated and experimentally performed cultivations. For the optimization of the initial glucose and glutamine concentration (see Figure 2), the number of experiments could be reduced by 50 % (8 for modeling/validation vs. 16). The number of experiments could be reduced by 72 % (8 for modeling/validation vs. 29) for the development of a bolus fed-batch strategy.

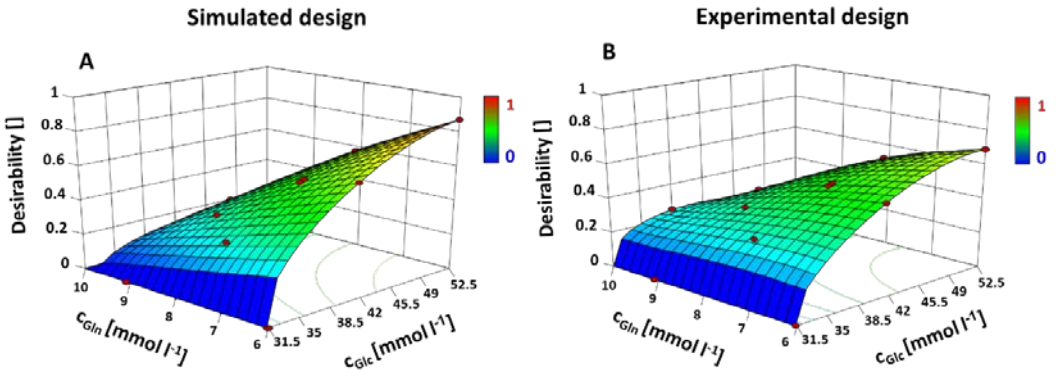

Figure 2. Desirability function for medium optimization, constraints: maximal antibody titer and minimal ammonium concentration. A: simulated responses, B: experimentally determined responses, cultivations as described in [4]

4. Conclusions

mDoE utilizes the currently available process understanding in form of a mathematical process model and significantly reduces the number of experiments.

Multivariate data analysis in gene therapy process development

Joe Emerson[1], Mark J. Willis[1], Jarka Glassey[1]

1 School of Engineering, Newcastle University, Merz Court, Newcastle upon Tyne, NE1 7RU

**Corresponding author: jtemerson@newcastle.ac.uk*

Highlights

- Multivariate techniques were applied to historical process data from vector production and cell processing
- Principal component analysis was used to assess batch-to-batch process variability
- Partial least squares enabled identification of critical process variables and modelled their relationship with critical quality attributes of the product

1. Introduction

Recent developments to vector safety and efficacy have brought about significant renewed interest in gene therapy and evidence of successful clinical trials has been mounting. However, the production processes are at an early stage of development, and process complexity and variability in vector/cell manufacturing processes, combined with the data-lean features of the early development stages in cell-gene therapy are significant contributing delaying factors in the new product development. In this work advanced modelling approaches are applied to process information from vector and cell expansion to bring benefits in process understanding and contribute to more rapid development of new products.

2. Methods

The nature of the data set is typical of bioprocesses, with a high number of inputs (process parameters) and outputs (performance parameters) [1]. In addition, the number of batches is low in many cases due to the treatments being personalized or targeted at rare diseases. The combination of many variables with a low number of repeats is a challenge for modelling practice. In this work, standard techniques were employed though it was necessary to modify the approach to modelling in order to cope with the challenges of the data set. For example, the use of sparse principal component analysis (PCA) was explored as an alternative to standard PCA in order to ease the interpretation of loadings with a high number of variables. Partial least squares (PLS) is an extension of multivariate linear regression, used to model the relationship between a set of independent variables and output variables of interest. PLS models were developed to link process variables to critical quality attributes of the product, critical process parameters were identified, and validation techniques were implemented to assess the predictive capability of the models. The validated models were interpreted to gain valuable process insights.

3. Results and discussion

Demonstrative PCA results are presented here along with a discussion, full results from PCA, sparse PCA and PLS modelling will be presented in the paper. PCA was applied to the production process variables and figure 1 shows the scores for the first three principal components. Figure 1

demonstrates the usefulness of PCA for highlighting and visualizing the differences in operating conditions that occur batch-to-batch. Batches that are close together have similar operating conditions whilst the opposite is true for batches that are further apart. Colouring the batches by the viral titre clearly shows that the operating conditions exhibited in batches 9 to 13 were favourable for a high titre.

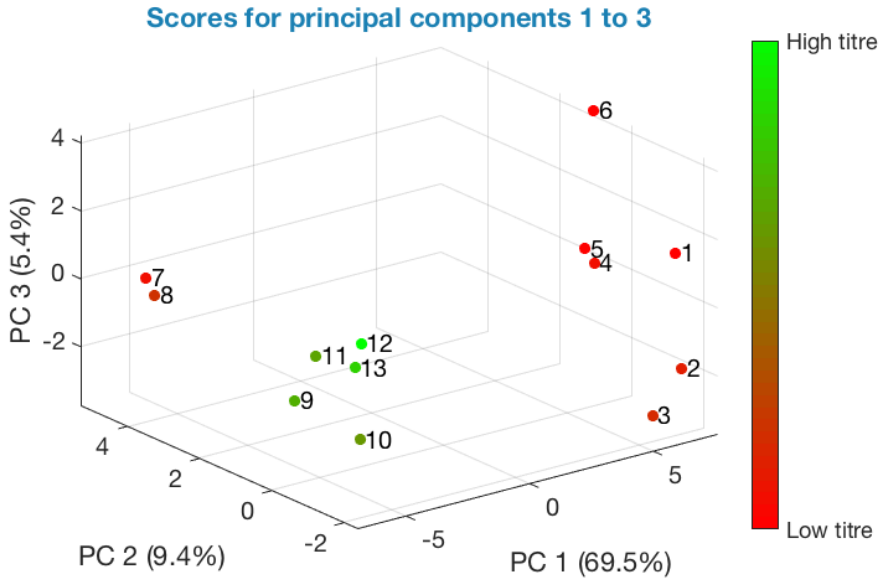

Figure 1. PCA applied to process variables: scores for principal components 1 to 3

To understand the driving forces behind the differences in batch scores, it is necessary to analyse the PCA loadings vector, in this way it is possible to identify variables with high variability and highlight the variables that were changed batch-to-batch and cluster-to-cluster. PLS was used model the relationship between process variables and the viral titre. Using variable selection techniques, it was possible to identify critical process parameters i.e. those influencing the viral titre and responsible for the high titre of batches 9 to 13 on figure 1. The PLS models were cross validated, and models with high predictive capability were selected. The sign on the standardized regression coefficients provided information on whether the variables positively or negatively influenced the viral titre, and the magnitude of coefficients indicated the relative importance of their effect.

4. Conclusions

Multivariate data analysis is a powerful tool for learning from historical process data; which may be particularly useful in cell gene therapy where complex biology and a large number of process parameters interacting, leads to a lack of process understanding. PCA is effective at identifying areas of the process with high variability and characterising the changes that were made during process development. The PLS models developed provided useful insights for process development, including identifying critical process parameters and indicating how these variables may be manipulated to increase the viral titre.

Investigation of the Mechanical Characteristics of Particle Separation with Dynamic Filtration - Analyzed by Surrogate Particles.

Henrik S. Marke[1*], Martin Peter Breil[2], Manuel Pinelo[1], Ernst Broberg[2], Ulrich Krühne[1]

1) Technical University of Denmark; 2) Novo Nordisk A/S

**Corresponding author: hensmar@kt.dtu.dk*

Highlights

- The mechanics of dynamic filtration has been studied by surrogate particles
- The particle specific pressure was isolated from known pressure components
- A model for the particle resistance was derived from the isolate particle pressure

1. Introduction

Solid separation by membrane filtration promises better separation, with a cleaner permeate fraction compared to centrifugation. Despite those advantages, most cell separations in the bio-chemical industry are still done by centrifugation. The filtration properties of the fermentation broth are too unfavorable for mass embracement of membrane separation for cell recovery [1]. To make membrane filtration of cells from fermentation broth economically variable, novel filtration technologies are needed. One such novel technology is dynamic filtration where filtration is enabled by movement of objects, not movement of liquid. Different methods to inducing such moment have been devised. For instance, by having an impeller rotating above the membrane, or by moving the membrane itself, ether by rotation or by vibration [2]. In this project a system with rotating membranes have been investigated.

The ultimate goal for this project is to describe how different process conditions affect the filtration performance of microorganisms in a rotating filtration system. Due to the complexity of biological

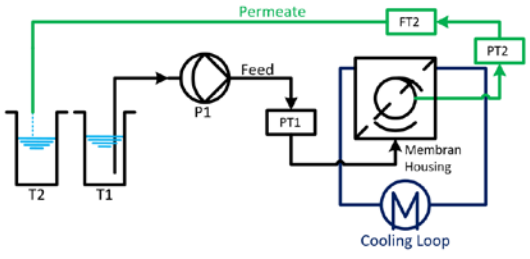

Figure 1: *Schematic of the experimental setup. Particles dilute from T1 are pumped into the membrane house, where they are concentrated. The permeate was collected in T2. The permeate Flow (FT2) and operational pressure (PT1, PT2) was measured*

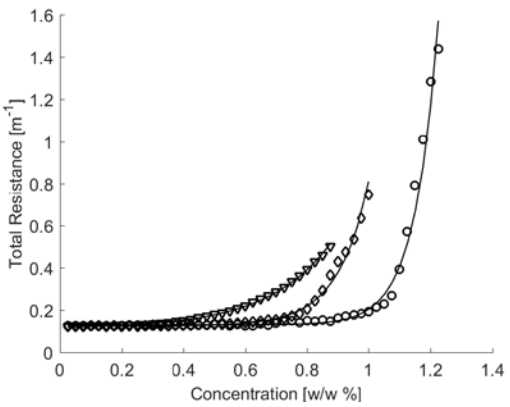

Figure 2: *Total Resistance (R_{tot}) plotted as a function of particle concentration for three different experiments. ◊: High rotation, High Flow. ∇: Low rotation, High Flow. ○: High rotation, low Flow. The solid lines represent the modelled resistance for each experiment.*

feeds, the system was simplified to a more manageable complexity level. The simplified filtration system was made with uniform particles of chalk ($CaCO_3$). The use of a well-defined system ensures experimental reproducibility, which would have been difficult with a biological system.

2. Methods

For the experiments, a dedicated filtration setup was assembled, according to the schematic shown in Figure 1. Operation parameters, such as pump speed and disc rotation were controlled with help of LabVIEW. Pressure and flow measurements were collected likewise. Each experiment consisted of two stages. First, the solvent system was measured, i.e. the membrane resistance was determined without particles. Secondly, the system was investigated with particles in the feed. For each experiment, a dilute solution of chalk particles was prepared. The particles used had a mean size of 2.5 µm, and the solution had a concentration between 1.2 % w/w and 2.7 % w/w. The filtration was performed as a dead-end filtration, meaning particles would accumulate in the house. The particle accumulation leads to an increased operational pressure with time.

3. Results and discussion

For a set of operational conditions, a filtration performance curve was recorded, based on the operational pressure (ΔP). The pressure curve was analyzed by decomposing it into known and unknown pressure components. The known components are related to the solvent system and to the rotation of the membrane. The known parts can be described as:

$$P_{sys} = \underbrace{\mu_s \cdot J \cdot R_m}_{Solvent} + \underbrace{(k_1\omega)^2 \cdot \frac{\rho}{4} \cdot (r_1^2 + r_2^2)}_{Rotation}$$

The unknown components are related to the particles and buildup of cake on the membrane surface. The pressure difference between ΔP and P_{sys} is the pressure resulting from the presents of particles. The difference can be used to find the particle resistance and the total resistance in the system, as presented in Figure 2:

$$R_C = \frac{\Delta P - P_{sys}}{J \cdot \mu_s} \qquad R_{tot} = R_C + R_m$$

Conducting the experiments at different operational conditions, such as different filtration rates, particle concentrations, and membrane rotational speeds, a model for R_C can be derived. With this model, a general performance description of a filtration unit will be derived, facilitating process design.

4. Conclusions

By isolating the particle pressure from the operational pressure, a resistance model can be derived. This model is a starting point for filtration process design.

Highlights

- Truly continuous solid-liquid separation
- New concept inclined plate settler
- Stable, high product yield

1. Introduction

With market pressure increasing in the biotechnological and biopharmaceutical industry, the trend is going towards continuous processing [1]. While, continuous chromatography is being readily adopted [2,3], alternative unit operations e.g. flocculation and precipitation are being mostly neglected. These techniques suffer from the fact that there is a lack of efficient continuous solid-liquid separation techniques [4].

2. Methods

We tested our inclined plate settler system with suspensions with different settling behavior. In these tests, operation parameters were optimized to ensure high product yield. The product was simulated to be either, comprised by the solid or by the liquid phase. We also tested the applicability of the optimized conditions during scale-up from one to multiple plates. The solid-liquid separation performance was monitored by online sensors and was verified and complemented by offline measurements.

3. Results and discussion

Using an improved concept for inclined plate settler based solid-liquid separation we were able to demonstrate efficient solid-liquid separation. We have optimized the operation conditions and have obtained high product yield in all operation scenarios. The separation process was highly stable after an initial ramp-up phase.

4. Conclusions

We have developed a new plate settler concept that broadens the application range of inclined plate settlers for solid-liquid separation tasks. Thereby, we provide a possible solution to the bottleneck in continuous processing, being solid-liquid separation.

Highlights

- Sustainable technologies to purify L-Asparaginase.
- Modified carbon nanomaterials have high affinity for L-Asparaginase.
- The pH and material/biopharmaceutical ratio influence the adsorption performance

1. Introduction

Getting older is the biggest risk factor for most fatal diseases, including cancer, heart diseases and neurological diseases. To overcome such age-related diseases, it is crucial to optimize the production and purification of biopharmaceuticals, such as nucleic-acid-based products, antibodies and recombinant proteins and enzymes. Low cost production combined with high purity levels will allow their routinely use by a widespread population. Amongst the available biopharmaceuticals, continuous progresses have been carried out for the development of recombinant therapeutic enzymes, namely L-asparaginase (LA), which presents antineoplastic properties for the treatment of leukemia, namely Acute Lymphoblastic Leukemia (ALL) [1]. The first-line biologic used to treat ALL, Oncaspar, is currently marketed in the United States, Germany and Poland, accounting with approximately USD $100 million in annual sales [2]. Given their high value, the demand for new biopharmaceuticals and cost-effective production/purification processes play now a priority role [3]. The common strategies for protein purification result in low yields and purity, requiring long processing times, while leading to a consequent increase of the process costs [4]. LA can be produced via fermentation and its purification usually comprises several steps. The methods to purify LA include precipitation, liquid-liquid extraction and chromatography techniques. Among these, ion exchange chromatography, which is often preceded by precipitation with salts as a first pre-chromatographic step, is the most used [4]. This work aims the development of cost-effective technologies to purify LA from the fermentation medium, which is rich in other proteins. Reusable functionalized nanomaterials, namely carbon nanomaterials (CNTs), are investigated as cost-effective purification techniques for the target enzyme, demonstrating to have high affinity for the target biopharmaceutical. The pH, material/biopharmaceutical ratio and contact time effects in the purity and yield of LA were optimized.

2. Methods

The surface chemistry of CNTs was modified by the treatment with nitric acid in liquid phase to introduce oxygen containing surface groups. Different CNTs were obtained and used for the purification of LA. Commercial LA was used for the first tests, in order to understand the behavior of the enzyme in contact with the nanomaterial. Experimental conditions, such as pH, and material/LA ratio, and contact time were studied. LA activity was quantified by Nessler reaction, which quantifies the amount of ammonium released after the enzymatic reaction [5].

3. Results and discussion

The first results reveal a total adsorption of LA by the CNTs. Depending on the CNT functionalization/ treatment, different values of recovered activity of LA were obtained. The pH and material/LA ratio also influence the adsorption of LA on the material surface.

4. Conclusions

The modified CNTs are promising nanomaterials for the purification of LA. The LA was easily attached to CNTs by adsorption under mild conditions. CNTs supports can be considered as a promising alternative for the adsorption and purification of LA.

Highlights

- Continuous H_2 production in bioreactors inoculated by synthetic consortium or sludge
- Optimization of HRT in both bioreactors gave the same results
- The recirculation ratio has a huge influence on H_2 production and metabolites' concentration profile

1. Introduction

Hydrogen represents a promising clean alternative to fossil fuels, because its combustion produces only energy and water and it is a powerful energy carrier. Among the processes that are commonly used to produce H_2, dark fermentation is considered one of the most attractive, because it employs the ability of anaerobic bacteria to produce H_2 from renewable feedstock such as wastewater. The technical feasibility of H_2 production from wastewater has been largely investigated in upflow anaerobic biofilm reactors (UABR) [1]. Indeed, biofilm provides a good protection to microorganisms against potential changes of operating parameters, thus allowing more flexible operating conditions. However, many studies found low H_2 yields (HY) and instable H_2 production, probably because of the variability of microbial communities and metabolic pathways. The experimental study described here focusses on a multi-scale experimental approach to improve the scale up the process of H_2 production via dark fermentation using wastewater as a substrate. First results from Benomar et al. [2] that have shown stable biofilm formation and improved HY using cocultures of *C. acetobutylicum* and *D. vulgaris* Hildenborough. Based on these results, two continuous UABR were designed, inoculated with the coculture and a natural sludge and operated in different conditions to decipher biological mechanisms of hydrogen production.

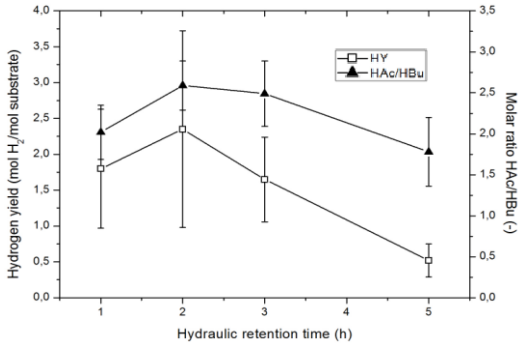
2. Methods

A 1L-reactor filled with Kaldnes K1 as biofilm carriers was inoculated with a synthetic consortium of *C. acetobutylicum* and *D. vulgaris* Hildenborough ratio 1:1. In parallel another 1L-UASB was inoculated with a pre-heated sludge from a municipal WWTP. These reactors were operated in continuous for several weeks and fed with a solution of glucose (1 g/L) as the main organic carbon source and micronutrients (ratio of C/N/P was 100/21.4/1.9, which is in the range of typical C/N/P

molar ratios of municipal wastewater) [3,4]. Biogas production was recorded by a Milligas counter (Ritter, Germany) set at the gas outlet of the reactor. H_2 content in biogas was determined using a gas chromatograph Agilent 7820A GC equipped with a 30m column GS-CarbonPLOT (Agilent Technology, USA). Liquid was sampled daily at the outlet of the reactor to follow pH and metabolites concentrations by HPLC system Agilent 1260 Infinity LC (Agilent Technology, USA). After stabilization of bioreactors performances the influence of HRT and inlet/outlet recirculation ratios were studied on hydrogen production rate (HPR) and metabolites' profiles.

3. Results and discussion

First experiments conducted on the consortium showed that the best HRT was 2 hours [3]. These results were confirmed by the experiments conducted with the sludge-inoculated bioreactor (figure 1a).



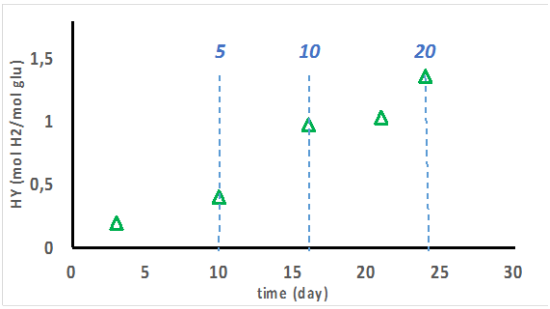


Figure 1a. Influence of HRT on HY and Acetate(HAc)/Butyrate(HBu) ratio [4] –

Figure 1b. Influence of recirculation ratio (in blue) on HY

Experiments conducted on the bioreactor inoculated with the synthetic consortium to determine the best liquid recirculation rate gave interesting results plotted in figure 1b. The recirculation ratio between inlet and outlet of the reactor is an important parameter to optimize HPR. This could be explained by its influence on the profiles of pH and metabolites' (to be shown on the conference).

4. Conclusions

The combination of experiments with a synthetic consortium and WWTP sludge gave interesting results leading to an optimization of hydrogen production via dark fermentation in a labscale reactor. This approach combining synthetic and natural consortium studies is promising for an efficient scale-up of the process.

The use of aqueous two-phase separation for the *in situ* production and purification of lipopeptides from *Bacillus amyloliquefaciens*

Robert W.M. Pott[1]

1 Department of Process Engineering, University of Stellenbosch, South Africa, rpott@sun.ac.za

Highlights

- *B. amyloliquefaciens* can be cultivated under two-phase conditions
- Lipopeptides preferentially report to the PEG-rich phase
- Differing PEG molecular weights can selectively partition different lipopeptides

1. Introduction

Significant quantities of fruit and vegetables are lost due to postharvest diseases(1). Disease control using synthetic chemicals are being phased out of use, particularly in the EU. Biomolecules, such as lipopeptides (LPs), that possess antifungal activity, biodegradability and digestibility have attracted interest as potential biocontrol agents as replacements(2). Particular focus has been placed on lipopeptides produced by *Bacillus* spp., as they provide a promising alternative in reducing postharvest spoilage due to fungal phytopathogens. The industrial production of these compounds is a developing field, with some LP products being commercially available(3), while antifungal LPs are not yet produced on an industrial scale. In order to develop a process which can produce these compounds at large scale, significant work in separating and purifying the different homologues of LP is required. In particular, in batch culture, as soon as the bacterial cells enter their stationary growth phase, they begin to metabolize the already produced LPs resulting in reduced product yields(4,5). Current concentration, recovery and purification methods employed such as acid precipitation, solvent extraction and membrane filtration take place after fermentation has been stopped and do not address this problem.

The primary aim of this study was therefore to explore the potential of PEG-salt ATPS as an *in situ* extractive fermentation process to reduce the metabolization of the LPs produced by *Bacillus amyloliquefaciens* DSM 23117. The effect of salt type (tartrate, sulphate, phosphate and citrate) and concentration (Standard media 0.2, 0.4 and 0.8 M) as well as the PEG molecular weight (6000 and 8000) on the growth of the microorganism and LP production were examined and compared against standard growth conditions.

2. Methods

ATPS partitioning in pure component systems was conducted using the appropriate salt, buffer and PEG wt. % determined from binodal curves of ATP systems used for protein purification in literature(6). ATP systems were prepared using known concentrations of salt, PEG, and LP mixtures (surfactin, fengycin). ATP systems were agitated in an incubator at 150 rpm for 15 min at 30°C. After mixing, the systems separated into phases. LP concentrations in top and bottom phases were determined using HPLC (Phenomenex Luna 3 µm C18 column, Dionex Ultimate 3000 Diode-array

detector, trifluoroacetic acid mobile phase). LP homologue partitioning was visualized using thin layer chromatography (as described in (7)). For culture experiments, shake flasks experiments, at 30°C, 100 rpm, in baffled 250ml flasks, were conducted growth rate, substrate utilization and lipopeptide production were determined using cell dry weight and HPLC for the quantification of glucose utilized and lipopeptides produced, respectively.

3. Results and discussion

Some sample results are presented here. Further details will be presented in the full conference presentation.

Surfactin and fengycin were successfully separated into top and bottom phases of several ATPS systems, an example of which is shown below in Figure 1. This is the first instance where comparatively simple separation of lipopeptide homologues has been shown. The implication of this is that fengycin, the compound desired in antifungal applications, is separated from the co-produced but undesired surfactin. Fengycin partitions to the top phase, and can thereafter be precipitated using acid precipitation and used as a purified product. The incidence of product consumption is thus minimized at the same time as purification of the product away from the fermentation broth is enacted.

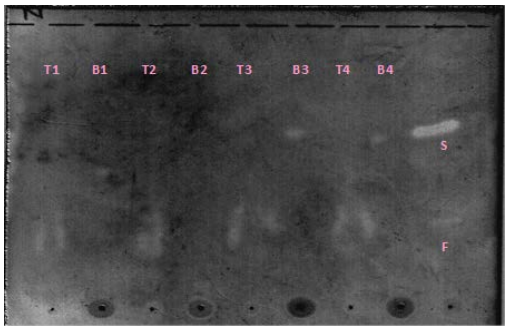

Figure 1. TLC image of lipopeptides in 40% (w/w) PEG 6000 and 49% (w/w) K_2HPO_4. T refers to top (PEG) phase, B refers to the bottom (salt) phase, S refers to the surfactin standard and F refers to the fengycin standard

The organism was found to be able to survive, and even thrive, under increased salt concentrations. This increased salt concentration is a necessary part of operating the culture under *in situ* extraction using ATPS, since 2-phase formation only occurs under sufficient salt concentrations. Following the demonstration of salt tolerance, experiments were conducted using PEG addition to the system. Very similar results were obtained, demonstrating that the organism can viably grow under ATPS conditions. Under the ATPS growth conditions lipopeptide concentration in the top PEG phase was monitored, and found to follow the same trend as standard growth media LP production

4. Conclusions

The production, *in situ* purification and recovery of LPs from *B amyloliquefaciens* was demonstrated using PEG-salt ATPS systems. This work opens the opportunity for the use of ATP systems in the continuous production of LPs, or for a simple purification method to separate LP homologues.

Highlights

- The sorption capacity of yeast cell walls changes depending on the type of adsorbate used
- The sorption profile differs between strains issued from the same species of *Saccharomyces cerevisiae*
- The sorption capacity of yeast cell walls changes according to the adsorbate/adsorbent ratio initially added

1. Introduction

During the winemaking process, *Brettanomyces bruxellensis* contaminates the wine by producing volatile phenols such as 4-ethylphenol (4-EP) that is the origin of the unpleasant aroma described as "horse sweat" [1,2]. Several methods were used to prevent wine contamination by these microorganisms such as filtration of wine, the addition of antimicrobial agents, applying high pressures to reduce populations of certain yeasts or the use of PVPP and charcoal to remove the volatile phenols. The latter resulted in the decrease of aromatic compounds concentration and color in red wines [3]. The benefit of using yeast cell walls as biosorbent is mostly driven by the presence of macromolecules such as mannoproteins which are located on the surface of the cell wall and able to retain volatile compounds [4]. The objective was to study the sorption profiles of p-coumaric acid and 4-EP with different specific yeast cell walls of *Saccharomyces cerevisiae*.

2. Methods

Yeast cell walls were produced from biomass that has undergone thermal autolysis and were dried either by lyophilization or spray-drying. The five specific yeast cell walls were provided by Lallemand, Blagnac (France) and were produced from different strains of *Saccharomyces cerevisiae*. Each experiment was conducted in 11 Erlenmeyer flasks containing synthetic wine medium composed of fructose, glucose, yeast extract, $(NH_4)_2SO_4$, citric acid, malic acid, tartaric acid, $MgSO_4$ and KH_2PO_4. The pH of the medium was adjusted at 3.5. Experiments were performed at 30°C in the presence of 3 g/L of yeast cell walls with 10 mg/L of p-coumaric acid or

20, 30, 40 or 50 mg/L of 4-EP and stirred at 250 rpm. Control sample was prepared in the same conditions but without yeast walls. The amount of adsorbate unbound to cell wall was measured by UV spectrophotometry and sorption kinetics for both adsorbates were plotted in order to determine the time required to reach the equilibrium.

3. Results and discussion

Thermodynamic equilibrium time are considered relatively long. This is explained by the microporous structure of the adsorbent, which slows down the diffusion of the liquid since its dimensions are close to the diameter of the molecule. Sorption capacities are really greater with 4-EP than with p-coumaric acid. The maximum percentage of adsorption reached with p-coumaric acid was 20% with the strain named CW1 **(Figure 1)** while the maximum percentage of 4-EP adsorbed by yeast cell walls was between 70 and 80% with the CW5 and CW2 specific cell-walls **(Figure 2)**. A differential mannoprotein content might explain the variation of adsorption capacity by cell wall strains. It is known that the sorption capacity depends on the composition of the cell wall which varies depending on the yeast strain and the culture conditions. Furthermore, *Saccharomyces cerevisiae* adsorb preferentially 4-EP while the *Brettanomyces* adsorb preferentially p-coumaric acid [5]. It is due to the differential cell wall chemical composition between these two genera. In addition, for all specific cell-walls tested, the optimal adsorption concentration of 4-EP is 20 mg/L. The percentage adsorbed decreases inversely proportional with the increased concentration of 4-EP added. This may be explained by the saturation of the yeast wall sorption sites that are specific to 4-EP.

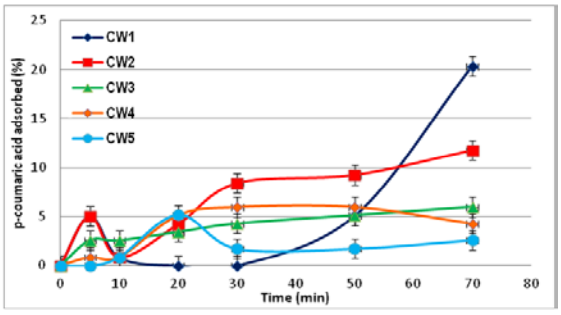

Figure 1. Sorption kinetics of p-coumaric acid

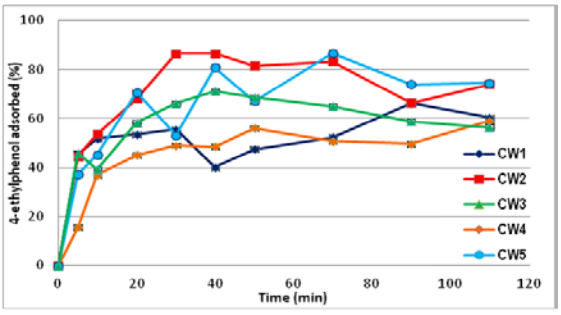

Figure 2. Sorption kinetics of 20 mg/L 4-ethylphenol solution

4. Conclusions

The sorption varies according to the type of adsorbate and the yeast cell wall's type (strain effect). The chemical composition of the yeast cell walls greatly influences the sorption profiles. In the end, this latter is a promising technique for the treatment of wine contaminated by volatile phenols.
